Preface

Machine learning and data mining are rapidly developing fields. Following the success of the first edition of the *Encyclopedia of Machine Learning*, we are delighted to bring you this updated and expanded edition. We have expanded the scope, as reflected in the revised title *Encyclopedia of Machine Learning and Data Mining*, to encompass more of the broader activity that surrounds the machine learning process. This includes new articles in such diverse areas as anomaly detection, online controlled experiments, and record linkage as well as substantial expansion of existing entries such as data preparation. We have also included new entries on key recent developments in core machine learning, such as deep learning. A thorough review has also led to updating of much of the existing content.

This substantial tome is the product of an intense effort by many individuals. We thank the Editorial Board and the numerous contributors who have provided the content. We are grateful to the Springer team of Andrew Spencer, Michael Hermann, and Melissa Fearon who have shepherded us through the long process of bringing this second edition to print. We are also grateful to the production staff who have turned the content into its final form.

We are confident that this revised encyclopedia will consolidate the first edition's place as a key reference source for the machine learning and data mining communities.

Abduction

Antonis C. Kakas
University of Cyprus, Nicosia, Cyprus

Definition

Abduction is a form of reasoning, sometimes described as "deduction in reverse," whereby given a rule that "$A\ follows\ from\ B$" and the observed result of "A" we infer the condition "B" of the rule. More generally, given a theory, T, modeling a domain of interest and an observation, "A," we infer a hypothesis "B" such that the observation follows deductively from T augmented with "B." We think of "B" as a possible explanation for the observation according to the given theory that contains our rule. This new information and its consequences (or ramifications) according to the given theory can be considered as the result of a (or part of a) learning process based on the given theory and driven by the observations that are explained by abduction. Abduction can be combined with ▶ induction in different ways to enhance this learning process.

Motivation and Background

Abduction is, along with induction, a *synthetic* form of reasoning whereby it generates, in its explanations, new information not hitherto contained in the current theory with which the reasoning is performed. As such, it has a natural relation to learning, and in particular to *knowledge intensive learning*, where the new information generated aims to complete, at least partially, the current knowledge (or model) of the problem domain as described in the given theory.

Early uses of abduction in the context of machine learning concentrated on how abduction can be used as a theory revision operator for identifying where the current theory could be revised in order to accommodate the new learning data. This includes the work of Michalski (1993), Ourston and Mooney (1994), and Ade et al. (1994). Another early link of abduction to learning was given by the ▶ explanation based learning method (DeJong and Mooney 1986), where the abductive explanations of the learning data (training examples) are generalized to all cases. An extensive survey of the role of abduction in Machine Learning during this early period can be found in Bergadano et al. (2000).

Following this, it was realized (Flach and Kakas 2000) that the role of abduction in learning could be strengthened by linking it to induction, culminating in a hybrid integrated approach to learning where abduction and induction are tightly integrated to provide powerful learning frameworks such as the ones of Progol 5.0

C. Sammut, G.I. Webb (eds.), *Encyclopedia of Machine Learning and Data Mining*,
DOI 10.1007/978-1-4899-7687-1

(Muggleton and Bryant 2000) and HAIL (Ray et al. 2003). On the other hand, from the point of view of abduction as "inference to the best explanation" (Josephson and Josephson 1994) the link with induction provides a way to distinguish between different explanations and to select those explanations that give a better inductive generalization result.

A recent application of abduction, on its own or in combination with induction, is in Systems Biology where we try to model biological processes and pathways at different levels. This challenging domain provides an important development test-bed for these methods of knowledge intensive learning (see e.g., King et al. 2004; Papatheodorou et al. 2005; Ray et al. 2006; Tamaddoni-Nezhad et al. 2004; Zupan et al. 2003).

Structure of the Learning Task

Abduction contributes to the learning task by first explaining, and thus rationalizing, the training data according to a given and current model of the domain to be learned. These abductive explanations either form on their own the result of learning or they feed into a subsequent phase to generate the final result of learning.

Abduction in Artificial Intelligence

Abduction as studied in the area of Artificial Intelligence and the perspective of learning is mainly defined in a logic-based approach. Other approaches to abduction include set covering (See, e.g., Reggia 1983) or case-based explanation, (e.g., Leake 1995). The following explanation uses a logic-based approach.

Given a set of sentences T (a theory or model), and a sentence O (observation), the abductive task is the problem of finding a set of sentences H (abductive explanation for O) such that:

1. $T \cup H \models O$,
2. $T \cup H$ is consistent,

where $\models$ denotes the deductive entailment relation of the formal logic used in the representation of our theory and consistency refers also to the corresponding notion in this logic. The particular choice of this underlying formal framework of logic is in general a matter that depends on the problem or phenomena that we are trying to model. In many cases, this is based on ▸ first order predicate calculus, as, for example, in the approach of theory completion in Muggleton and Bryant (2000). But other logics can be used, e.g., the nonmonotonic logics of default logic or logic programming with negation as failure when the modeling of our problem requires this level of expressivity.

This basic formalization as it stands, does not fully capture the explanatory nature of the abductive explanation H in the sense that it necessarily conveys some reason why the observations hold. It would, for example, allow an observation O to be explained by itself or in terms of some other observations rather than in terms of some "deeper" reason for which the observation must hold according to the theory T. Also, as the above specification stands, the observation can be abductively explained by generating in H some new (general) theory completely unrelated to the given theory T. In this case, H does not account for the observations O according to the given theory T and in this sense it may not be considered as an explanation for O relative to T. For these reasons, in order to specify a "level" at which the explanations are required and to understand these relative to the given general theory about the domain of interest, the members of an explanation are normally restricted to belong to a special preassigned, domain-specific class of sentences called *abducible*.

Hence abduction, is typically applied on a model, T, in which we can separate two disjoint sets of predicates: the *observable* predicates and the *abducible* (*or open*) predicates. The basic assumption then is that our model T has reached a sufficient level of comprehension of the domain such that all the incompleteness of the model can be isolated (under some working hypotheses) in its abducible predicates. The observable predicates are assumed to be completely defined (in T) in terms of the abducible predicates and other background auxiliary predicates; any incompleteness in their representation comes from the incompleteness in the abducible predicates. In practice, the empirical observations that drive the learning task are described using the observable predicates. Observations are represented by formulae that refer only to the observable predicates (and possibly some background auxiliary predicates) typically by ground atomic facts on these observable predicates. The abducible predicates describe underlying (theoretical) relations in our model that are not observable directly but can, through the model T, bring about observable information.

The assumptions on the abducible predicates used for building up the explanations may be subject to restrictions that are expressed through *integrity constraints*. These represent additional knowledge that we have on our domain expressing general properties of the domain that remain valid no matter how the theory is to be extended in the process of abduction and associated learning. Therefore, in general, an *abductive theory* is a triple, denoted by $\langle T, A, \mathrm{IC}\rangle$, where T is the background theory, A is a set of abducible predicates, and IC is a set of integrity constraints. Then, in the definition of an abductive explanation given above, one more requirement is added:

3. $T \cup H$ satisfies IC.

The satisfaction of integrity constraints can be formally understood in several ways (see Kakas et al. 1992 and references therein). Note that the integrity constraints reduce the number of explanations for a set of observations filtering out those explanations that do not satisfy them. Based on this notion of abductive explanation a *credulous* form of abductive entailment is defined. Given an abductive theory, $T = \langle T, A, \mathrm{IC}\rangle$, and an observation O then, O is *abductively entailed* by T, denoted by $T \models_A O$, if there exists an abductive explanation of O in T.

This notion of abductive entailment can then form the basis of a coverage relation for learning in the face of incomplete information.

Abductive Concept Learning

Abduction allows us to reason in the face of incomplete information. As such when we have learning problems where the background data on the training examples is incomplete the use of abduction can enhance the learning capabilities.

Abductive concept learning (ACL) (Kakas and Riguzzi 2000) is a learning framework that allows us to learn from incomplete information and to later be able to classify new cases that again could be incompletely specified. Under ACL, we learn abductive theories, $\langle T, A, \mathrm{IC}\rangle$ with abduction playing a central role in the covering relation of the learning problem. The abductive theories learned in ACL contain both rules, in T, for the concept(s) to be learned as well as general clauses acting as integrity constraints in IC.

Practical problems that can be addressed with ACL: (1) concept learning from incomplete background data where some of the background predicates are incompletely specified and (2) concept learning from incomplete background data together with given integrity constraints that provide some information on the incompleteness of the data. The treatment of incompleteness through abduction is integrated within the learning process. This allows the possibility of learning more compact theories that can alleviate the problem of over fitting due to the incompleteness in the data. A specific subcase of these two problems and important third application problem of ACL is that of (3) multiple predicate learning, where each predicate is required to be learned from the incomplete data for the other predicates. Here the abductive reasoning can be used to suitably connect and integrate the learning of the different predicates. This can help to overcome some of the nonlocality difficulties of multiple predicate learning, such as order-dependence and global consistency of the learned theory.

ACL is defined as an extension of ▸ Inductive Logic Programming (ILP) where both the background knowledge and the learned theory are abductive theories. The central formal definition of ACL is given as follows where examples are atomic ground facts on the target predicate(s) to be learned.

Definition 1 (Abductive Concept Learning) Given

- A set of positive examples E^+
- A set of negative examples E^-
- An abductive theory $T = \langle P, A, I \rangle$ as background theory
- An hypothesis space $\mathcal{T} = \langle \mathcal{P}, \mathcal{I} \rangle$ consisting of a space of possible programs $\mathcal{P}$ and a space of possible constraints $\mathcal{I}$

Find

A set of rules $P' \in \mathcal{P}$ and a set of constraints $I' \in \mathcal{I}$ such that the new abductive theory $T' = \langle P \cup P', A, I \cup I' \rangle$ satisfies the following conditions

- $T' \models_A E^+$
- $\forall e^- \in E^-, T' \not\models_A e^-$

where E^+ stands for the conjunction of all positive examples.

An individual example e is said to be *covered* by a theory T' if $T' \models_A e$. In effect, this definition replaces the deductive entailment as the example coverage relation in the ILP problem with abductive entailment to define the ACL learning problem.

The fact that the conjunction of positive examples must be covered means that, for every positive example, there must exist an abductive explanation and the explanations for all the positive examples must be consistent with each other. For negative examples, it is required that no abductive explanation exists for any of them. ACL can be illustrated as follows.

Example 1 Suppose we want to learn the concept $father$. Let the background theory be $T = \langle P, A, \emptyset \rangle$ where:

$$P = \{parent(john, mary), male(john), parent(david, steve), parent(kathy, ellen), female(kathy)\},$$
$$A = \{male, female\}.$$

Let the training examples be:

$$E^+ = \{father(john, mary), father(david, steve)\},$$
$$E^- = \{father(kathy, ellen), father(john, steve)\}.$$

In this case, a possible hypotheses $T' = \langle P \cup P', A, I' \rangle$ learned by ACL would consist of

$$P' = \{father(X,Y) \leftarrow parent(X,Y), male(X)\},$$
$$I' = \{\leftarrow male(X), female(X)\}.$$

This hypothesis satisfies the definition of ACL because:

1. $T' \models_A father(john, mary), father(david, steve)$ with $\Delta = \{male(david)\}$.
2. $T' \not\models_A father(kathy, ellen)$, as the only possible explanation for this goal, namely $\{male(kathy)\}$ is made inconsistent by the learned integrity constraint in I'.
3. $T' \not\models_A father(john, steve)$, as this has no possible abductive explanations.

Hence, despite the fact that the background theory is incomplete (in its abducible predicates), ACL can find an appropriate solution to the learning problem by suitably extending the background theory with abducible assumptions. Note that the learned theory without the integrity constraint would not satisfy the definition of ACL, because there would exist an abductive explanation for the negative example $father(kathy, ellen)$, namely $\Delta^- = \{male(kathy)\}$. This explanation is prohibited in the complete theory by the learned constraint together with the fact $female(kathy)$.

The algorithm and learning system for ACL is based on a decomposition of this problem into two subproblems: (1) learning the rules in P' together with appropriate explanations for the training examples and (2) learning integrity constraints driven by the explanations generated in the first part. This decomposition allows ACL to be developed by combining the two IPL settings of explanatory (predictive) learning and confirmatory (descriptive) learning. In fact, the first subproblem can be seen as a problem of learning from entailment, while the second subproblem as a problem of learning from interpretations.

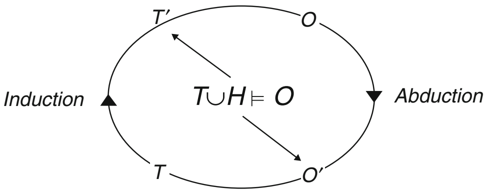
Abduction and Induction

The utility of abduction in learning can be enhanced significantly when this is integrated with *induction*. Several approaches for synthesizing abduction and induction in learning have been developed, e.g., Ade and Denecker (1995), Muggleton and Bryant (2000), Yamamoto (1997), and Flach and Kakas (2000). These approaches aim to develop techniques for knowledge intensive learning with complex background theories. One problem to be faced by purely inductive techniques, is that the training data on which the inductive process operates, often contain gaps and inconsistencies. The general idea is that abductive reasoning can feed information into the inductive process by using the background theory for inserting new hypotheses and removing inconsistent data. Stated differently, abductive inference is used to complete the training data with hypotheses about missing or inconsistent data that explain the example or training data, using the background theory. This process gives alternative possibilities for assimilating and generalizing this data.

Induction is a form of synthetic reasoning that typically generates knowledge in the form of new general rules that can provide, either directly, or indirectly through the current theory T that they extend, new interrelationships between the predicates of our theory that can include, unlike abduction, the observable predicates and even in some cases new predicates. The inductive hypothesis thus introduces new, hitherto unknown, links between the relations that we are studying thus allowing new predictions on the observable predicates that would not have been possible before from the original theory under any abductive explanation.

An inductive hypothesis, H, extends, like in abduction, the existing theory T to a new theory $T'=T \cup \ H$, but now H provides new links between observables and nonobservables that was missing or incomplete in the original theory T. This is particularly evident from the fact that induction can be performed even with an empty given theory T, using just the set of observations. The observations specify incomplete (usually extensional) knowledge about the observable predicates, which we try to *generalize* into new knowledge. In contrast, the generalizing effect of abduction, if at all present, is much more limited. With the given current theory T, that abduction always needs to refer to, we implicitly restrict the generalizing power of abduction as we require that the basic model of our domain remains that of T. Induction has a stronger and genuinely new generalizing effect on the observable predicates than abduction. While the purpose of abduction is to extend the theory with an explanation and then reason with it, thus enabling the generalizing potential of the given theory T, in induction the purpose is to extend the given theory to a new theory, which can provide new possible observable consequences.

This complementarity of abduction and induction – abduction providing explanations from the theory while induction generalizes to form new parts of the theory – suggests a basis for their integration within the context of theory formation and theory development. A *cycle of integration* of abduction and induction (Flach and Kakas 2000) emerges that is suitable for the task of incremental modeling (Fig. 1). Abduction is used to transform (and in some sense normalize) the observations to information on the abducible predicates. Then, induction takes this as input and tries to generalize this information to general



Abduction, Fig. 1 The cycle of abductive and inductive knowledge development. The cycle is governed by the "equation" $T \cup H \models O$, where T is the current theory, O the observations triggering theory development, and H the new knowledge generated. On the left-hand side we have induction, its output feeding into the theory T for later use by abduction on the right; the abductive output in turn feeds into the observational data O' for later use by induction, and so on rules for the abducible predicates now treating these as observable predicates for its own purposes. The cycle can then be repeated by adding the learned information on the abducibles back in the model as new partial information on the incomplete abducible predicates. This will affect the abductive explanations of new observations to be used again in a subsequent phase of induction. Hence, through this cycle of integration the abductive explanations of the observations are added to the theory, not in the (simple) form in which they have been generated, but in a generalized form given by a process of induction on these.

A simple example, adapted from Ray et al. (2003), that illustrates this cycle of integration of abduction and induction is as follows. Suppose that our current model, T, contains the following rule and background facts:

$$sad(X) \leftarrow tired(X), poor(X),$$

$$tired(oli), tired(ale), tired(kr),$$

$$academic(oli), academic(ale), academic(kr),$$

$$student(oli), lecturer(ale), lecturer(kr),$$

where the only observable predicate is $sad/1$.

Given the observations $O = \{sad(ale), sad(kr), not\ \ sad(oli)\}$ can we improve our model? The incompleteness of our model resides in the predicate $poor$. This is the only abducible predicate in our model. Using abduction we can explain the observations O via the explanation:

$$E = \{poor(ale), poor(kr), not\ poor(oli)\}.$$

Subsequently, treating this explanation as training data for inductive generalization we can generalize this to get the rule:

$$poor(X) \leftarrow lecturer(X)$$

thus (partially) defining the abducible predicate $poor$ when we extend our theory with this rule.

This combination of abduction and induction has recently been studied and deployed in several ways within the context of ILP. In particular, *inverse entailment* (Muggleton and Bryant 2000) can be seen as a particular case of integration of abductive inference for constructing a “bottom” clause and inductive inference to generalize it. This is realized in Progol 5.0 and applied to several problems including the discovery of the function of genes in a network of metabolic pathways (King et al. 2004), and more recently to the study of inhibition in metabolic networks (Tamaddoni-Nezhad et al. 2006, 2004). In Moyle (2000), an ILP system called ALECTO, integrates a phase of *extraction-case abduction* to transform each case of a training example to an abductive hypothesis with a phase of induction that generalizes these abductive hypotheses. It has been used to learn robot navigation control programs by completing the specific domain knowledge required, within a general theory of planning that the robot uses for its navigation (Moyle 2002).

The development of these initial frameworks that realize the cycle of integration of abduction and induction prompted the study of the problem of *completeness* for finding any hypotheses H that satisfies the basic task of finding a consistent hypothesis H such that $T \cup H \models O$ for a given theory T, and observations O. Progol was found to be incomplete (Yamamoto 1997) and several new frameworks of integration of abduction and induction have been proposed such as SOLDR (Ito and Yamamoto 1998), CF-induction (Inoue 2001), and HAIL (Ray et al. 2003). In particular, HAIL has demonstrated that one of the main reasons for the incompleteness of Progol is that in its cycle of integration of abduction and induction, it uses a very restricted form of abduction. Lifting some of these restrictions, through the employment of methods from abductive logic programming (Kakas et al. 1992), has allowed HAIL to solve a wider class of problems. HAIL has been extended to a framework, called XHAIL (Ray 2009), for learning nonmonotonic ILP, allowing it to be applied to learn Event Calculus theories for action description (Alrajeh et al. 2009) and complex scientific theories for systems biology (Ray and Bryant 2008).

Applications of this integration of abduction and induction and the cycle of knowledge development can be found in the recent proceedings of the Abduction and Induction in Artificial Intelligence workshops in 2007 (Flach and Kakas 2009) and 2009 (Ray et al. 2009).

Abduction in Systems Biology

Abduction has found a rich field of application in the domain of systems biology and the declarative modeling of computational biology. In a project called, Robot scientist (King et al. 2004), Progol 5.0 was used to generate abductive hypotheses about the function of genes. Similarly, learning the function of genes using abduction has been studied in GenePath (Zupan et al. 2003) where experimental genetic data is explained in order to facilitate the analysis of genetic networks. Also in Papatheodorou et al. (2005) abduction is used to learn gene interactions and genetic pathways from microarray experimental data. Abduction and its integration with induction has been used in the study of inhibitory effect of toxins in metabolic networks (Tamaddoni-Nezhad et al. 2004, 2006) taking into account also the temporal variation that the inhibitory effect can have. Another bioinformatics application of abduction (Ray et al. 2006) concerns the modeling of human immunodeficiency virus (HIV) drug resistance and using this in order to assist medical practitioners in the selection of antiretroviral drugs for patients infected with HIV. Also, the recently developed frameworks of XHAIL and CF-induction have been applied to several problems in systems biology, see e.g., Ray (2009), Ray and Bryant (2008), and Doncescu et al. (2007), respectively. Finally, the recent book edited by Cerro and Inoue (2014) on the logical modeling of biological systems contains several articles on the application of abduction in systems biology.

Absolute Error Loss

▶ Mean Absolute Error

Accuracy

Definition

Accuracy refers to a measure of the degree to which the predictions of a model matches the reality being modeled. The term *accuracy* is often applied in the context of ▶ classification models. In this context, *accuracy* = P($\lambda(X) = Y$), where XY is a joint distribution and the classification model λ is a function $X \rightarrow Y$. Sometimes, this quantity is expressed as a percentage rather than a value between 0.0 and 1.0.

The accuracy of a model is often assessed or estimated by applying it to test data for which the ▶ labels (Y values) are known. The accuracy of a classifier on test data may be calculated as *number of correctly classified objects/total number of objects*. Alternatively, a smoothing function may be applied, such as a ▶ Laplace estimate or an *m*-estimate.

Accuracy is directly related to ▶ error rate, such that *accuracy* = 1.0 – *error rate* (or when expressed as a percentage, *accuracy* = 100 – *error rate*).

Active Learning

David Cohn
Mountain View, CA, USA
Edinburgh, UK

Definition

The term *Active Learning* is generally used to refer to a learning problem or system where the learner has some role in determining on what data it will be trained. This is in contrast to *Passive Learning*, where the learner is simply presented with a ▶ training set over which it has no control. Active learning is often used in settings where obtaining ▶ labeled data is expensive or time-consuming; by sequentially identifying which examples are most likely to be useful, an active learner can sometimes achieve good performance, using far less ▶ training data than would otherwise be required.

Structure of Learning System

In many machine learning problems, the training data are treated as a fixed and given part of the problem definition. In practice, however, the training data are often not fixed beforehand. Rather, the learner has an opportunity to play a role in deciding what data will be acquired for training. This process is usually referred to as "active learning," recognizing that the learner is an active participant in the training process.

The typical goal in active learning is to select training examples that best enable the learner to minimize its loss on future test cases. There are many theoretical and practical results demonstrating that, when applied properly, active learning can greatly reduce the number of training examples, and even the computational effort required for a learner to achieve good generalization.

A toy example that is often used to illustrate the utility of active learning is that of learning a threshold function over a one-dimensional interval. Given $+/-$ labels for N points drawn uniformly over the interval, the expected error between the true value of the threshold and any learner's best guess is bounded by $O(1/N)$. Given the opportunity to sequentially select the position of points to be labeled, however, a learner can pursue a binary search strategy, obtaining a best guess that is within $O(1/2^N)$ of the true threshold value.

This toy example illustrates the sequential nature of example selection that is a component of most (but not all) active learning strategies: the learner makes use of initial information to discard parts of the solution space, and to focus future data acquisition on distinguishing parts that are still viable.

Related Problems

The term "active learning" is usually applied in supervised learning settings, though there are many related problems in other branches of machine learning and beyond. The "exploration" component of the "exploration/exploitation" strategy in reinforcement learning is one such example. The learner *must* take actions to gain information, and must decide what actions will give him/her the information that will best minimize future loss. A number of fields of Operations Research predate and parallel machine learning work on active learning, including Decision Theory (North 1968), Value of Information Computation, Bandit problems (Robbins 1952), and Optimal Experiment Design (Fedorov 1972; Box and Draper 1987).

Active Learning Scenarios

When active learning is used for classification or regression, there are three common settings: *constructive* active learning, *pool-based* active learning, and *stream-based* active learning (also called *selective sampling*).

Constructive Active Learning

In constructive active learning, the learner is allowed to propose arbitrary points in the input space as examples to be labeled. While this in theory gives the learner the most power to explore, it is often not practical. One obstacle is the observation that most learning systems train on only a reduced representation of the instances they are presented with: text classifiers on bags of words (rather than fully-structured text) and speech recognizers on formants (rather than raw audio). While a learning system may be able to identify what pattern of formants would be most informative to label, there is no reliable way to generate audio that a human could recognize (and label) from the desired formants alone.

Pool-Based Active Learning

Pool-based active learning (McCallum and Nigam 1998) is popular in domains such as text classification and speech recognition where unlabeled data are plentiful and cheap, but labels are expensive and slow to acquire. In pool-based active learning, the learner may not propose arbitrary points to label, but instead has access to a set of unlabeled examples, and is allowed to select which of them to request labels for.

A special case of pool-based learning is transductive active learning, where the test distribution is exactly the set of unlabeled examples. The goal then is to sequentially select and label a small number of examples that will best allow predicting the labels of those points that remain unlabeled.

A theme that is common to both constructive and pool-based active learning is the principle of sequential experimentation. Information gained from early queries allows the learner to focus its search on portions of the domain that are most likely to give it additional information on subsequent queries.

Stream-Based Active Learning

Stream-based active learning resembles pool-based learning in many ways, except that the learner only has access to the unlabeled instances as a stream; when an instance arrives, the learner must decide whether to ask for its label or let it go.

Other Forms of Active Learning

By virtue of the broad definition of active learning, there is no real limit on the possible settings for framing it. Angluin's early work on learning regular sets (Angluin 1987) employed a "counterexample" oracle: the learner would propose a solution, and the oracle would either declare it correct, or divulge a counterexample – an instance on which the proposed and true solutions disagreed. Jin and Si (2003) describe a Bayesian method for selecting informative items to recommend when learning a collaborative filtering model, and Steck and Jaakkola (2002) describe a method best described as *unsupervised* active learning to build Bayesian networks in large domains.

While most active learning work assumes that the cost of obtaining a label is independent of the instance to be labeled, there are many scenarios where this is not the case. A mobile robot taking surface measurements must first travel to the point it wishes to sample, making distant points more expensive than nearby ones. In some cases, the cost of a query (e.g., the difficulty of traveling to a remote point to sample it) may not even be known until it is made, requiring the learner to learn a model of that as well. In these situations, the sequential nature of active learning is greatly accentuated, and a learner faces the additional challenges of planning under uncertainty (see "Greedy vs. Batch Active Learning," below).

Common Active Learning Strategies

1. *Version space partitioning*. The earliest practical active learning work (Ruff and Dietterich

1989; Mitchell 1982) explicitly relied on ▶ version space partitioning. These approaches tried to select examples on which there was maximal disagreement between hypotheses in the current version space. When such examples were labeled, they would invalidate as large a portion of the version space as possible. A limitation of explicit version space approaches is that, in underconstrained domains, a learner may waste its effort differentiating portions of the version space that have little effect on the classifier's predictions, and thus on its error.

2. *Query by Committee* (Seung et al. 1992). In query by committee, the experimenter trains an ensemble of models, either by selecting randomized starting points (e.g., in the case of a neural network) or by bootstrapping the training set. Candidate examples are scored based on disagreement among the ensemble models – examples with high disagreement indicate areas in the sample space that are underdetermined by the training data, and therefore potentially valuable to label. Models in the ensemble may be looked at as samples from the version space; picking examples where these models disagree is a way of splitting the version space.
3. *Uncertainty sampling* (Lewis and Gail 1994). Uncertainty sampling is a heuristic form of statistical active learning. Rather than sampling different points in the version space by training multiple learners, the learner itself maintains an explicit model of uncertainty over its input space. It then selects for labeling those examples on which it is least confident. In classification and regression problems, uncertainty contributes directly to expected loss (as the variance component of the "error = bias + variance" decomposition), so that gathering examples where the learner has greatest uncertainty is often an effective loss-minimization heuristic. This approach has also been found effective for non-probabilistic models, by simply selecting examples that lie near the current decision boundary. For some learners, such as support vector machines, this heuristic can be shown to be an approximate partitioning of the learner's version space (Tong and Koller 2001).
4. *Loss minimization* (Cohn 1996). Uncertainty sampling can stumble when parts of the learner's domain are inherently noisy. It may be that, regardless of the number of samples labeled in some neighborhood, it will remain impossible to accurately predict these. In these cases, it would be desirable to not only model the learner's uncertainty over arbitrary parts of its domain, but also to model what effect labeling any future example is expected to have on that uncertainty. For some learning algorithms it is feasible to explicitly compute such estimates (e.g., for locally-weighted regression and mixture models, these estimates may be computed in closed form). It is, therefore, practical to select examples that directly minimize the expected loss to the learner, as discussed below under "Statistical Active Learning."

Statistical Active Learning

Uncertainty sampling and direct loss minimization are two examples of *statistical* active learning. Both rely on the learner's ability to statistically model its own uncertainty. When learning with a statistical model, such as a linear regressor or a mixture of Gaussians (Dasgupta 1999), the objective is usually to find model parameters that minimize some form of expected loss. When active learning is applied to such models, it is natural to also select training data so as to minimize that same objective. As statistical models usually give us estimates on the probability of (as yet) unknown values, it is often straightforward to turn this machinery upon itself to assist in the active learning process (Cohn 1996). The process is usually as follows:

1. Begin by requesting labels for a small random subsample of the examples x_1, x_2, K, $x_n x$ and fit our model to the labeled data.
2. For any x in our domain, a statistical model lets us estimate both the conditional expec-

tation $\hat{y}(x)$ and $\sigma^2_{\hat{y}(x)}$, the variance of that expectation. We estimate our current loss by drawing a new random sample of unlabeled data, and computing the averaged $\sigma^2_{\hat{y}(x)}$.

3. We now consider a candidate point $\tilde{x}$, and ask what reduction in loss we would obtain if we had labeled it $\tilde{y}$. If we knew its label with certainty, we could simply add the point to the training set, retrain, and compute the new expected loss. While we do not know the true $\tilde{y}$, we could, in theory, compute the new expected loss for every possible $\tilde{y}$ and average those losses, weighting them by our model's estimate of $p(\tilde{y}|\tilde{y})$. In practice, this is normally unfeasible; however, for some statistical models, such as locally-weighted regression and mixtures of Gaussians, we can compute the distribution of $p(\tilde{y}|\tilde{y})$ and its effect on $\sigma^2_{\hat{y}(x)}$ in closed form (Cohn 1996).
4. Given the ability to estimate the expected effect of obtaining label $\tilde{y}$ for candidate $\tilde{x}$, we repeat this computation for a sample of M candidates, and then request a label for the candidate with the largest expected decrease in loss. We add the newly-labeled example to our training set, retrain, and begin looking at candidate points to add on the next iteration.

The Need for Reference Distributions

Step (2) above illustrates a complication that is unique to active learning approaches. Traditional "passive" learning usually relies on the assumption that the distribution over which the learner will be tested is the same as the one from which the training data were drawn. When the learner is allowed to select its own training data, it still needs some form of access to the distribution of data on which it will be tested. A pool-based or stream-based learner can use the pool or stream as a proxy for that distribution, but if the learner is allowed (or required) to construct its own examples, it risks wasting all its effort on resolving portions of the solution space that are of no interest to the problem at hand.

A Detailed Example: Statistical Active Learning with LOESS

LOESS (Cleveland et al. 1988) is a simple form of locally-weighted regression using a kernel function. When asked to predict the unknown output y corresponding to a given input x, LOESS computes a ▶ linear regression over known (x, y) pairs, in which it gives pair (x_i, y_i) weight according to the proximity of x_i to x. We will write this weighting as a kernel function, $K(x_i, x)$, or simplify it to k_i when there is no chance of confusion.

In the active learning setting, we will assume that we have a large supply of unlabeled examples drawn from the test distribution, along with labels for a small number of them. We wish to label a small number more so as to minimize the mean squared error (MSE) of our model. MSE can be decomposed into two terms: squared ▶ bias and variance. If we make the (inaccurate but simplifying) assumption that LOESS is approximately unbiased for the problem at hand, minimizing MSE reduces to minimizing the variance of our estimates.

Given n labeled pairs, and a prediction to make for input x, LOESS computes the following covariance statistics around x:

$$\mu_x = \frac{\Sigma_i k_i x_i}{n}, \quad \sigma^2_x = \frac{\Sigma_i k_i (x_i - \mu_x)^2}{n},$$

$$\sigma_{xy} = \frac{\Sigma_i k_i (x_i - \mu_x)(y_i - \mu_y)}{n}$$

$$\mu_y = \frac{\Sigma_i k_i y_i}{n}, \quad \sigma^2_y = \frac{\Sigma_i k_i (y_i - \mu_y)^2}{n},$$

$$\sigma^2_{y|x} = \sigma^2_y - \frac{\sigma_{xy}}{\sigma^2_x}$$

We can combine these to express the conditional expectation of y (our estimate) and its variance as:

$$\hat{y} = \mu_y + \frac{\sigma_{xy}}{\sigma^2_x}(x - \mu_x), \sigma^2_{\hat{y}} = \frac{\sigma^2_{y|x}}{n^2}$$

$$\times \left(\sum_i k_i^2 + \frac{(x - \mu_x)^2}{\sigma^2_x} \sum_i k_i^2 \frac{(x_i - \mu_x)^2}{\sigma^2_x} \right).$$

Our proxy for model error is the variance of our prediction, integrated over the test distribution $\left\langle \sigma_{\hat{y}}^2 \right\rangle$. As we have assumed a pool-based setting in which we have a large number of unlabeled examples from that distribution, we can simply compute the above variance over a sample from the pool, and use the resulting average as our estimate.

To perform statistical active learning, we want to compute how our estimated variance will change if we add an (as yet unknown) label $\tilde{y}$ for an arbitrary $\tilde{x}$. We will write this new expected variance as $\left\langle \tilde{\sigma}_{\hat{y}}^2 \right\rangle$. While we do not *know* what value $\tilde{y}$ will take, our model gives us an estimated mean $\hat{y}(\tilde{x})$ and variance $\sigma_{\hat{y}(\tilde{x})}^2$ for the value, as above. We can add this "distributed" y value to LOESS just as though it were a discrete one, and compute the resulting expectation $\left\langle \tilde{\sigma}_{\hat{y}}^2 \right\rangle$ in closed form. Defining $\tilde{k}$ as $K(\tilde{x}, x)$, we write:

$$\left\langle \tilde{\sigma}_{\hat{y}}^2 \right\rangle = \frac{\left\langle \tilde{\sigma}_{y|x}^2 \right\rangle}{(n+\tilde{k})^2} \left(\sum_i k_i^2 + \tilde{k}^2 + \frac{(x-\tilde{\mu}_x)^2}{\tilde{\sigma}_x^2} \right. \\ \left. \times \left(\sum_i k_i^2 \frac{(x_i-\tilde{\mu}_x)^2}{\tilde{\sigma}_x^2} + \tilde{k}^2 \frac{(\tilde{x}-\tilde{\mu}_x)^2}{\tilde{\sigma}_x^2} \right) \right),$$

where the component expectations are computed as follows:

$$\left\langle \tilde{\sigma}_{y|x}^2 \right\rangle = \left\langle \tilde{\sigma}_y^2 \right\rangle - \frac{\left\langle \tilde{\sigma}_{xy}^2 \right\rangle}{\tilde{\sigma}_x^2},$$

$$\left\langle \tilde{\sigma}_y^2 \right\rangle = \frac{n\sigma_y^2}{n+\tilde{k}} + \frac{n\tilde{k}(\sigma_{y1\overline{x}}^2 + (\hat{y}(\tilde{x})-\mu_y)^2)}{(n+\tilde{k})^2},$$

$$\tilde{\mu}_x = \frac{n\mu_x + \tilde{k}\tilde{x}}{n+\tilde{k}},$$

$$\left\langle \tilde{\sigma}_{xy} \right\rangle = \frac{n\sigma_{xy}}{n+\tilde{k}} + \frac{n\tilde{k}(\tilde{x}-\mu_x)(\hat{y}(\tilde{x})-\mu_y)}{(n+\tilde{k})^2},$$

$$\tilde{\sigma}_x^2 = \frac{n\sigma_x^2}{n+\tilde{k}} + \frac{n\tilde{k}(\tilde{x}-\mu_x)^2}{(n+\tilde{k})^2},$$

$$\left\langle \tilde{\sigma}_{xy}^2 \right\rangle = \left\langle \tilde{\sigma}_{xy} \right\rangle^2 + \frac{n^2\tilde{k}^2\sigma_{y|\overline{x}}^2(\tilde{x}-\mu_x)^2}{(n+\tilde{k})^4}.$$

Greedy Versus Batch Active Learning

It is also worth pointing out that virtually all active learning work relies on greedy strategies – the learner estimates what single example best achieves its objective, requests that one, retrains, and repeats. In theory, it is possible to plan some number of queries ahead, asking what point is best to label now, given that N-1 more labeling opportunities remain. While such strategies have been explored in Operations Research for very small problem domains, their computational requirements make this approach unfeasible for problems of the size typically encountered in machine learning.

There are cases where retraining the learner after every new label would be prohibitively expensive, or where access to labels is limited by the number of iterations as well as by the total number of labels (e.g., for a finite number of clinical trials). In this case, the learner may select a set of examples to be labeled on each iteration. This batch approach, however, is only useful if the learner is able to identify a set of examples whose expected contributions are non-redundant, which substantially complicates the process.

Active Learning Theory

Sanjoy Dasgupta
University of California, San Diego, La Jolla, CA, USA

Definition

The term *active learning* applies to a wide range of situations in which a learner is able to exert some control over its source of data. For instance, when fitting a regression function, the learner may itself supply a set of data points at which to measure response values, in the hope of reducing the variance of its estimate. Such problems have been studied for many decades under the rubric of *experimental design* (Chernoff 1972; Fedorov 1972). More recently, there has been substantial interest within the machine learning community in the specific task of actively learning binary classifiers. This task presents several fundamental statistical and algorithmic challenges, and an understanding of its mathematical underpinnings is only gradually emerging. This brief survey will describe some of the progress that has been made so far.

Learning from Labeled and Unlabeled Data

In the machine learning literature, the task of learning a classifier has traditionally been studied in the framework of *supervised learning*. This paradigm assumes that there is a training set consisting of data points x (from some set $\mathcal{X}$) and their labels y (from some set $\mathcal{Y}$), and the goal is to learn a function $f : \mathcal{X} \to \mathcal{Y}$, that will accurately predict the labels of data points arising in the future. Over the past 50 years, tremendous progress has been made in resolving many of the basic questions surrounding this model, such as "how many training points are needed to learn an accurate classifier?"

Although this framework is now fairly well understood, it is a poor fit for many modern learning tasks because of its assumption that all training points automatically come labeled. In practice, it is frequently the case that the raw, abundant, easily obtained form of data is *unlabeled*, whereas labels must be explicitly procured and are expensive. In such situations, the reality is that the learner starts with a large pool of unlabeled points and must then strategically decide which ones it wants labeled: how best to spend its limited budget.

Example: Speech recognition. When building a speech recognizer, the unlabeled training data consists of raw speech samples, which are very easy to collect: just walk around with a microphone. For all practical purposes, an unlimited quantity of such samples can be obtained. On the other hand, the “label” for each speech sample is a segmentation into its constituent phonemes, and producing even one such label requires substantial human time and attention. Over the past decades, research labs and the government have expended an enormous amount of money, time, and effort on creating labeled datasets of English speech. This investment has paid off, but our ambitions are inevitably moving past what these datasets can provide: we would now like, for instance, to create recognizers for other languages, or for English in specific contexts. Is there some way to avoid more painstaking years of data labeling, to somehow leverage the easy availability of raw speech so as to significantly reduce the number of labels needed? This is the hope of active learning.

Some early results on active learning were in the *membership query* model, where the data is assumed to be *separable* (that is, some hypothesis h perfectly classifies all points) and the learner is allowed to query the label of *any* point in the input space $\mathcal{X}$ (rather than being constrained to a prespecified unlabeled set), with the goal of eventually returning the perfect hypothesis h^*. There is a significant body of beautiful theoretical work in this model (Angluin 2001), but early experiments ran into some telling difficulties. One study (Baum and Lang 1992) found that when training a neural network for handwritten digit recognition, the queries synthesized by the learner were such bizarre and unnatural images that they were impossible for a human to classify. In such contexts, the membership query model is of limited practical value; nonetheless, many of the insights obtained from this model carry over to other settings (Hanneke 2007a).

We will fix as our standard model one in which the learner is *given* a source of unlabeled data, rather than being able to generate these points himself. Each point has an associated label, but the label is initially *hidden*, and there is a cost for revealing it. The hope is that an accurate classifier can be found by querying just a few labels, much fewer than would be required by regular supervised learning.

How can the learner decide which labels to probe? One option is to select the query points at random, but it is not hard to show that this yields the same label complexity as supervised learning. A better idea is to choose the query points *adaptively*: for instance, start by querying some random data points to get a rough sense of where the decision boundary lies, and then gradually refine the estimate of the boundary by specifically querying points in its immediate vicinity. In other words, ask for the labels of data points whose particular positioning makes them especially informative. Such strategies certainly sound good, but can they be fleshed out into practical algorithms? And if so, do these algorithms work well in the sense of producing good classifiers with fewer labels than would be required by supervised learning?

On account of the enormous practical importance of active learning, there are a wide range of algorithms and techniques already available, most of which resemble the aggressive, adaptive sampling strategy just outlined, and many of which show promise in experimental studies. However, a big problem with this kind of sampling is that very quickly the set of labeled points no longer reflects the underlying data distribution. This makes it hard to show that the classifiers learned have good statistical properties (for instance, that they converge to an optimal classifier in the limit of infinitely many labels). This survey will only discuss methods that have proofs of statistical well-foundedness, and whose label complexity can be explicitly analyzed.

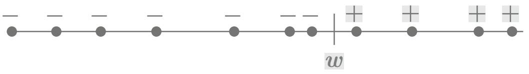
Motivating Examples

We will start by looking at a few examples that illustrate the enormous potential of active learning and that also make it clear why analyses of this new model require concepts and intuitions that are fundamentally different from those that have already been developed for supervised learning.

Example: Thresholds on the Line

Suppose the data lie on the real line, and the available classifiers are simple thresholding functions, $\mathcal{H} = \{h_w : w \in \mathbb{R}\}$:

$$h_w(x) = \begin{cases} +1 & \text{if } x \geq w \\ -1 & \text{if } x < w \end{cases}$$



To make things precise, let us denote the (unknown) underlying distribution on the data $(X, Y) \in \mathbb{R} \times \{+1, -1\}$ by $\mathbb{P}$, and let us suppose that we want a hypothesis $h \in \mathcal{H}$ whose error with respect to $\mathbb{P}$, namely $\text{err}_{\mathbb{P}} = \mathbb{P}(h(X) \neq Y)$, is at most some ϵ. How many labels do we need?

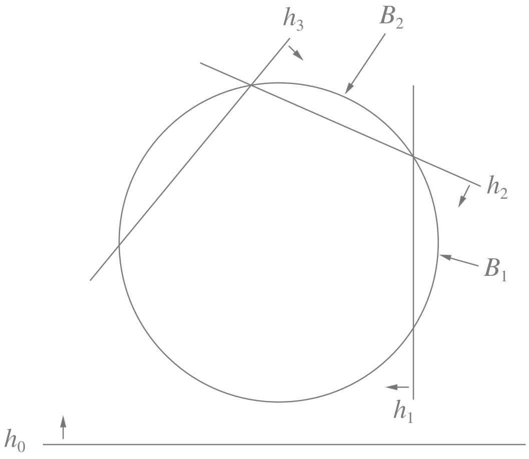
In supervised learning, such issues are well understood. The standard machinery of sample complexity (using VC theory) tells us that if the data are *separable* – that is, if they can be perfectly classified by some hypothesis in $\mathcal{H}$ – then we need approximately $1/\epsilon$ random labeled examples from $\mathbb{P}$, and it is enough to return any classifier consistent with them.

Now suppose we instead draw $1/\epsilon$ *unlabeled* samples from $\mathbb{P}$. If we lay these points down on the line, their hidden labels are a sequence of −s followed by a sequence of +s, and the goal is to discover the point w at which the transition occurs. This can be accomplished with a simple binary search which asks for just log $1/\epsilon$ labels: first ask for the label of the median point; if it is +, move to the 25th percentile point, otherwise move to the 75th percentile point; and so on. Thus, for this hypothesis class, active learning gives an *exponential* improvement in the number of labels needed, from $1/\epsilon$ to just $\log 1/\epsilon$. For instance, if supervised learning requires a million labels, active learning requires just $\log 1{,}000{,}000 \approx 20$, literally!

It is a tantalizing possibility that even for more complicated hypothesis classes $\mathcal{H}$, a sort of generalized binary search is possible. A natural next step is to consider linear separators in *two* dimensions.

Example: Linear Separators in $\mathbb{R}^2$

Let $\mathcal{H}$ be the hypothesis class of linear separators in $\mathbb{R}^2$, and suppose the data is distributed according to some density supported on the perimeter of the unit circle. It turns out that the positive results of the one-dimensional case do not generalize: there are some target hypotheses in $\mathcal{H}$ for which $\Omega(1/\epsilon)$ labels are needed to find a classifier with error rate less than ϵ, no matter what active learning scheme is used.



Active Learning Theory, Fig. 1 $\mathbb{P}$ is supported on the circumference of a circle. Each B_i is an arc of probability mass ϵ

To see this, consider the following possible target hypotheses (Fig. 1):

- h_0: all points are positive.
- $h_i (1 \leq i \leq 1/\epsilon)$: all points are positive except for a small slice B_i of probability mass ϵ.

The slices B_i are explicitly chosen to be disjoint, with the result that $\Omega(1/\epsilon)$ labels are needed to distinguish between these hypotheses. For instance, suppose nature chooses a target hypothesis at random from among the h_i, $1 \leq i \leq 1/\epsilon$. Then, to identify this target with probability at least 1/2, it is necessary to query points in at least (about) half the B_is.

Thus for these particular target hypotheses, active learning offers little improvement in sample complexity over regular supervised learning. What about other target hypotheses in $\mathcal{H}$, for instance those in which the positive and negative regions are more evenly balanced? It is quite easy (Dasgupta 2005) to devise an active learning scheme which asks for $O(\min\{1/i(h), 1/\epsilon\}) + O(\log 1/\epsilon)$ labels, where $i(h) = \min\{$positive

Pool-based active learning

```
Get a set of unlabeled points $U \subset \mathcal{X}$
Repeat until satisfied:
  Pick some $x \in U$ to label
Return a hypothesis $h \in \mathcal{H}$
```

Stream-based active learning

```
Repeat for $t = 0, 1, 2, \ldots$:
  Choose a hypothesis $h_t \in \mathcal{H}$
  Receive an unlabeled point $x \in \mathcal{X}$
  Decide whether to query its label
```

Active Learning Theory, Fig. 2 Models of pool-and stream-based active learning. The data are draws from an underlying distribution $\mathbb{P}_X$, and hypotheses h are evaluated by $\mathrm{err}_{\mathbb{P}}(h)$. If we want to get this error below ϵ, how many labels are needed, as a function of ϵ?

mass of h, negative mass of $h\}$. Thus even within this simple hypothesis class, the label complexity can run anywhere from $O(\log 1/\epsilon)$ to $\Omega(1/\epsilon)$, depending on the specific target hypothesis!

Example: An Overabundance of Unlabeled Data

In our two previous examples, the amount of unlabeled data needed was $O(\log 1/\epsilon)$, exactly the usual sample complexity of supervised learning. But it is sometimes helpful to have significantly more unlabeled data than this. In Dasgupta (2005), a distribution $\mathbb{P}$ is described for which if the amount of unlabeled data is small (below any prespecified threshold), then the number of labels needed to learn the target linear separator is $\Omega(1/\epsilon)$; whereas if the amount of unlabeled data is much larger, then only $O(\log 1/\epsilon)$ labels are needed. This is a situation where most of the data distribution is fairly uninformative while a miniscule fraction is highly informative. A lot of unlabeled data is needed in order to get even a few of the informative points.

The Sample Complexity of Active Learning

We will think of the unlabeled points $x_1, \ldots, x_n$ as being drawn i.i.d. from an underlying distribution $\mathbb{P}_X$ on $\mathcal{X}$ (namely, the marginal of the distribution $\mathbb{P}$ on $\mathcal{X} \times \mathcal{Y}$), either all at once (a *pool*) or one at a time (a *stream*). The learner is only allowed to query the labels of points in the pool/stream; that is, it is restricted to "naturally occurring" data points rather than synthetic ones (Fig. 2). It returns a hypothesis $h \in \mathcal{H}$ whose quality is measured by its error rate, $\mathrm{err}_{\mathbb{P}}(h)$

In regular supervised learning, it is well known that if the VC dimension of $\mathcal{H}$ is d, then the number of labels that will with high probability ensure $\mathrm{err}_{\mathbb{P}}(h) \leq \epsilon$ is roughly $O(d/\epsilon)$ if the data is separable and $O(d/\epsilon^2)$ otherwise (Haussler 1992); various logarithmic terms are omitted here. For active learning, it is clear from the examples above that the VC dimension alone does not adequately characterize label complexity. Is there a different combinatorial parameter that does?

Generic Results for Separable Data

For separable data, it is possible to give upper and lower bounds on label complexity in terms of a special parameter known as the *splitting index* (Dasgupta et al. 2005). This is merely an existence result: the algorithm needed to realize the upper bound is intractable because it involves explicitly maintaining an ϵ-cover (a coarse approximation) of the hypothesis class, and the size of this cover is in general exponential in the VC dimension. Nevertheless, it does give us an idea of the kinds of label complexity we can hope to achieve.

Example Suppose the hypothesis class consists of intervals on the real line: $\mathcal{X} = \mathbb{R}$ and $\mathcal{H} = \{h_{a,b} : a, b \in \mathbb{R}\}$, where $h_{a,b}(x) = \mathbf{1}(a \leq x \leq b)$. Using the splitting index, the label complexity of active learning is seen to be $\tilde{\Theta}(\min\{1/\mathbb{P}_X([a,b]), 1/\epsilon\} + \log 1/\epsilon)$ when the target hypothesis is $h_{a,b}$ (Dasgupta 2005). Here the $\tilde{\Theta}$ notation is used to suppress logarithmic terms.

Example Suppose $\mathcal{X} = \mathbb{R}^d$ and $\mathcal{H}$ consists of linear separators through the origin. If $\mathbb{P}_X$ is the uniform distribution on the unit sphere, the number of labels needed to learn a hypothesis of error $\leq \epsilon$ is just $\tilde{\Theta}(d \log 1/\epsilon)$, exponentially smaller than the $\tilde{O}(d/\epsilon)$ label complexity of supervised learning. If $\mathbb{P}_X$ is not the uniform distribution but is everywhere within a multiplicative factor $\lambda > 1$ of it, then the label complexity becomes $\tilde{O}((d \log 1/\epsilon) \log^2 \lambda)$, provided the amount of unlabeled data is increased by a factor of λ^2 (Dasgupta 2005).

These results are very encouraging, but the question of an *efficient* active learning algorithm remains open. We now consider two approaches.

Mildly Selective Sampling

The label complexity results mentioned above are based on querying maximally informative points. A less aggressive strategy is to be *mildly selective*, to query all points except those that are quite clearly uninformative. This is the idea behind one of the earliest generic active learning schemes (Cohn et al. 1994). Data points $x_1, x_2, \ldots$ arrive in a stream, and for each one the learner makes a spot decision about whether or not to request a label. When x_t arrives, the learner behaves as follows.

- Determine whether both possible labelings, $(x_t, +)$ and $(x_t, -)$, are consistent with the labeled examples seen so far.
- If so, ask for the label y_t. Otherwise set y_t to be the unique consistent label.

Fortunately, the check required for the first step can be performed efficiently by making two calls to a supervised learner. Thus this is a very simple and elegant active learning scheme, although as one might expect, it is suboptimal in its label complexity (Balcan et al. 2007). Interestingly, there is a parameter called the *disagreement coefficient* that characterizes the label complexity of this scheme and also of some other mildly selective learners (Friedman 2009; Hanneke 2007b).

In practice, the biggest limitation of the algorithm above is that it assumes the data are separable. Recent results have shown how to remove this assumption (Balcan et al. 2006; Dasgupta et al. 2007) and to accommodate classification loss functions other than $0-1$ loss (Beygelzimer et al. 2009). Variants of the disagreement coefficient continue to characterize label complexity in the agnostic setting (Beygelzimer et al. 2009; Dasgupta et al. 2007).

A Bayesian Model

The *query by committee* algorithm (Seung et al. 1992) is based on a Bayesian view of active learning. The learner starts with a prior distribution on the hypothesis space, and is then exposed to a stream of unlabeled data. Upon receiving x_t, the learner performs the following steps.

- Draw two hypotheses h, h' at random from the posterior over $\mathcal{H}$.
- If $h(x_t) \neq h'(x_t)$ then ask for the label of x_t and update the posterior accordingly.

This algorithm queries points that substantially shrink the posterior, while at the same time taking account of the data distribution. Various theoretical guarantees have been shown for it (Freund et al. 1997); in particular, in the case of linear separators with a uniform data distribution, it achieves a label complexity of $O(d \log 1/\epsilon)$, the best possible.

Sampling from the posterior over the hypothesis class is, in general, computationally prohibitive. However, for linear separators with a uniform prior, it can be implemented efficiently using random walks on convex bodies (Gilad-Bachrach et al. 2005).

Other Work

In this survey, I have touched mostly on active learning results of the greatest generality, those that apply to arbitrary hypothesis classes. There is also a significant body of more specialized results.

- Efficient active learning algorithms for specific hypothesis classes.

This includes an online learning algorithm for linear separators that only queries some of the points and yet achieves similar regret bounds to algorithms that query all the points (Cesa-Bianchi et al. 2004). The label complexity of this method is yet to be characterized.

- Algorithms and label bounds for linear separators under the uniform data distribution.

  This particular setting has been amenable to mathematical analysis. For separable data,it turns out that a variant of the perceptron algorithm achieves the optimal $O(d \log 1/\epsilon)$ label complexity (Dasgupta 2005). A simple algorithm is also available for the agnostic setting (Balcan et al. 2007).

Conclusion

The theoretical frontier of active learning is mostly an unexplored wilderness. Except for a few specific cases, we do not have a clear sense of how much active learning can reduce label complexity: whether by just a constant factor, or polynomially, or exponentially. The fundamental statistical and algorithmic challenges involved, together with the huge practical importance of the field, make active learning a particularly rewarding terrain for investigation.

Adaboost

Adaboost is an ▶ ensemble learning technique, and the most well-known of the ▶ Boosting family of algorithms. The algorithm trains models sequentially, with a new model trained at each round. At the end of each round, mis-classified examples are identified and have their emphasis increased in a new training set which is then fed back into the start of the next round, and a new model is trained. The idea is that subsequent models should be able to compensate for errors made by earlier models. See ▶ ensemble learning for full details.

Adaptive Real-Time Dynamic Programming

Andrew G. Barto
University of Massachusetts, Amherst, MA, USA

Synonyms

ARTDP

Definition

Adaptive Real-Time Dynamic Programming (ARTDP) is an algorithm that allows an agent to improve its behavior while interacting over time with an incompletely known dynamic environment. It can also be viewed as a heuristic search algorithm for finding shortest paths in incompletely known stochastic domains. ARTDP is based on ▶ Dynamic Programming (DP), but unlike conventional DP, which consists of off-line algorithms, ARTDP is an on-line algorithm because it uses agent behavior to guide its computation. ARTDP is adaptive because it does not need a complete and accurate model of the environment but learns a model from data collected during agent-environment interaction. When a good model is available, ▶ Real-Time Dynamic Programming (RTDP) is applicable, which is ARTDP without the model-learning component.

Motivation and Background

RTDP combines strengths of heuristic search and DP. Like heuristic search – and unlike conventional DP – it does not have to evaluate the entire state space in order to produce an optimal solution. Like DP – and unlike most heuristic search algorithms – it is applicable to nondeterministic problems. Additionally, RTDP's performance as an ▶ anytime algorithm is better than conventional DP and heuristic search algorithms. ARTDP extends these strengths to problems for which a good model is not initially available.

In artificial intelligence, control engineering, and operations research, many problems require finding a policy (or control rule) that determines how an agent (or controller) should generate actions in response to the states of its environment (the controlled system). When a "cost" or a "reward" is associated with each step of the agent's behavior, policies can be compared according to how much cost or reward they are expected to accumulate over time.

The usual formulation for problems like this in the discrete-time case is the ▶ Markov Decision Process (MDP). The objective is to find a policy that minimizes (maximizes) a measure of the total cost (reward) over time, assuming that the agent–environment interaction can begin in any of the possible states. In other cases, there is a designated set of "start states" that is much smaller than the entire state set (e.g., the initial board configuration in a board game). In these cases, any given policy only has to be defined for the set of states that can be reached from the starting states when the agent is using that policy.

The rest of the states will never arise when that policy is being followed, so the policy does not need to specify what the agent should do in those states.

ARTDP and RTDP exploit situations where the set of states reachable from the start states is a small subset of the entire state space. They can dramatically reduce the amount of computation needed to determine an optimal policy for the relevant states as compared with the amount of computation that a conventional DP algorithm would require to determine an optimal policy for all the states. These algorithms do this by focussing computation around simulated behavioral experiences (if there is a model available capable of simulating these experiences), or around real behavioral experiences (if no model is available).

RTDP and ARTDP were introduced by Barto et al. (1995). The starting point was the novel observation by Bradtke that Korf's Learning Real-Time A* heuristic search algorithm (Korf 1990) is closely related to DP. RTDP generalizes Learning Real-Time A* to stochastic problems. ARTDP is also closely related to Sutton's Dyna system (Sutton 1990) and Jalali and Ferguson's (1989) Transient DP. Theoretical analysis relies on the theory of Asynchronous DP as described by Bertsekas and Tsitsiklis (1989).

ARTDP and RTDP are ▸ model-based reinforcement learning algorithms, so called because they take advantage of an environment model, unlike ▸ model-free reinforcement learning algorithms such as ▸ Q-Learning and Sarsa.

Structure of Learning System

Backup Operations

A basic step of many DP and RL algorithms is a *backup operation*. This is an operation that updates a current estimate of the *cost* of an MDP's state. (We use the cost formulation instead of reward to be consistent with the original presentation of the algorithms. In the case of rewards, this would be called the *value* of a state and we would maximize instead of minimize.) Suppose X is the set of MDP states. For each state $x \in X$, $f(x)$, the cost of state x, gives a measure (which varies with different MDP formulations) of the total cost the agent is expected to incur over the future if it starts in x. If $f_k(x)$ and $f_{k+1}(x)$, respectively, denote the estimate of $f(x)$ before and after a backup, a typical backup operation applied to x looks like this:

$$f_{k+1}(x) = min_{a \in A}[c_x(a) + \sum_{y \in X} p_{xy}(a) f_k(fv)],$$

where A is the set of possible agent actions, $c_x(a)$ is the immediate cost the agent incurs for performing action a in state x, and $p_{xy}(a)$ probability that the environment makes a transition from state x to state y as a result of the agent's action a. This backup operation is associated with the DP algorithm known as ▸ value iteration. It is also the backup operation used by RTDP and ARTDP.

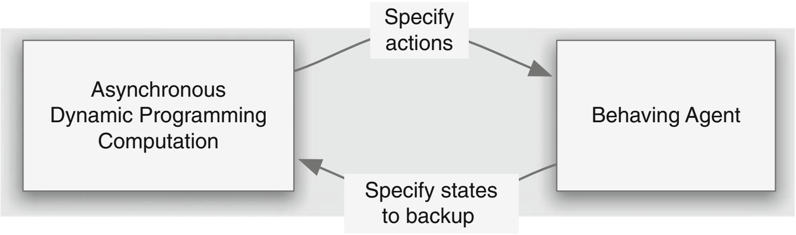
Conventional DP algorithms consist of successive "sweeps" of the state set. Each sweep consists of applying a backup operation to each state. Sweeps continue until the algorithm converges to a solution. Asynchronous DP, which underlies RTDP and ARTDP, does not use systematic sweeps. States can be chosen in any way whatsoever, and as long as backups continue to be applied to all states (and some other conditions are satisfied), the algorithm will converge. RTDP is an instance of asynchronous DP in which the states chosen for backups are determined by the agent's behavior.

The backup operation above is *model-based* because it uses known rewards and transition probabilities, and the values of all the states appear on the right-hand-side of the equation. In contrast, a *sample backup* uses the value of just one sample successor state. RTDP and ARTDP are like RL algorithms in that they rely on real or simulated behavioral experience, but unlike many (but not all) RL algorithms, they use full backups like DP.

Off-Line Versus On-Line

A conventional DP algorithm typically executes off-line. When applied to finding an optimal policy for an MDP, this means that the DP algorithm executes to completion before its result (an optimal policy) is used to control the agent's behavior. The sweeps of DP sequentially "visit" the states of the MDP, performing a backup operation on each state. But it is important not to confuse these visits with the behaving agent's visits to states: the agent is not yet behaving while the off-line DP computation is being done. Hence, the agent's behavior has no influence on the DP computation. The same is true for off-line asynchronous DP.

RTDP is an on-line, or "real-time," algorithm. It is an asynchronous DP computation that executes *concurrently* with the agent's behavior so that the agent's behavior can influence the DP computation. Further, the concurrently executing DP computation can influence the agent's behavior. The agent's visits to states directs the "visits" to states made by the concurrent asynchronous DP computation. At the same time, the action performed by the agent is the action specified by the policy corresponding to the latest results of the DP computation: it is the "greedy" action with respect to the current estimate of the cost function.



In the simplest version of RTDP, when a state is visited by the agent, the DP computation performs the model-based backup operation given above on that same state. In general, for each step of the agent's behavior, RTDP can apply the backup operation to each of an arbitrary set of states, provided that the agent's current state is included. For example, at each step of behavior, a limited-horizon look-ahead search can be conducted from the agent's current state, with the backup operation applied to each of the states generated in the search. Essentially, RTDP is an asynchronous DP computation with the computational effort focused along simulated or actual behavioral trajectories.

Learning A Model

ARTDP is the same as RTDP except that (1) an environment model is updated using any on-line model-learning, or system identification, method, (2) the current environment model is used in performing the RTDP backup operations, and (3) the agent has to perform exploratory actions occasionally instead of always greedy actions as in RTDP. This last step is essential to ensure that the environment model eventually converges to the correct model. If the state and action sets are finite, the simplest way to learn a model is to keep counts of the number of times each transition occurs for each action and convert these frequencies to probabilities, thus forming the maximum-likelihood model.

Summary of Theoretical Results

When RTDP and ARTDP are applied to *stochastic optimal path problems*, one can prove that under certain conditions they converge to optimal policies without the need to apply backup operations to all the states. Indeed, is some problems, only a small fraction of the states need to be visited. A stochastic optimal path problem is an MDP with a nonempty set of start states and a nonempty set of goal states. Each transition until a goal state is reached has a nonnegative immediate cost, and once the agent reaches a goal state, it stays there and thereafter incurs zero cost. Each episode of agent experience begins with a start state. An optimal policy is one that minimizes the cost of every state, i.e., minimizes $f(x)$ for all states x. Under some relatively mild conditions, every optimal policy is guaranteed to eventually reach a goal state.

A state x is *relevant* if a start state s and an optimal policy exist such that x can be reached from s when the agent uses that policy. If we could somehow know which states are relevant, we could restrict DP to just these states and obtain an optimal policy. But this is not possible because knowing which states are relevant requires knowledge of optimal policies, which is what one is seeking. However, under certain conditions, without requiring repeated visits to all the irrelevant states, RTDP produces a policy that is optimal for all the relevant states. The conditions are that (1) the initial cost of every goal state is zero, (2) there exists at least one policy that guarantees that a goal state will be reached with probability one from any start state, (3) all immediate costs for transitions from non-goal states are strictly positive, and (4) none of the initial costs are larger than the actual costs. This result is proved in Barto et al. (1995) by combining aspects of Korf's (1990) proof for LRTA* with results for asynchronous DP.

Special Cases and Extensions

A number of special cases and extensions of RTDP have been developed that improve performance over the basic version. Some examples are as follows. Bonet and Geffner's (2003a) Labeled RTDP labels states that have already been "solved," allowing faster convergence than RTDP. Feng et al. (2003) proposed Symbolic RTDP, which selects a set of states to update at each step using symbolic model-checking techniques. The RTDP convergence theorem still applies because this is a special case of RTDP. Smith and Simmons (2006) developed Focused RTDP that maintains a priority value for each state to better direct search and produce faster convergence. Hansen and Zilberstein's (2001) LAO* uses some of the same ideas as RTDP to produce a heuristic search algorithm that can find solutions with loops to non-deterministic heuristic search problems. Many other variants are possible. Extending ARTDP instead of RTDP in all of these ways would produce analogous algorithms that could be used when a good model is not available.

Abstract

Computational models based on cognitive and neural systems are now deeply embedded in the standard repertoire of machine learning and data mining methods, with intelligent learning systems enhancing performance in nearly every existing application area. Beyond data mining, this article shows how models based on adaptive resonance theory (ART) may provide entirely new questions and practical solutions for technological applications. ART models carry out hypothesis testing, search, and incremental fast or slow, self-stabilizing learning, recognition, and prediction in response to large nonstationary databases (big data). Three computational examples, each based on the distributed ART neural network, frame questions and illustrate how a learning system (each with no free parameters) may enhance the analysis of large-scale data. Performance of each task is simulated on a common mapping platform, a remote sensing dataset called the Boston Testbed, available online along with open-source system code. Key design elements of ART models and links to software for each system are included. The article further points to future applications for integrative ART-based systems that have already been computationally specified and simulated. New application directions include autonomous robotics, general-purpose machine vision, audition, speech recognition, language acquisition, eye movement control, visual search, figure-ground separation, invariant object recognition, social cognition, object and spatial attention, scene understanding, space-time integration, episodic memory, navigation, object tracking, system-level analysis of mental disorders, and machine consciousness.

Adaptive Resonance Theory

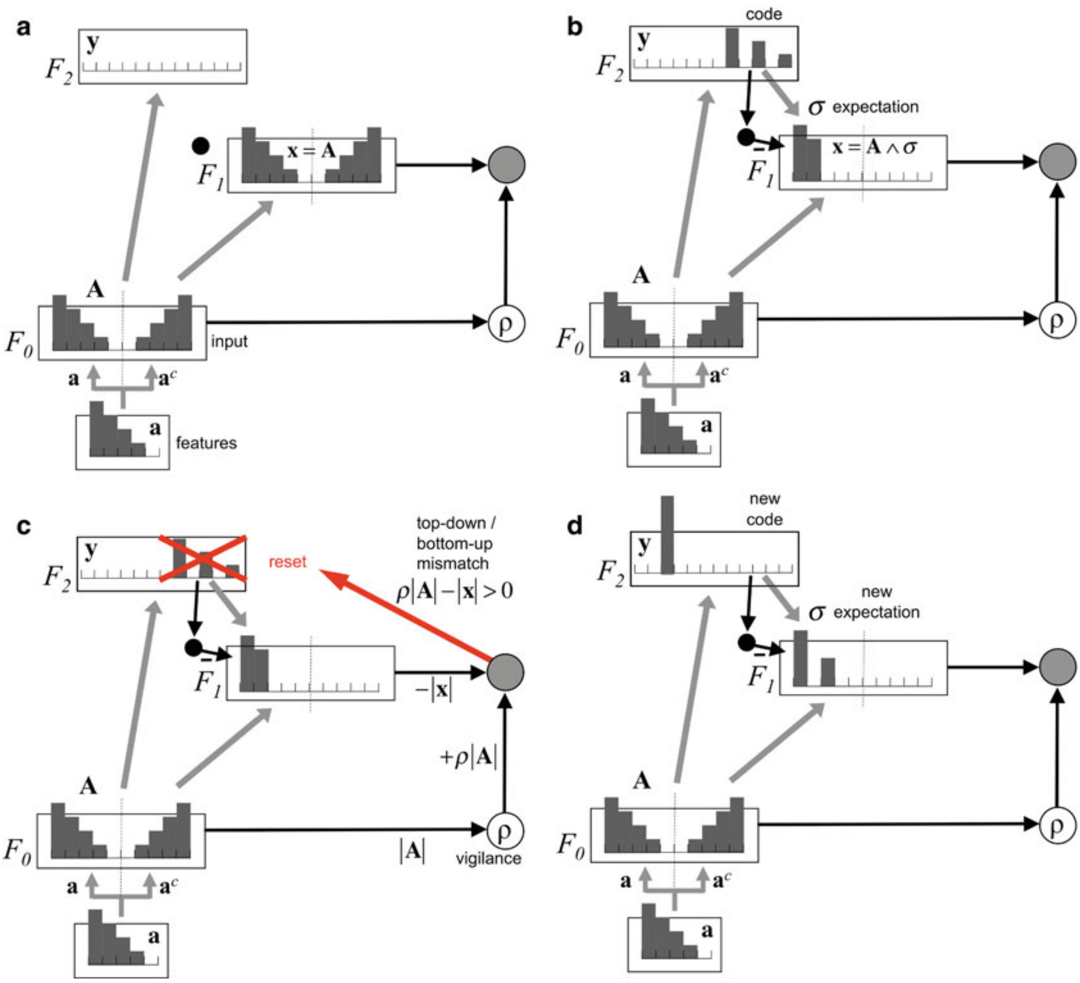
Adaptive resonance theory (ART) neural networks model real-time hypothesis testing, search, learning, recognition, and prediction. Since the 1980s, these models of human cognitive information processing have served as computational engines for a variety of neuromorphic technologies (http://techlab.bu.edu/resources/articles/C5). This article points to a broader range of technology transfers that bring new methods to new problem domains. It describes applications of three specific systems, ART knowledge discovery, self-supervised ART, and biased ART, and summarizes future application areas for large-scale, brain-based model systems.

ART Design Elements

In this article, *ART* refers generally to a theory of cognitive information processing and to an inclusive family of neural models. Design principles derived from scientific analyses and design constraints imposed by targeted applications have jointly guided the development of variants of the basic systems.

Stable Fast Learning with Distributed and Winner-Take-All Coding

ART systems permit fast online learning, whereby long-term memories reach their asymptotes on each input trial. With slow learning, memories change only slightly on each trial. One characteristic that distinguishes classes of ART systems from one another is the nature of their patterns of persistent activation at the coding field F_2 (Fig. 1). The coding field is functionally analogous to the hidden layer of multilayer perceptrons (*Encyclopedia* cross reference). At the perceptron hidden layer, activation is distributed across many nodes, learning needs



Adaptive Resonance Theory, Fig. 1 Distributed ART (dART) (Carpenter 1997). (**a**) At the field F_0, complement coding transforms the feature pattern **a** to the system input **A**, which represents both scaled feature values $a_i \in [0, 1]$ and their complements $(1 - a_i)$ $(i = 1 \ldots M)$. (**b**) F_2 is a competitive field that transforms its input pattern into the working memory code **y**. The F_2 nodes that remain active following competition send the pattern σ of learned top-down expectations to the match field F_1. The pattern active at F_1 becomes $\mathbf{x} = \mathbf{A} \wedge \sigma$, where $\wedge$ denotes the component-wise minimum, or fuzzy intersection. (**c**) A parameter $\rho \in [0, 1]$, called vigilance, sets the matching criterion. The system registers a mismatch if the size of **x** is less than ρ times the size of **A**. A top-down/bottom-up mismatch triggers a signal that resets the active F_2 code. (**d**) Medium-term memories in the F_0-to-F_2 dynamic weights allow the system to activate a new code **y**. When only one F_2 node remains active following competition, the code is maximally compressed, or winner-take-all. When $|\mathbf{x}| \geq \rho|\mathbf{A}|$, the activation pattern **y** persists until the next reset, even if input **A** changes or F_0-to-F_2 signals habituate. During learning, thresholds τ_{ij} in paths from F_0 to F_2 increase according to the dInstar law; and thresholds τ_{ji} in paths from F_2 to F_1 increase according to the dOutstar law

to be slow, and activation does not persist once inputs are removed. The ART coding field is a competitive network where, typically, one or a few nodes in the normalized F_2 pattern **y** sustain persistent activation, even as their generating inputs shift, habituate, or vanish. The pattern **y** persists until an active reset signal (Fig. 1c) prepares the coding field to register a new F_0-to-F_2 input. Early ART networks (Carpenter and Grossberg 1987; Carpenter et al. 1991a, 1992) employed *localist*, or *winner-take-all*, coding, whereby strongly competitive feedback results in only one F_2 node staying active until the next reset. With fast as well as slow learning, memory stability in these early networks relied on their winner-take-all architectures.

Achieving stable fast learning with distributed code representations presents a computational challenge to any learning network. In order to meet this challenge, distributed ART (Carpenter 1997) introduced a new network configuration (Fig. 1) in which system fields are identified with cortical layers (Carpenter 2001). New learning laws (*dInstar* and *dOutstar*) that realize stable fast learning with distributed coding predict adaptive dynamics between cortical layers.

Distributed ART (dART) systems employ a new unit of long-term memory, which replaces the traditional multiplicative weight (*Encyclopedia* cross reference) with a *dynamic weight* (Carpenter 1994). In a path from the F_2 coding node j to the F_1 matching node i, the dynamic weight equals the amount by which coding node activation y_j exceeds an *adaptive threshold* τ_{ji}. The total signal σ_i from F_2 to the i^{th} F_1 node is the sum of these dynamic weights, and F_1 node activation x_i equals the minimum of the top-down expectation σ_i and the bottom-up input A_i. During dOutstar learning, the top-down pattern σ converges toward the matched pattern $\mathbf{x}$.

When coding node activation $y_j$is below τ_{ji}, the dynamic weight is zero and no learning occurs in that path, even if y_j is positive. This property is critical for stable fast learning with distributed codes. Although the dInstar and dOutstar laws are compatible with F_2 patterns $\mathbf{y}$ that are arbitrarily distributed, in practice, following an initial learning phase, most changes in paths to and from a coding node j occur only when its activation y_j is large. This type of learning is therefore called *quasi-localist*. In the special case where coding is winner-take-all, the dynamic weight is equivalent to a multiplicative weight that formally equals the *complement* of the adaptive threshold.

Complement Coding: Learning Both Absent Features and Present Features

ART networks employ a preprocessing step called *complement coding* (Carpenter et al. 1991b), which models the nervous system's ubiquitous computational design known as *opponent processing* (Hurvich and Jameson 1957). Balancing an entity against its opponent, as in opponent colors such as red vs. green or agonist-antagonist muscle pairs, allows a system to act upon relative quantities, even as absolute magnitudes fluctuate unpredictably. In ART systems, complement coding is analogous to retinal on-cells and off-cells (Schiller 1982). When the learning system is presented with a set of input features $\mathbf{a} \equiv (a_1 \ldots a_i \ldots a_M)$, complement coding doubles the number of input components, presenting to the network an input $\mathbf{A}$ that concatenates the original feature vector and its complement (Fig. 1a).

Complement coding produces normalized inputs $\mathbf{A}$ that allow a model to encode features that are consistently *absent* on an equal basis with features that are consistently *present*. Features that are sometimes absent and sometimes present when a given F_2 node is highly active are regarded as uninformative with respect to that node, and the corresponding *present* and *absent* top-down feature expectations shrink to zero. When a new input activates this node, these features are suppressed at the match field F_1 (Fig. 1b). If the active code then produces an error signal, attentional biasing can enhance the salience of input features that it had previously ignored, as described below.

Matching, Attention, and Search

A neural computation central to both scientific and technological analyses is the *ART matching rule* (Carpenter and Grossberg 1987), which controls how attention is focused on critical feature patterns via dynamic matching of a bottom-up sensory input with a top-down learned expectation. Bottom-up/top-down pattern matching and attentional focusing are, perhaps, the primary features common to all ART models across their many variations. Active input features that are not confirmed by top-down expectations are inhibited (Fig. 1b). The remaining activation pattern defines a focus of attention, which, in turn, determines what feature patterns are learned. Basing memories on attended features rather than whole patterns supports the design goal of encoding stable memories with fast as well as slow learning. Encoding attended feature subsets also enables one-to-many learning, where the system may attach many context-dependent labels (*Spot*, *dog*, *animal*) to one input. This capability promotes knowledge discovery ($Spot \Rightarrow dog$ and $dog \Rightarrow animal$) in a learning system that experiences one input at a time, with no explicit connection between inputs.

When the match is good enough, F_2 activation persists and learning proceeds. Where they exceed the corresponding bottom-up input components, top-down signals decay as expectations converge toward the attended pattern at F_1. The coding field F_2 contains a reserve of *uncommitted* coding nodes, which compete with the previously active *committed* nodes. When a previously uncommitted node is first activated during supervised learning, it is associated with its designated output class. During testing, the selection of an uncommitted node means *I don't know*. ART networks for supervised learning are called *ARTMAP* (Carpenter et al. 1991a, 1992).

A mismatch between an active top-down expectation and the bottom-up input leads to a parallel memory search (Fig. 1c). The ART matching criterion is set by a *vigilance parameter* ρ. Low vigilance permits the learning of broad classes, across diverse exemplars, while high vigilance limits learning to narrow classes. When a new input arrives, vigilance equals a baseline level. Baseline vigilance is set equal to zero to maximize generalization. ARTMAP vigilance increases following a predictive error or negative reinforcement (*Encyclopedia* cross reference). The internal computation that determines how far ρ rises to correct the error is called *match tracking* (Carpenter et al. 1991a). As vigilance rises, the network pays more attention to how well top-down expectations match the bottom-up input. The match tracking modification MT– (Carpenter and Markuzon 1998) also allows the system to learn inconsistent cases. For example, three similar, even identical, map regions may have been correctly labeled by different observers as *ocean* or *water* or *natural*. The ability to learn one-to-many maps, which can label a single test input as *ocean* and *water* and *natural*, is a key feature of the ART knowledge discovery system described below.

Applications

Three computational examples illustrate how cognitive and neural systems can introduce new approaches to the analysis of large datasets. Application 1 (self-supervised ART) addresses the question: how can a neural system learning from one example at a time absorb information that is inconsistent but correct, as when a family pet is called *Spot* and *dog* and *animal*, while rejecting similar incorrect information, as when the same pet is called *wolf*? How does this system transform scattered information into knowledge that *dogs are animals*, but not conversely? Application 2 (ART knowledge discovery) asks: how can a real-time system, initially trained with a few labeled examples and a limited feature set, continue to learn from experience, without supervision, when confronted with oceans of additional information, without eroding reliable early memories? How can such individual systems adapt to their unique application contexts? Application 3 (biased ART) asks: how can a neural system that has made an error refocus attention on features that it initially ignored?

The Boston Testbed

The Boston Testbed was developed to compare performance of learning systems applied to challenging problems of spatial analysis. Each multispectral Boston image pixel produces 41 feature values: 6 Landsat 7 Thematic Mapper (TM) bands at 30 m resolution, 2 thermal bands at 60 m resolution, 1 panchromatic band at 15 m resolution, and 32 derived bands representing local contrast, color, and texture. In the Boston dataset, each of 28,735 ground truth pixels is labeled as belonging to one of seven classes (*beach, ocean, ice, river, park, residential, industrial*). For knowledge discovery system training, some *ocean, ice*, and *river* pixels are instead labeled as belonging to broader classes such as *water* or *natural*. No pixel has more than one label, and the learning system is given no information about relationships between target classes. The labeled dataset is available from the CNS Technology Lab Website [http://techlab.bu.edu/classer/data_sets/].

A cross-validation procedure divides an image into four vertical strips: two for training, one for validation (if needed for parameter selection), and one for testing. Class mixtures differ markedly across strips. For example, one strip contains many *ocean* pixels, while another strip contains neither *ocean* nor *beach* pixels. Geographically dissimilar training and testing areas robustly assess regional generalization. In this article, spatial analysis simulations on the Boston Testbed follow this protocol to illustrate ART systems for self-supervised learning, knowledge discovery, and attentional control. Since each system in Applications 1–3 requires no parameter selection, training uses randomly chosen pixels from three strips, with testing on the fourth strip.

Application 1: Learning from Experience with Self-Supervised ART

Computational models of supervised pattern recognition typically utilize two learning phases. During an initial training phase, input patterns, described as specified values of a set of features, are presented along with output class labels or patterns. During a subsequent testing phase, the model generates output predictions for unlabeled inputs, and no further learning takes place.

Although supervised learning has been successfully applied in diverse settings, it does not reflect many natural learning situations. Humans do learn from explicit training, as from a textbook or a teacher, and they do take tests. However, students do not stop learning when they leave the classroom. Rather, they continue to learn from experience, incorporating not only more information but new types of information, all the while building on the foundation of their earlier knowledge. Self-supervised ART models such life-long learning.

An unsupervised learning system clusters unlabeled input patterns. *Semi-supervised* learning incorporates both labeled and unlabeled inputs in its training set, but all inputs typically have the same number of specified feature values. Without any novel features from which to learn, semi-supervised learning systems use unlabeled data to refine the model parameters defined using labeled data. Reviews of semi-supervised learning (Chapelle et al. 2006) have found that many of the successful models are carefully selected and tuned, using a priori knowledge of the problem. Chapelle et al. (2006) conclude that none of the semi-supervised models they review is robust enough to be general purpose. The main difficulty seems to be that, whenever unlabeled instances are different enough from labeled instances to merit learning, these differences could contain misinformation that may damage system performance.

The *self-supervised* paradigm models two learning stages. During Stage 1 learning, the system receives all output labels, but only a subset of possible feature values for each input. During Stage 2 learning, the system may receive more feature values for each input, but no output labels. In Stage 1, when the system can confidently incorporate externally specified output labels, self-supervised ART (Amis and Carpenter 2010) employs winner-take-all coding and fast learning. In Stage 2, when the system internally generates its own output labels, codes are distributed so that incorrect hypotheses do not abruptly override reliable "classroom learning" of Stage 1. The distributed ART learning laws, dInstar (Carpenter 1997) and dOutstar (Carpenter 1994), scale memory changes to internally generated measures of prediction confidence and prevent memory changes altogether for most inputs. Memory stability derives from the dynamic weight representation of long-term memories, which permits learning only in paths to and from highly active coding nodes. Dynamic weights solve a problem inherent in learning laws based on multiplicative weights, which are prone to catastrophic forgetting when implemented with distributed codes and huge datasets, even when learning is very slow.

In addition to emulating the human learning experience, self-supervised learning maps to technological applications that need to cope with huge, ever-changing datasets. A supervised learning system that completes all training before making test predictions does not adapt to new information and individual contexts. A semi-supervised system risks degrading its supervised knowledge. Self-supervised ART continues to learn from new experiences, with built-in safeguards that conserve useful memories. Self-supervised ART code is available from the CNS Technology Lab Website (http://techlab.bu.edu/SSART/).

A simulation study based on the Boston Testbed (Amis and Carpenter 2010) illustrates ways in which high-dimensional problems may challenge *any system* learning without labels. As in most ground truth datasets, labeled pixels consist primarily of clear exemplars of single classes. Because sensors have a 15–60 m resolution, many unlabeled pixels cover multiple classes, such as *ice* and *industrial*. Stage 2 inputs thus mix and distort features from multiple classes, placing many of the unlabeled feature vectors far from the distinct class clusters of the Stage 1 training set. Although the distributed ART learning laws are open to unrestricted adaptation on any pixel, the distributed codes of Stage 2 minimize the influence of mixed pixels. Most memory changes occur on unambiguous cases, despite the fact that the unlabeled pixels provide no external indices of class ambiguity. Self-supervised Stage 2 learning dramatically improves performance compared to learning that ends after Stage 1. On every one of 500 individual simulations, Stage 2 learning improves test accuracy, as unlabeled fully featured inputs consistently expand knowledge from Stage 1 training.

Application 2: Transforming Information into Knowledge Using ART Knowledge Discovery

Classifying terrain or objects may require the resolution of conflicting information from sensors working at different times, locations, and scales and from users with different goals and situations. *Image fusion* has been defined as "the acquisition, processing and synergistic combination of information provided by various sensors or by the same sensor in many measuring contexts" (Simone et al. 2002, p. 3). When multiple sources provide inconsistent data, fusion methods are called upon to appraise information components to decide among various options and to resolve inconsistencies, as when evidence suggests that an object is a *car* or a *truck* or a *bus*. Fusion methods weigh the confidence and reliability of each source, merging complementary information or gathering more data. In any case, at most one of these answers is correct.

The method described here defines a complementary approach to the information fusion problem, considering the case where sensors and sources are both nominally inconsistent and reliable, as when evidence suggests that an object is a *car* and a *vehicle* and *man-made* or when a *car* is alternatively labeled *automobile*. Underlying relationships among classes are assumed to be unknown to the automated system or the human user, as if the labels were encrypted.

The ART knowledge discovery model acts as a self-organizing expert system to derive consistent knowledge structures from such nominally inconsistent data (Carpenter et al. 2005). Once derived, a rule set can be used to assign classes to levels. For each rule $x \Rightarrow y$, class x is located at a lower level than class$y$. Classes connected by arrows that codify a list of rules and confidence values form a graphical representation of a knowledge hierarchy. For spatial data, the resulting diagram of the relationships among classes can guide the construction of orderly layered maps. ART knowledge discovery code is available from the CNS Technology Lab Website (http://techlab.bu.edu/classer/classer_toolkit_overview). On the Boston Testbed, the ART knowledge discovery system places each class at its correct level and finds all the correct rules for this example.

Application 3: Correcting Errors by Biasing Attention Using Biased ART

Memories in ART networks are based on matched patterns that focus attention on *critical features*, where bottom-up inputs match active top-down expectations. While this learning strategy has proved successful for both brain models and applications, computational examples demonstrate that paying too much attention to critical features that have been selected to represent a given category early on may distort memory representations during subsequent learning. If training inputs are repeatedly presented, an ART system will correct these initial errors. However, real-time learning may not afford such repeat opportunities. Biased ART (bART) (Carpenter and Gaddam 2010) solves the problem of overemphasis on early critical features by directing attention away from initially attended features after the system makes a predictive error.

Activity $\mathbf{x}$ at the ART field F_1 computes the match between the field's bottom-up and top-down input patterns (Fig. 1). A reset signal shuts off the active F_2 code when $\mathbf{x}$ fails to meet the matching criterion determined by vigilance ρ. Reset alone does not, however, induce a different code: unless the prior code has left an enduring trace within the F_0–F_2 subsystem, the network will simply reactivate the same pattern at F_2.

Following reset, all ART systems shift attention away from previously active *coding* nodes at the field F_2. As modeled in ART 3 (Carpenter and Grossberg 1990), biasing the bottom-up input to the coding field to favor previously inactive F_2 nodes implements search by enabling the network to activate a new code in response to a reset signal. The ART 3 search mechanism defines a medium-term memory in the F_0-to-F_2 adaptive filter so that the system does not perseverate indefinitely on an output class that had just produced a reset. A presynaptic interpretation of this bias mechanism is transmitter depletion or habituation.

The biased ART network (Carpenter and Gaddam 2010) introduces a second, top-down, medium-term memory which, following reset, shifts attention away from previously active *feature* nodes at the match field F_1. In Fig. 1, the first feature is strongly represented in the input $\mathbf{A}$ and in the matched patterns $\mathbf{x}$ at F_1 both before reset (Fig. 1b) and after reset (Fig. 1d). Following the same sequence as in Fig. 1a–c, biased ART would diminish the size of the first feature in the matched pattern. The addition of featural biasing helps the system to pay more attention to input features that it had previously ignored.

The biasing mechanism is a small modular element that can be added to any ART network. While computational examples and Boston Testbed simulations demonstrate how featural biasing in response to predictive errors improves performance on supervised learning tasks, the error signal that gates biasing could have originated from other sources, as in reinforcement learning. Biased ART code is available from the CNS Technology Lab Website (http://techlab.bu.edu/bART).

Future Directions

Applications for tested software based on computational intelligence abound. This section outlines areas where ART systems may open qualitatively new frontiers for novel technologies. Future applications summarized here would adapt and specialize brain models that have already been mathematically specified and computationally simulated to explain and predict large psychological and neurobiological databases. By linking the brain to mind, these models characterize both mechanism (how the model works) and function (what the model is for). Both mechanism and function are needed to design new applications. These systems embody new designs for autonomous adaptive agents, including new computational paradigms that are called Complementary Computing and Laminar Computing. These paradigms enable the autonomous adaptation in real time of individual persons or machines to nonstationary situations filled with unexpected events. See Grossberg (2013) for a review.

New Paradigms for Autonomous Intelligent Systems: Complementary Computing and Laminar Computing

Functional integration is essential to the design of a complex autonomous system such as a robot moving and learning freely in an unpredictable environment. Linking independent modules for, say, vision and motor control will not necessarily produce a coordinated system that can adapt to unexpected events in changeable contexts. How, then, should such an autonomous adaptive system be designed?

A clue can be found in the nature of brain specialization. How have brains evolved while interacting with the physical world and embodying its invariants? Many scientists have proposed that our brains possess independent modules. The brain's organization into distinct anatomical areas and processing streams shows that brain regions are indeed specialized. Whereas independent modules compute their particular processes on their own, behavioral data argue against this possibility. *Complementary Computing* (Grossberg 2000a,b, 2013) concerns the discovery that pairs of parallel cortical processing streams compute computationally complementary properties. Each stream has complementary strengths and weaknesses, much as in physical principles like the Heisenberg uncertainty principle. Each cortical stream can also possess multiple processing stages. These stages realize a *hierarchical resolution of uncertainty*. "Uncertainty" here means that computing one set of properties at a given stage prevents computation of a complementary set of properties at that stage. Complementary Computing proposes that the computational unit of brain processing that has behavioral significance consists of parallel and hierarchical interactions between complementary cortical processing streams with multiple processing stages. These interactions overcome complementary weaknesses to compute necessary information about a particular type of biological intelligence.

Five decades of neural modeling have shown how Complementary Computing is embedded as a fundamental design principle in neural systems for vision, speech and language, cognition, emotion, and sensory-motor control. Complementary Computing hereby provides a blueprint for designing large-scale autonomous adaptive systems that are poised for technological implementation.

A unifying anatomical theme that enables communication among cortical systems is *Laminar Computing*. The cerebral cortex, the seat of higher intelligence in all modalities, is organized into layered circuits (often six main layers) that undergo characteristic bottom-up, top-down, and horizontal interactions. As information travels up and down connected regions, distributed decisions are made in real time based on a preponderance of evidence. Multiple levels suppress weaker groupings while communicating locally coherent choices. The distributed ART model (Fig. 1), for example, features three cortical layers, with its distributed code (e.g., at a cortical layer 6) producing a distributed output. Stacks of match fields (inflow) and coding fields (outflow) lay the substrate for cortical hierarchies.

How do specializations of this shared laminar design embody different types of biological intelligence, including vision, speech, language, and cognition? How does this shared design enable seamless intercortical interactions? Models of Laminar Computing clarify how these different types of intelligence all use variations of the same laminar circuitry (Grossberg 2013; Grossberg and Pearson 2008). This circuitry represents a revolutionary synthesis of desirable computational properties of feedforward and feedback processing, digital and analog processing, and bottom-up data-driven processing and top-down attentive hypothesis-driven processing. Realizing such designs in hardware that embodies biological intelligence promises to facilitate the development of increasingly general-purpose adaptive autonomous systems for multiple applications.

Complementary Computing in the Design of Perceptual/Cognitive and Spatial/Motor Systems

Many neural models that embody subsystems of an autonomous adaptive agent have been developed and computationally characterized. It remains to unify and adapt them to particular machine learning applications. Complementary Computing implies that not all of these subsystems could be based on variants of ART. In particular, accumulating experimental and theoretical evidence shows that perceptual/cognitive and spatial/motor processes use different learning, matching, and predictive laws for their complementary functions (Fig. 2). ART-like processing is ubiquitous in perceptual and cognitive processes, including excitatory matching and match-based learning that enables self-stabilizing memories to form. Vector

Adaptive Resonance Theory, Fig. 2 Complementary What and Where cortical processing streams for spatially invariant object recognition and spatially variant spatial representation and action, respectively. Perception and recognition use top-down excitatory matching and match-based fast or slow learning without catastrophic forgetting. Spatial and motor tasks use inhibitory matching and mismatch-based learning to achieve adaptation to changing bodily parameters. *IT* inferotemporal cortex, *PPC* posterior parietal cortex

Associative Map (VAM) processing is often found in spatial and motor processes, which rely on inhibitory matching and mismatch-based learning. In these modalities, spatial maps and motor plants are adaptively updated without needing to remember past maps and parameters. Complementary mechanisms create a self-stabilizing perceptual/cognitive front end for intelligently manipulating the more labile spatial/motor processes that enable our changeable bodies to act effectively upon a changing world.

Some of the existing large-scale ART systems are briefly reviewed here, using visually based systems for definiteness. Citations refer to articles that specify system equations and simulations and that can be downloaded from http://cns.bu.edu/~steve.

Where's Waldo? Unifying Spatial and Object Attention, Learning, Recognition, and Search of Valued Objects and Scenes

ART models have been incorporated into larger system architectures that clarify how individuals autonomously carry out intelligent behaviors as they explore novel environments. One such development is the ARTSCAN family of architectures, which model how individuals rapidly learn to search a scene to detect, attend, invariantly recognize, and look at a valued target object (Fig. 3; Cao, Grossberg, and Markowitz 2011; Chang, Grossberg, and Cao 2014; Fazl, Grossberg, and Mingolla 2009; Foley, Grossberg, and Mingolla 2012; Grossberg, Srinivasan, and Yazdanbakhsh 2014). Such a competence represents a proposed solution of the Where's Waldo problem.

The ventral What stream is associated with object learning, recognition, and prediction, whereas the dorsal Where stream carries out processes such as object localization, spatial attention, and eye movement control. To achieve efficient object recognition, the What stream learns object category representations that become increasingly invariant under view, size, and position changes at higher processing stages. Such invariance enables objects to be learned and recognized without causing a combinatorial explosion. However, by stripping away the positional coordinates of each object exemplar, the What stream loses the ability to command actions to the positions of valued objects. The Where stream computes positional representations of the world and controls actions to acquire objects in it, but does not represent detailed properties of the objects themselves.

ARTSCAN architectures model how an autonomous agent can determine when the views that are foveated by successive scanning movements belong to the same object and thus determine which view-selective categories should be associatively linked to an emerging view- , size-, and positionally-invariant object category. This competence, which avoids the problem of erroneously merging pieces of different objects, works even under the unsupervised learning conditions that are the norm during many object learning experiences in vivo. The model identifies a new role for spatial attention in the Where stream, namely, control of invariant object category learning by the What stream. Interactions across the What and Where streams overcome the deficiencies of computationally complementary properties of these streams.

In the ARTSCAN Search model, both Where-to-What and What-to-Where stream interactions are needed to overcome complementary weaknesses: Where stream processes of spatial attention and predictive eye movement control regulate What stream processes whereby multiple view- and positionally-specific object categories are learned and associatively linked to view- and positionally-invariant object categories through bottom-up and object-attentive top-down interactions. What stream cognitive-emotional learning processes enable the focusing of motivated attention upon the invariant object categories of desired objects (Brown, Bullock, and Grossberg 1999, 2004; Dranias, Grossberg, and Bullock 2008; Grossberg and Seidman 2006). What stream cognitive names or motivational drives can, together with volitional signals, drive a search for Waldo. Mediated by object attention, search proceeds from What stream positionally-invariant representations to Where stream positionally-specific representations that focus spatial attention on Waldo's position. ARTSCAN architectures hereby model how the dynamics of multiple brain regions are coordinated to achieve clear functional goals.

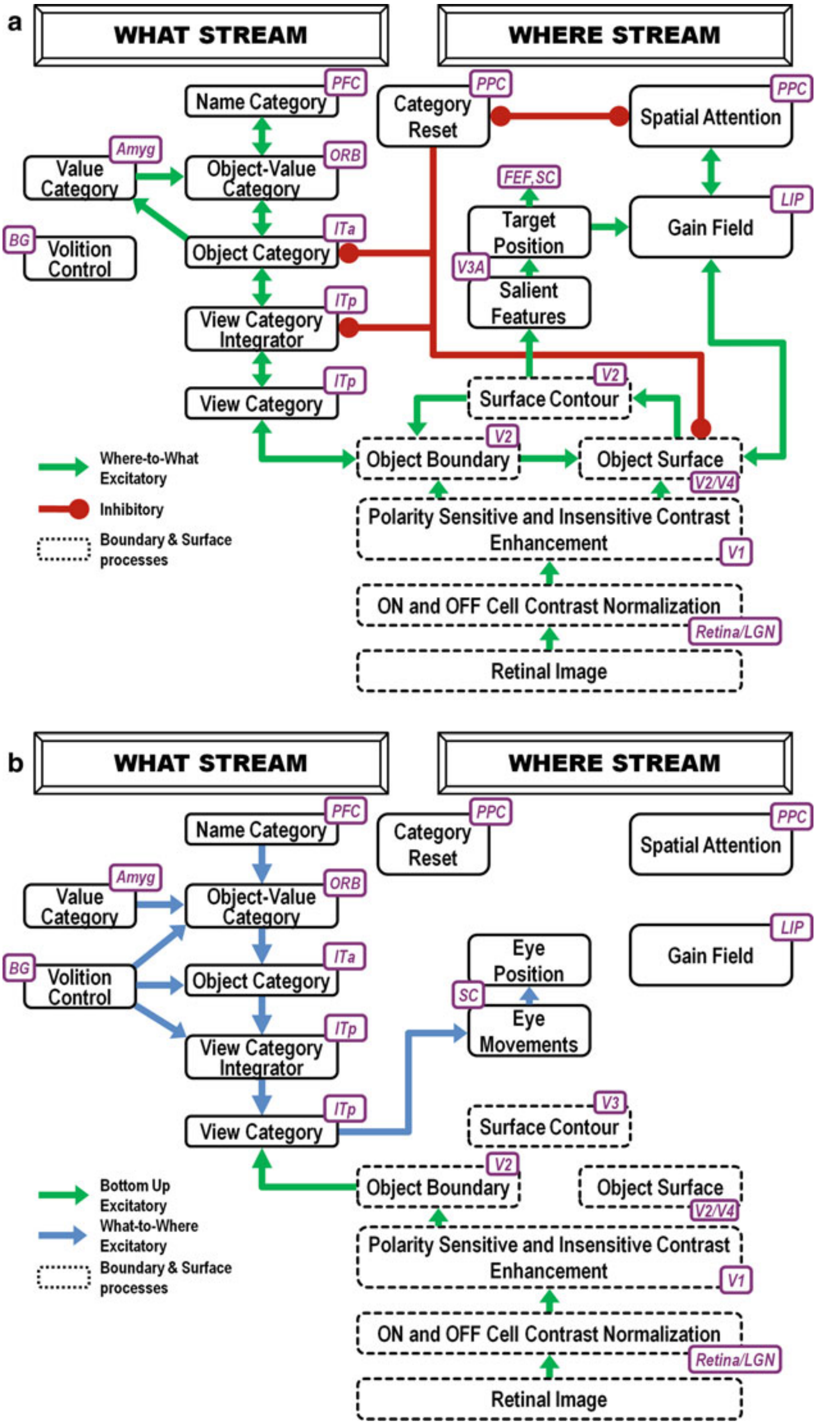
The focus of spatial attention on Waldo's position in the Where stream can be used to control eye and hand movements toward Waldo, after navigational circuits (see below) bring the observer close enough to contact him. VAM-type learning circuits have been developed for the control of goal-oriented eye and hand movements that can be used for this purpose (e.g., Bullock and Grossberg 1988, 1991; Bullock, Cisek, and Grossberg 1998; Contreras-Vidal, Grossberg, and Bullock 1997; Gancarz and Grossberg 1999; Grossberg, Srihasam, and Bullock 2012; Pack, Grossberg, and Mingolla 2001; Srihasam, Bullock, and Grossberg 2009).

The ARTSCENE system (Grossberg and Huang 2009) models how humans can incrementally learn and rapidly predict scene identity by gist and then accumulates learned evidence from scenic textures to refine its initial hypothesis, using the same kind of spatial attentional shrouds that help to learn invariant object categories in ARTSCAN. The ARTSCENE Search system (Huang and Grossberg 2010) models how humans use target-predictive contextual information to guide search for desired targets in familiar scenes. For example, humans can learn that a certain combination of objects may define a context for a kitchen and trigger a more efficient search for a typical object, such as a sink, in that context.

General-Purpose Vision and How It Supports Object Learning, Recognition, and Tracking

Visual preprocessing constrains the quality of visually based learning and recognition. On an assembly line, automated vision systems successfully scan for target objects in this carefully controlled environment. In contrast, a human or robot navigating a natural scene faces overlaid textures, edges, shading, and depth information, with multiple scales and shifting perspectives. In the human brain, evolution has produced a huge preprocessor, involving multiple brain regions, for object and scene representation and for target tracking and navigation. One reason for this is that visual boundaries and surfaces, visual form and motion, and target tracking and visually based navigation are computationally complementary, thus requiring several distinct but interacting cortical processing streams.

Prior to the development of systems such as ARTSCAN and ARTSCENE, the FACADE (Form-And-Color-And-DEpth) model provided



Adaptive Resonance Theory, Fig. 3 (continued) a neural theory of form perception, including 3D vision and figure-ground separation (e.g., Cao and Grossberg 2005, 2012; Fang and Grossberg 2009; Grossberg, Kuhlmann, and Mingolla 2007; Grossberg and Swaminathan 2004; Kelly and Grossberg 2000). The 3D FORMOTION model provides a neural theory of motion processing and form-motion interactions (e.g., Baloch and Grossberg 1997; Baloch, Grossberg, Mingolla, and Nogueira 1999; Berzhanskaya, Grossberg, and Mingolla 2007; Grossberg, Leveille, and Versace 2011; Grossberg, Mingolla, and Viswanathan 2001; Grossberg and Rudd 1992). The FACADE model has just the properties that are needed for solving the Where's Waldo problem, and the 3D FORMOTION model has just the properties that are needed for tracking unpredictably moving targets. Their complementary properties enabled these extensions.

Visual and Spatial Navigation, Cognitive Working Memory, and Planning

In addition to being able to see, learn, recognize, and track valued goal objects, an animal or autonomous robot must also be able to navigate to or away from them and to interact with them through goal-oriented hand and arm movements. Navigation is controlled by two distinct and interacting systems: a visually guided system and a spatial path integration system.

Visually guided navigation through a cluttered natural scene is modeled using the 3D FORMOTION model as a front end. The STARS and ViSTARS neural systems (Browning, Grossberg, and Mingolla 2009a,b; Elder, Grossberg, and Mingolla 2009) model how primates use object motion information to segment objects and optic flow information to determine heading (self-motion direction), for purposes of goal approach and obstacle avoidance in response to realistic environments. The models predict how computationally complementary processes in parallel streams within the visual cortex compute object motion for tracking and self-motion for navigation. The models' steering decisions compute goals as attractors and obstacles as repellers, as do humans.

Spatial navigation based upon path integration signals has been a topic of great interest recently. Indeed, the 2014 Nobel Prize in Physiology or Medicine was awarded to John O'Keefe for his discovery of place cells in the hippocampal cortex and to Edvard and May-Britt Moser for their discovery of grid cells in the entorhinal cortex. The GridPlaceMap neural system (Grossberg and Pilly 2012, 2014; Pilly and Grossberg 2012, 2014; Mhatre, Grossberg, and Gorchetch-

Adaptive Resonance Theory, Fig. 3 ARTSCAN Search macrocircuit and corresponding brain regions. *Dashed boxes* indicate boundary and surface preprocessing. (**a**) Category learning system. *Arrows* represent excitatory cortical processes. Spatial attention in the Where stream regulates view-specific and view-invariant category learning and recognition, and attendant reinforcement learning, in the What stream. Connections ending in circular disks indicate inhibitory connections. (**b**) Where's Waldo search system. Search begins when a name category or value category is activated and subliminally primes an object-value category via the *ART matching rule*. A volition control signal enables the primed object-value category to fire output signals. Bolstered by volitional control signals, these output signals can, in turn, propagate through a positionally-invariant object category to all the positionally-variant view category integrators whose various views and positions are represented by the object category. The view category integrators can subliminally prime, but not fully activate, these view categories. All this occurs in the What stream. When the bottom-up input from an object's boundary/surface representation also activates one of these view categories, its activity becomes suprathreshold, wins the competition across view categories for persistent activation, and activates a spatial attentional representation of Waldo's position in the Where stream. *ITa* anterior part of inferotemporal cortex, *ITp* posterior part of inferotemporal cortex, *PPC* posterior parietal cortex, *LIP* lateral intraparietal cortex, *LGN* lateral geniculate nucleus, *ORB* orbitofrontal cortex, *Amyg* amygdala, *BG* basal ganglia, *PFC* prefrontal cortex, *SC* superior colliculus, *V1* striate visual cortex, *V2, V3,* and *V4* prestriate visual cortices nikov 2012; Pilly and Grossberg 2014) proposes how entorhinal grid cells and hippocampal place cells may be learned as spatial categories in a hierarchy of self-organizing maps. The model responds to realistic rat navigational trajectories by learning both grid cells with hexagonal grid firing fields of multiple spatial scales, and place cells with one or more firing fields. Model dynamics match neurophysiological data about their development in juvenile rats. The GridPlaceMap model enjoys several parsimonious design features that will facilitate their embodiment in technological applications, including hardware: (1) similar ring attractor mechanisms process both linear and angular path integration inputs that drive map learning; (2) the same self-organizing map mechanisms can learn grid cell and place cell receptive fields in a hierarchy of maps, and both grid and place cells can develop by detecting, learning, and remembering the most frequent and energetic co-occurrences of their inputs; and (3) the learning of the dorsoventral organization of grid cell modules with multiple spatial scales that occur in the pathway from the medial entorhinal cortex to hippocampus seems to use mechanisms that are homologous to those for adaptively timed temporal learning that occur in the pathway from the lateral entorhinal cortex to hippocampus (Grossberg and Merrill 1989, 1992; Grossberg and Schmajuk 1989). The homologous mechanisms for representing space and time in this entorhinal-hippocampal system has led to the phrase “neural relativity” for this parsimonious design.

Finally, the GridPlaceMap model is an ART system. It proposes how top-down hippocampus-to-entorhinal attentional mechanisms may stabilize map learning and thereby simulates how hippocampal inactivation may disrupt grid cell properties and explains challenging data about theta, beta, and gamma oscillations.

Visual and path integration information cooperate during navigation. Cognitive planning also influences navigational decisions. More research is needed to show how learning fuses visual, path integration, and planning circuits into a unified navigational system. The design of a general planning system will be facilitated by the fact that similar circuits for short-term storage of event sequences (working memory) and for learning of sequential plans are used by the brain to control linguistic, spatial, and motor behaviors (Grossberg and Pearson 2008; Silver, Grossberg, Bullock, Histed, and Miller 2011).

Social Cognition

How can multiple autonomous systems interact intelligently? Individuals experience the world from self-centered perspectives. What we learn from each other is thus computed in different coordinates within our minds. How do we bridge these diverse coordinates? A model of social cognition that explains how a teacher can instruct a learner who experiences the world from a different perspective can be used to enable a single human or robotic teacher to instruct a large “class” of embodied robots that all experience the teacher from different perspectives.

Piaget’s *circular reaction* notes the feedback loop between the eye and hand in the learning infant, laying the foundation for visually guided reaching. Similarly, feedback between babbled sounds and hearing forms the learned substrate of language production. These *intra*personal circular reactions were extended to *inter*personal circular reactions within the Circular Reactions for Imitative Behavior (CRIB) model (Grossberg and Vladusich 2010). This model shows how social cognition builds upon ARTSCAN mechanisms. These mechanisms clarify how an infant learns how to share joint attention with adult teachers and to follow their gaze toward valued goal objects. The infant also needs to be capable of view-invariant object learning and recognition whereby it can carry out goal-directed behaviors, such as the use of tools, using different object views than the ones that its teachers use. Such capabilities are often attributed to *mirror neurons*. This attribution does not, however, explain the brain processes whereby these competences arise. CRIB proposes how intrapersonal circular reactions create a foundation for interpersonal circular reactions when infants and other learners interact with external teachers in space. Both types of circular reactions involve learned coordinate transformations between body-centered arm movement commands and retinotopic visual feedback, and coordination of processes within and between the What and Where cortical processing streams. Specific breakdowns of model processes generate formal symptoms similar to clinical symptoms of autism.

Mental Disorders and Homeostatic Plasticity

Optimally functioning autonomous intelligent systems require properly balanced complementary systems. What happens when they become imbalanced? In humans, they can experience mental disorders.

Scientific literature on human mental disorders such as autism and schizophrenia is, of necessity, more anecdotal than parametric and is, therefore, an insufficient foundation for model construction. Real-time models of normal mental behavior that are based on the huge databases from decades of psychological and neurobiological experiments have, however, provided insights into the mechanisms of abnormal behaviors (e.g., Carpenter and Grossberg 1993; Grossberg 1984, 2000a,b; Grossberg and Seidman 2006).

Imbalanced processes across the complementary systems that control normal behaviors can produce constellations of model symptoms that strikingly resemble mental disorders. For example, fixing the ART vigilance parameter ρ at too high a level leads to symptoms familiar in autistic individuals, notably learning of hyperconcrete categories and difficulty paying attention to the meaning of a task. Underarousal of the model amygdala can lead to insensitivity to social meanings and also to intense emotional outbursts and coping strategies to reduce event complexity and unexpectedness. Damage to the model cerebellum can lead to defects of adaptively timed learning and thus a host of problems in socialization.

In both humans and robots, it remains an open problem to model how biologically based autonomous systems can discover and maintain their own optimal operating parameters in response to the challenges of an unpredictable world. An initial step toward solving this *homeostatic plasticity* problem was made in Chandler and Grossberg (2012).

Machine Consciousness?

An early ART prediction is that *all conscious states are resonant states,* though not all resonant states are conscious. Since that time, ART has predicted how specific resonances support different kinds of consciousness. These observations suggest the question: can machines that embody ART resonant dynamics experience a type of consciousness? For example, ART models predict that *surface-shroud resonances* subserve conscious percepts of visual qualia, *feature-category resonances* subserve recognition of familiar objects and scenes, *spectral-shroud resonances* subserve conscious percepts of auditory streams, spectral-pitch-and-timbe resonances subserve conscious recognition of auditory streams, *item-list resonances* subserve conscious percepts of speech and language, and *cognitive-emotional resonances* subserve conscious feelings and knowing the objects or events that cause them. ART models also identify the brain regions and interactions that would support these resonances.

These results about model correlates of consciousness emerge from ART analyses of the mechanistic relationships among processes of Consciousness, Learning, Expectation, Attention, Resonance, and Synchrony (the CLEARS processes). Recall, however, that not all resonant states are conscious states. For example, entorhinal-hippocampal resonances are predicted to dynamically stabilize the learning of entorhinal grid cells and hippocampal place cells, and parietal-prefrontal resonances are predicted to trigger the selective opening of basal ganglia gates to enable the read-out of context-appropriate actions. Grossberg (2013; 2016) reviews these and other aspects of ART as a cognitive and neural theory.

Adaptive System

▶ Complexity in Adaptive Systems

Agent

In computer science, the term "agent" usually denotes a software abstraction of a real entity which is capable of acting with a certain degree of autonomy. For example, in artificial societies, agents are software abstractions of real people, interacting in an artificial, simulated environment. Various authors have proposed different definitions of agents. Most of them would agree on the following set of agent properties:

- Persistence: Code is not executed on demand but runs continuously and decides autonomously when it should perform some activity.
- Social ability: Agents are able to interact with other agents.
- Reactivity: Agents perceive the environment and are able to react.

Algorithm Evaluation

Geoffrey I. Webb
Faculty of Information Technology, Monash University, Victoria, Australia

Definition

Algorithm evaluation is the process of assessing a property or properties of an algorithm.

Motivation and Background

It is often valuable to assess the efficacy of an algorithm. In many cases, such assessment is relative, that is, evaluating which of several alternative algorithms is best suited to a specific application.

Processes and Techniques

Many machine learning and data mining algorithms have been proposed. In order to understand the relative merits of these alternatives, it is necessary to evaluate them. The primary approaches to evaluation can be characterized as either theoretical or experimental. Theoretical evaluation uses formal methods to infer properties of the algorithm, such as its computational complexity (Papadimitriou 1994), and also employs the tools of computational learning theory to assess learning theoretic properties. Experimental evaluation applies the algorithm to learning tasks to study its performance in practice.

There are many different types of property that may be relevant to assess depending upon the intended application. These include algorithmic properties, such as time and space complexity. These algorithmic properties are often assessed separately with respect to performance when learning a ▸ model, that is, at ▸ training time, and performance when applying a learned model, that is, at ▸ test time.

Other types of property that are often studied are the properties of the models that are learned (see ▸ Model Evaluation). Strictly speaking, such properties should be assessed with respect to a specific application or class of applications. However, much machine learning research includes experimental studies in which algorithms are compared using a set of data sets with little or no consideration given to what class of applications those data sets might represent. It is dangerous to draw general conclusions about relative performance in general across any application from relative performance on this sample of some unknown class of applications. Such experimental evaluation has become known disparagingly as a *bake-off*.

An approach to experimental evaluation that may be less subject to the limitations of bake-offs is the use of experimental evaluation to assess a learning algorithm's ▸ bias and variance profile. Bias and variance measure properties of an algorithm's propensities in learning models rather than directly being properties of the models that are learned. Hence, they may provide more general insights into the relative characteristics of alternative algorithms than do assessments of the performance of learned models on a finite number of applications. One example of such use of bias–variance analysis is found in Webb (2000).

Techniques for experimental algorithm evaluation include ▸ bootstrap sampling, ▸ cross-validation, ▸ holdout evaluation, ▸ out-of-sample evaluation and ▸ prospective evaluation.

Abstract

Anomalies correspond to the behavior of a system which does not conform to its expected or normal behavior. Identifying such anomalies from observed data, or the task of anomaly detection, is an important and often critical analysis task. This includes finding abnormalities in a medical image, fraudulent transactions in a credit card history, or structural defects in an aircraft's engine. The importance of this problem has resulted in a large body of literature on this topic. However, given that the definition of an anomaly is strongly tied to the underlying application, the existing research is often embedded in the application domains, and it is unclear how methods developed for one domain would perform in another. The goal of this article is to provide a general introduction of the anomaly detection problem. We start with the basic formulation of the problem and then discuss the various extensions. In particular, we discuss the challenges associated with identifying anomalies in structured data and provide an overview of existing research in this area. We hope that this article will provide a better understanding of the different directions in which research has been done on this topic, and how techniques developed in one area can be applied in domains for which they were not intended to begin with.

Introduction

Anomalies are the unusual, unexpected, surprising patterns in the observed world. Identifying, understanding, and predicting anomalies from data form one of the key pillars of modern data mining. Effective detection of anomalies allows extracting critical information from data which can then be used for a variety of applications, such as to stop malicious intruders, detect and repair faults in complex systems, and better understand the behavior of natural, social, and engineered systems.

Anomaly detection refers to the problem of finding anomalies in data. While "anomaly" is a generally accepted term, other synonyms, such as outliers, discordant observations, exceptions, aberrations, surprises, peculiarities, or contaminants, are often used in different application domains. In particular, anomalies and outliers are often used interchangeably. Anomaly detection finds extensive use in a wide variety of applications such as fraud detection for credit cards, insurance or healthcare, intrusion detection for cybersecurity, fault detection in safety critical systems, and military surveillance for enemy activities. The importance of anomaly detection stems from the fact that for a variety of application domains, anomalies in data often translate to significant (and often critical) actionable insights. For example, an anomalous traffic pattern in a computer network could mean that a hacked computer is sending out sensitive data to an unauthorized destination (Kumar 2005). An anomalous remotely sensed weather variable such as temperature could imply a heat wave or cold snap or even faulty remote sensing equipment. An anomalous MRI image may indicate early signs of Alzheimer's or the presence of malignant tumors (Spence et al. 2001). Anomalies in credit card transaction data could indicate credit card or identity theft (Aleskerov et al. 1997), or anomalous readings from a spacecraft sensor could signify a fault in some component of the spacecraft (Fujimaki et al. 2005).

Anomaly detection is generally considered as a core machine learning or data mining problem, in the same vein as classification and clustering. Given the practical significance of anomalies, there has been a tremendous interest in studying this problem, starting from statistical methods proposed as early as the nineteenth century (Edgeworth 1887). Over time, a variety of anomaly detection techniques have been developed in several research communities. Many of these techniques have been specifically developed for certain application domains, while others are more generic. Several books and surveys have been published in recent years that provide an overview of the vast literature on this topic (Chandola et al. 2009; Aggarwal 2013; Hodge and Austin 2004; Chandola et al. 2012; Akoglu et al. 2015).

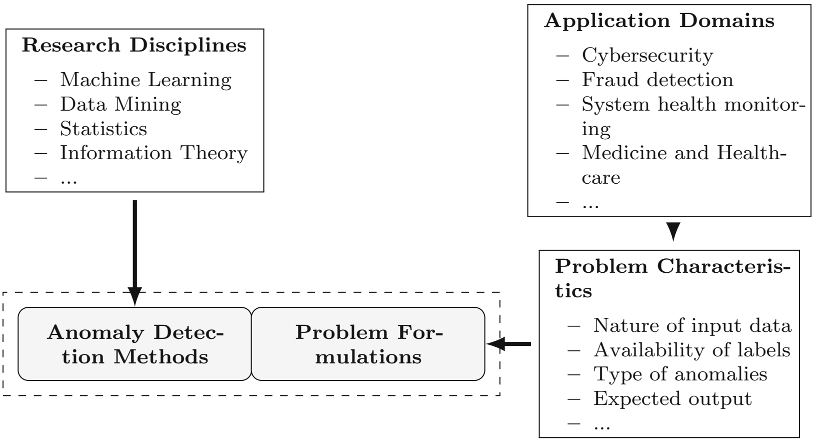
However, one key characteristic of anomaly detection sets it apart from other machine learning problems. Anomaly detection is a highly application-oriented problem which means that there is a lack of a consistent definition of an anomaly across tasks and application domains. Researchers typically define an anomaly in a way that best suits the target application. Thus, several different formulations of the anomaly detection problem exist. Existing solutions for these problem formulations have borrowed concepts from a variety of disciplines in mathematics, statistics, and computer science. This has resulted in a rich and complex landscape for anomaly detection research (See Fig. 1).

The goal of this article is to provide the readers a general understanding of the complex problem space of anomaly detection. Starting with the most basic problem setting, i.e., identifying anomalous data instances from a data set, we then discuss other formulations and the corresponding methods. To highlight the practical importance of anomaly detection, we provide an application-oriented overview of existing methods. Finally, we discuss open challenges and research questions that exist in this area to motivate future research.

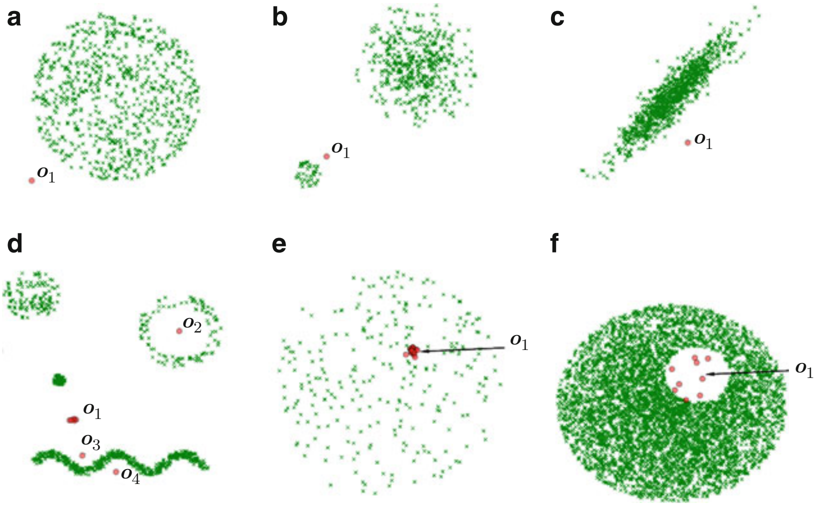
Point Anomaly Detection

In the most widely accepted setting for anomaly detection, also referred to as *point anomaly detection*, the goal is to identify points (objects, instances, etc.) in a data set that do not conform to the accepted normal behavior. Typically, no other knowledge about the normal or anomalous behavior is available. The lack of any ground truth for training makes this an *unsupervised anomaly detection problem*. In the sequel, we briefly talk about other formulations in which partial knowledge of normal and/or anomalous behavior is available.

Even in the basic setting of point anomaly detection, a uniform definition of anomaly does not exist. Figure 2 shows several hypothetical examples of anomalies in a two-dimensional data set. In each of the example, anomalies have a different interpretation. For instance, the point o_1 in Fig. 2a is anomalous because it is far away from the rest of the data points which belong to a dense region. In Fig. 2b, however, the point o_1



Anomaly Detection, Fig. 1 Anatomy of an anomaly detection problem



Anomaly Detection, Fig. 2 Examples of anomalies in 2-D data. (**a**) Anomaly with respect to rest of the data points. (**b**) Anomaly with respect to local neighborhood. (**c**) Anomaly with respect to the data distribution. (**d**) Anomaly with respect to local dense regions. (**e**) Anomalous tight cluster in a sparse region. (**f**) Anomalous sparse cluster in a dense region

is anomalous because it lies relatively far away from a dense region, even though there are points in the second sparse region which are equally distant from their nearest points. In the third example (see Fig. 2c), the point o_1 is anomalous because it lies away from the statistical distribution (bivariate normal) of the data. On the other hand, there are several points located at the ends of the elliptical distribution that are farther away from the points that o_1. The anomalies o_2, o_3, and o_4 in Fig. 2d are points that are away from their closest dense regions. The points in the anomalous set o_1 in Fig. 2d, e, and f are all groups of points whose density is anomalous with respect to the rest of the data set. As shown in the above simple 2-D example, even for point anomaly detection, one can define anomalies in multiple ways. Most existing anomaly detection methods, on the other hand, have been developed, by starting from a different notion of anomaly often motivated by a specific application domain. Thus, one method might be successful in one scenario and not in the other. We now discuss some prominent classes of point anomaly detection methods and the definitions of anomalies that they are best suited for. The various classes of point anomaly detection methods are briefly discussed below:

Nearest neighbor-based methods analyze the nearest neighborhood of a test instance to assign it an anomaly score (Ramaswamy et al. 2000; Knorr and Ng 1999; Knorr et al. 2000; Otey et al. 2006; Tang et al. 2002; Breunig et al. 2000, 1999). The key assumption underlying nearest neighbor-based anomaly detection methods is that normal points lie in dense neighborhoods and anomalous points lie in sparse neighborhoods. Nearest neighbor methods consider suitable measures of density, e.g., distance to the k-th nearest neighbor (Ramaswamy et al. 2000), radius needed to enclose a certain number of points (Knorr and Ng 1999; Knorr et al. 2000), etc. Such methods are capable of identifying global anomalies (See Fig. 2a) but are shown to perform poorly when the data has regions with varying densities (See Fig. 2b). For such scenarios, methods such as local outlier factor (Breunig et al. 1999) and commute distance-based outlier factor (Khoa and Chawla 2010) have been proposed. When data is high dimensional, such methods typically suffer from the "curse of dimensionality." Methods such as angle-based outlier detection (Kriegel et al. 2008) and subspace-based approaches (Zhang and Wang 2006) have been proposed to address this issue.

Clustering-based methods learn clusters from a given data set and assign an anomaly score to a test instance based on its relationship with its nearest cluster (Eskin et al. 2002; He et al. 2003; Marchette 1999; Eskin et al. 2002; Portnoy et al. 2001; Mahoney et al. 2003). Clustering-based methods assume that while normal points exhibit cluster structure, anomalous points do not belong to a cluster or are far away from the nearest normal cluster representative. In certain settings, if the anomalies themselves may form a cluster, one assumes that normal points form large and dense clusters, whereas anomalous points form small clusters or clusters with low density (see Fig. 2d, e and f). While such methods identify anomalies as a post-clustering phase, recently, there have been methods that focus on identifying anomalies simultaneously with the clusters (Ott et al. 2014; Chawla and Gionis 2013).

Statistical methods estimate a parametric or nonparametric model from the data and apply a statistical test on the probability of the instance to be generated by the estimated model to assign an anomaly score to the test instance (Barnett and Lewis 1994; Fox 1972; Abraham and Chuang 1989; Laurikkala et al. 2000; Chow and Yeung 2002). Such statistical models assume that normal points appear in the high probability regions of the distribution, thereby having high likelihood of occurring and hence low anomaly scores. On the other hand, anomalous points appear in the low probability regions of the distribution and have high anomaly score. Such methods are effective if the normal instances can be modeled by a statistical distribution. For instance, if the data in Fig. 2c is modeled as a bivariate normal distribution, the anomalous point o_1 can be easily identified using a standard Mahalanobis statistic, while rest of the points will appear normal.

Classification-based methods learn a classifier from a labeled (or unlabeled) training data and assign an anomaly score or label to a test data instance (Tax 2001; Tax and Duin 1999a, b; Barbara et al. 2001; Roth 2004; Hawkins et al. 2002; Mahoney and Chan 2002, 2003). The key assumption underlying classification-based anomaly detection methods is that based on the available training data, one can learn a classifier in the given feature space to distinguish between normal and anomalous points. Classification-based anomaly detection methods can be categorized into one-class methods, which have one model for the normal class and any point which does not fit that model is deemed anomalous, and multi-class methods, which have multiple normal classes and points which do not fit any of the normal classes are deemed anomalous. A variety of models such as support vector machines, neural networks, Bayesian models, and rule-based systems have been used for classification-based anomaly detection. However, such methods are limited by their dependence on availability of labels for normal and/or anomalous behavior. There are, however, methods that can operate in a purely unsupervised setting, such as the one-class support vector machines (Schölkopf et al. 2001; Tax 2001).

Spectral decomposition-based methods find an approximation of the data using a combination of attributes that capture the bulk of variability in the data. Instances that are significantly different from others in the lower approximation are detected as anomalies (Agovic et al. 2007; Parra et al. 1996; Shyu et al. 2003; Fujimaki et al. 2005). Such methods are particularly effective in scenarios where the data is being generated from a lower dimensional manifold, e.g., See Fig. 2c.

Information theoretic methods are based on the assumption that anomalies in data induce irregularities in the information content of the data set. Such methods analyze the *information content* of a data set using different information theoretic measures such as *Kolmogorov complexity, entropy, relative entropy*, etc. and detect instance that induces irregularities in the information content of the data set as anomalies (Arning et al. 1996; Keogh et al. 2004; Lee and Xiang 2001; He et al. 2005, 2006).

Extensions to Point Anomaly Detection

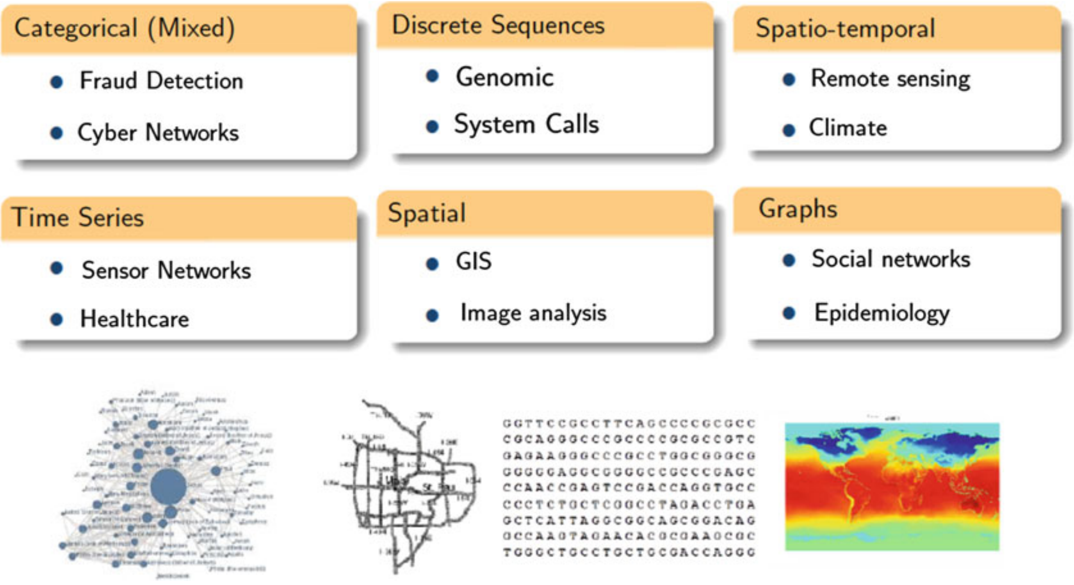
In certain settings, the unsupervised point anomaly detection problem discussed in section "Point Anomaly Detection" is not rich enough to capture all requirements of an application domain. Here we discuss some of the different ways in which the basic problem setting is typically extended.

Nature of Input Data

The modality of the data determines the applicability of anomaly detection techniques. For example, for statistical techniques, different statistical models have to be used for continuous and categorical data. Similarly, for nearest neighbor-based techniques, the nature of attributes would determine the distance measure to be used. Often, instead of the actual data, the pairwise distance between instances might be provided in the form of a distance (or similarity) matrix. In such cases, techniques that require original data instances are not applicable, e.g., many statistical methods and certain classification-based techniques. However, many of the nearest neighbor-based or clustering-based methods discussed in section "Point Anomaly Detection" are still applicable.

Input data can also be categorized based on the relationship present among data instances (Tan et al. 2005). Most of the existing anomaly detection techniques deal with data represented as a vector of attributes (record or point data, if the data can be mapped onto a coordinate space), as discussed in section "Point Anomaly Detection." Typically, no relationship is assumed among the data instances.

In general, data instances can be related to each other. Some examples are *sequence data*, *spatial data*, and *graph data* (See Fig. 3 for an overview). In sequence data, the data instances are linearly ordered, e.g., time-series data, genome sequences, protein sequences. In *spatial data*, each data instance is related to its neighboring instances, e.g., vehicular traffic data, ecological data. When the spatial data has a temporal (sequential) component, it is referred to as *spatiotemporal* data, e.g., climate data. In *graph data*, data instances are represented as vertices in a graph and are connected to other vertices with edges. Later in this section, we will



Anomaly Detection, Fig. 3 Complex data types encountered by anomaly detection and some sample application domains discuss situations where such relationship among data instances becomes relevant for anomaly detection.

Type of Anomaly

Anomaly detection techniques vary depending on the nature of the desired anomaly. We have already discussed point anomalies in section "Point Anomaly Detection," which is the most common form of anomaly. While point anomalies are isolated by nature, several applications need to consider anomalies in a context or small collection of observations which appear anomalous. One can define two additional types of anomalies to capture such structures: contextual anomalies and collective anomalies.

Contextual Anomalies

Data instances which are anomalous in a specific context, but not otherwise, are called contextual anomaly (also referred to as *conditional anomaly* Song et al. 2007). For example, a temperature of 70 °F may be normal over summer, but is anomalous in the context of winter; a heart rate of 130 may be normal for an individual exercising or running, but is anomalous when the individual is resting. In the setting of contextual anomaly detection, the context, such as summer/winter and exercising/resting, has to be specified as a part of the problem formulation. In particular, the data instances are defined using following two sets of attributes:

1. *Contextual attributes*. The contextual attributes are used to determine the context (or neighborhood) for that instance. For example, in spatial data sets, the longitude and latitude of a location are the contextual attributes. In time-series data, time is a contextual attribute which determines the position of an instance on the entire sequence.
2. *Behavioral attributes*. The behavioral attributes define the non-contextual characteristics of an instance. For example, in a spatial data set describing the average rainfall of the entire world, the amount of rainfall at any location is a behavioral attribute.

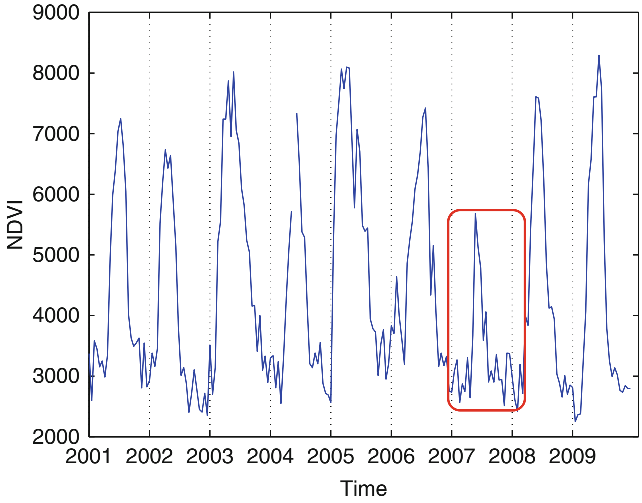
The context determines the normal behavioral attributes, and the normal can be different in different contexts. Anomalous behavior is determined using the values for the behavioral attributes within a specific context, in particular when such values deviate from what is normal in that context. A data instance might be a contextual anomaly in a given context, but an identical data instance (in terms of behavioral attributes) could be considered normal in a different context. This property is key in identifying contextual and behavioral attributes for a contextual anomaly detection technique.

Contextual anomalies have been most commonly explored in time-series data (Weigend et al. 1995; Salvador and Chan 2003) and spatial data (Kou et al. 2006; Shekhar et al. 2001). In spatial data domain, an observation has a neighborhood specified by its location component (refer to our earlier discussion on spatial data). Consider an example in which each data instance is a county location which is defined over several attributes. If these attributes show high pollution levels for a particular county, but the neighborhood of this county is also highly polluted, then this county is not an anomaly. But if the neighborhood has very low pollution, then this county becomes an anomaly.

A similar example can be found in the credit card fraud detection domain. A contextual attribute in credit card domain can be the *time* of purchase. Suppose an individual usually has a weekly shopping bill of $100 except during the Christmas week, when it reaches $1000. A new purchase of $1000 in a week in July will be considered a contextual anomaly, since it does not conform to the normal behavior of the individual in the context of time (even though the same amount spent during Christmas week will be considered normal).

The choice of applying a contextual anomaly detection technique is determined by the meaningfulness of the contextual anomalies in the target application domain. Another key factor is the availability of *contextual* attributes. In several cases, defining a context is straightforward, and hence applying a contextual anomaly detection technique makes sense. In other cases, defining

Anomaly Detection, Fig. 4 Example of a collective anomaly—MODIS NDVI Time Series for 2001–2009 for a Southern California location with a known forest fire (*Canyon fire*) in 2007 [*src:* http://cdfdata.fire.ca.gov/incidents/incidents_archived?archive_year=2007]



a context is not easy, making it difficult to apply such techniques.

Collective Anomalies

If a collection of related data instances is anomalous with respect to the entire data set, it is termed as a collective anomaly. The individual data instances in a collective anomaly may not be anomalies by themselves, but their occurrence together as a collection is anomalous. Figure 4 illustrates an example which shows a greenness measurement called normalized difference vegetation index (NDVI) for a geographic location obtained from a satellite instrument (MODIS). The highlighted region denotes an anomaly where the greenness values are abnormally low for the entire year of 2007 due to a wildfire during that time. Note that the individual measurements during the year are not anomalous by themselves.

As an another illustrative example, consider a sequence of actions occurring in a computer as shown below:

… http-web, buffer-overflow, http-web, http-web, smtp-mail, ftp, http-web, ssh, smtp-mail, http-web, **ssh**, **buffer-overflow**, **ftp**, http-web, ftp, smtp-mail,http-web …

The highlighted sequence of events (**buffer-overflow**, **ssh**, **ftp**) corresponds to a typical web-based attack by a remote machine followed by copying of data from the host computer to remote destination via *ftp*. It should be noted that this collection of events is an anomaly, but the individual events are not anomalies when they occur in other locations in the sequence.

Collective anomalies have been explored for sequence (discrete and time series) data (Forrest et al. 1999; Sun et al. 2006), graph data (Noble and Cook 2003; Li et al. 2014; Akoglu et al. 2015), and spatial data (Shekhar et al. 2001). It should be noted that while point anomalies can occur in any data set, collective anomalies can occur only in data sets in which data instances are related. In contrast, occurrence of contextual anomalies depends on the availability of context attributes in the data. A point anomaly or a collective anomaly can also be a contextual anomaly if analyzed with respect to a context. Thus a point anomaly detection problem or collective anomaly detection problem can be transformed to a contextual anomaly detection problem by incorporating the context information.

Data Labels

In some scenarios, labels associated with data instances denote if that instance is *normal* or *anomalous*. (Also referred to as normal and anomalous classes.) Obtaining labeled data which is accurate as well as representative of all types of normal and anomalous behaviors is often prohibitively expensive. Labels are often provided by human domain experts and hence usually require substantial effort and time. Even in settings where a human expert is able to provide labels, it is usually easier to give examples of normal instances, since the number of different ways an anomaly can occur is quite large and finding examples of the different types of anomalies is difficult. Further, anomalous behavior is often dynamic in nature, e.g., new types of anomalies might arise, for which there is no labeled training data. In certain cases, such as aviation safety, anomalous instances would translate to catastrophic events, and hence will be very rare.

Based on the extent to which the labels are available, anomaly detection techniques can operate in one of the following three modes: supervised, semi-supervised, and unsupervised anomaly detection. Several of the anomaly detection methods discussed in section "Point Anomaly Detection" are unsupervised methods. Semi-supervised methods typically assume availability of a training data that represents the normal behavior. The general approach for such methods is to construct a statistical or machine learning model of normal behavior and then apply a statistical or proximity test to detect new instances which are not consistent with the learnt model. Supervised methods assume availability training data that represents both normal and anomalous behavior. Typically, anomalous events have a much smaller prior probability, and one can leverage methods for rare-class classification, cost-sensitive classification, and other ways of handling class imbalance. However, such methods find limited applicability since obtaining representative training data for anomalous behavior is typically infeasible.

Output of Algorithm

An important aspect for any anomaly detection technique is the manner in which the anomalies are reported. Typically, the outputs produced by anomaly detection techniques are one of the following two types: scores or binary predictions. Scores allow analysts to rank the anomalies in terms of the severity. Typically a threshold is then applied to the scores to identify the anomalies on which to act upon. The threshold is often set by either identifying a natural cutoff point in the sorted scores or based on the number of desired anomalies for further analysis. Methods that assign a binary label to data objects (anomaly or normal) are often easier to understand, though they lack the capability of ranking the anomalies. There are some research in calibrating the scores as probabilities (Gao and Tan 2006) for better interpretability (Kriegel et al. 2011; Schubert et al. 2012).

Anomaly Detection for Complex Data

In section "Point Anomaly Detection" we discussed anomaly detection in the context of data without any explicit relationship defined among them. However, in many applications, data objects are related, and often the anomalous behavior can only be identified by analyzing the relationships between the objects. In this section, we discuss the anomaly detection methods developed to handle the different types of relationships.

Symbolic Sequences

In this section, we provide an overview of the existing research on anomaly detection for symbolic sequences. Methods in this area can be grouped into following categories:

- **Kernel-Based Techniques:** These techniques treat the entire test sequence as a unit element in the analysis (Budalakoti et al. 2006, 2007; Yang and Wang 2003) and hence are analogous to point-based anomaly detection techniques. They typically apply a proximity-based point anomaly detection technique by defining an appropriate similarity kernel for the sequences.
- **Window-Based Techniques:** These techniques analyze a short window of symbols—a short subsequence—within the test sequence at a time (Forrest et al. 1996; Hofmeyr et al. 1998; Endler 1998; Debar et al. 1998; Ghosh et al. 1999a, b; Lane and Brodley 1997, 1999; Cabrera et al. 2001). Thus such techniques treat a subsequence within the test sequence as a unit element for analysis. These techniques require an additional step

in which the anomalous nature of the entire test sequence is determined, based on the analysis on the subsequences within the entire sequence.

- **Markovian Techniques:** These techniques predict the probability of observing each symbol of the test sequence, using a probabilistic model, and use the per-symbol probabilities to obtain an anomaly score for the test sequence (Sun et al. 2006; Ye 2004; Michael and Ghosh 2000; Eskin et al. 2001; Lee et al. 1997). These techniques analyze each symbol with respect to previous few symbols.
- **Hidden Markov Model-Based Techniques:** These techniques transform the input sequences into sequences of hidden states and then detect anomalies in the transformed sequences (Forrest et al. 1999; Qiao et al. 2002; Zhang et al. 2003; Florez-Larrahondo et al. 2005).

Though several techniques have been proposed for symbolic sequences in various application domains, there has not been any cross domain evaluation and understanding of the existing techniques. Forrest et al. (1999) compared four different anomaly detection techniques, but evaluated them in the context of system call intrusion detection. Sun et al. (2006) proposed a technique for protein sequences, but no evaluation with techniques proposed for system call data was done. Similarly, while Budalakoti et al. (2006) proposed a clustering-based techniques to detect anomalies in flight sequences, it has not been shown how the same technique would perform on system call intrusion detection data or protein data.

Most of the above methods identify an anomalous sequence from a set of sequences, assuming that majority of the sequences are normal. Other methods focus on a different problem formulation, also referred to as *discord detection*, in which the goal is to identify a subsequence within a long sequence which is anomalous with respect to the rest of the sequence. Most of the existing techniques that handle this problem formulation slide a fixed length window across the given long sequence and compare each window with the remaining sequence to detect anomalous windows (Keogh et al. 2005a, 2006; Lin et al. 2005; Wei et al. 2005).

Time Series

Most methods that handle time-series data deal primarily with univariate signals, i.e., a single measurement captured over time. Several statistical techniques detect anomalous observations (also referred to as *outliers*) within a single time series using various time series modeling techniques such as regression (Fox 1972; Abraham and Chuang 1989; Rousseeuw and Leroy 1987), autoregression (AR) (Fujimaki et al. 2005; Wu and Shao 2005), ARMA (Pincombe 2005), ARIMA (Zare Moayedi and Masnadi-Shirazi 2008), support vector regression (SVR) (Ma and Perkins 2003), Kalman filters Knorn and Leith (2008), etc. The general approach behind such techniques is to forecast the next observation in the time series, using the statistical model and the time series observed so far, and compare the forecasted observation with the actual observation to determine if an anomaly has occurred.

Two broad categories of techniques have been proposed to identify anomalous time series in a time-series database (Chandola et al. 2009), viz., segmentation-based and kernel-based anomaly detection techniques. The general approach behind segmentation-based techniques is to segment the normal time series and treat each segment as a state in a *finite-state automaton* (FSA) and then use the FSA to determine if a test time series is anomalous or not. Several variants of the segmentation-based technique have been proposed (Chan and Mahoney 2005; Mahoney and Chan 2005; Salvador and Chan 2005). Kernel-based anomaly detection techniques compute similarity/distance between time series and apply a nearest neighbor-based anomaly detection technique on the similarity "kernel" (Protopapas et al. 2006; Wei et al. 2006; Yankov et al. 2007). Protopapas et al. (2006) use *cross correlation* as the similarity measure and compute the anomaly score of a test time series as the inverse of its average similarity to all other time series in the given data set. Wei et al. (2006) use a *rotation invariant* version of Euclidean distance to compute distance between time series and then assign an anomaly score to each time series as equal to its distance to its nearest neighbor. Yankov et al. (2007) proposed pruning-based heuristics to improve the efficiency of the nearest neighbor technique (Wei et al. 2006).

Several anomaly detection techniques for time series data identify anomalous subsequences within a long time series (also referred to as *discords*) (Keogh et al. 2004, 2005a, 2006; Lin et al. 2005; Fu et al. 2006; Bu et al. 2007; Yankov et al. 2007). Such techniques analyze fixed length windows obtained from the time series by comparing each window with the rest of the time series or against all other windows from that time series. A window which is significantly different from other windows is declared as a discord.

Limited research has been done to identify anomalies in multivariate time series data. Most existing methods for multivariate time series focus on detecting a single anomalous multivariate observation (Baragona and Battaglia 2007; Galeano et al. 2004; Tsay et al. 2000). Baragona and Battaglia (2007) propose an ICA-based technique to detect outliers in multivariate time series. The underlying idea is to isolate the multivariate time series into a set of independent univariate components and an outlier signal and analyze the univariate outlier signal to determine the outliers. The ICA-based technique assumes that the observed signals are linear combination of independent components as well as independent noise signal, and the added noise has a high kurtosis.

Cheng et al. (2009) proposed a distance-based approach to detect anomalous subsequences within a given multivariate sequence. For a given multivariate sequence S, all w length windows are extracted. The distance between each pair of windows is computed to obtain a symmetric $(T - w + 1) \times (T - w + 1)$ kernel matrix. A fully connected graph is constructed using the kernel matrix in which each node represents a w length window and the weight on the edges between the pair of windows is equal to the similarity (inverse of distance) between the pair. The nodes (or components) of the graph that have least connectivity are declared as anomalies.

Graphs and Networks

There has been considerable work done in the area of anomaly detection in graphs (Akoglu et al. 2015). Two broad categories of methods exist for detecting anomalies in graphs. The first type of methods looks for anomalous substructures or patterns within a graph (collective anomalies), while the second type of methods focuses on identifying anomalous nodes (contextual anomalies).

The first type of methods typically operates on graphs in which the nodes and/or edges are described using a set of attributes. Such graphs are often referred to as attributed graphs. The general approach here is to identify subgraphs within a large graph that have similar distribution of attributes (Noble and Cook 2003; Eberle and Holder 2007). In particular, the work by Noble and Cook (2003) identifies the frequent subgraphs in a graph with categorical attributes. Any subgraph that does not match the frequent subgraphs is considered to be anomaly. Subsequently, several variants of the original method have been proposed (Gao et al. 2010; Li et al. 2014; Sánchez et al. 2014).

The second type of methods analyzes each node in a graph with respect to its neighborhood. For instance, the OddBall method (Akoglu et al. 2010), analyzes each node with respect to its *egonet* which is the subgraph induced by the node and the other nodes connected to it in the graph. Other similar methods identify nodes that do not belong to densely connected communities (Sun et al. 2005; Ding et al. 2012; Tong and Lin 2011). Similar methods have been proposed to identify anomalies in attributed graphs (Gao et al. 2010; Müller et al. 2013).

Conclusions and Future Directions

The notion of anomaly is important in most real world settings. Data-driven methods for timely and effective identification of anomalies are essential, and this has triggered tremendous interest in the research community. However, the key difference between anomaly detection and other machine learning problems such as classification and clustering is the lack of a consistent definition of anomalies. Instead, several definitions of anomalies exist, each tailored to the need of an underlying application. In this article, we have provided an overview of this rich area by discussing the key aspects of this problem.

We have discussed different classifications of anomaly detection methods and provided understanding of the strengths and weaknesses of these classes of methods. One of the important subareas in this context is the class of methods that handle complex structured data. We have discussed methods that have been specifically developed to handle sequences, time series, and network data.

Given the unstructured nature of current research, a theoretical understanding of the anomaly detection is challenging to obtain. A possible future work would be to unify the assumptions made by different techniques regarding the normal and anomalous behavior into a statistical or machine learning framework. A limited attempt in this direction is provided by Knorr et al. (1997), where the authors show the relation between distance based and statistical anomalies for two-dimensional data sets.

There are several promising directions for further research in anomaly detection. Contextual and collective anomaly detection techniques are beginning to find increasing applicability in several domains, and there is much scope for development of new techniques in this area. The presence of data across different distributed locations has motivated the need for distributed anomaly detection techniques (Zimmermann and Mohay 2006). While such techniques process information available at multiple sites, they often have to simultaneously protect the information present in each site, thereby requiring privacy preserving anomaly detection techniques (Vaidya and Clifton 2004). With the emergence of sensor networks, processing data as it arrives has become a necessity. Many techniques discussed in this article require the entire test data before detecting anomalies. Recently, techniques have been proposed that can operate in an online fashion (Pokrajac et al. 2007); such techniques not only assign an anomaly score to a test instance as it arrives, but also incrementally update the model.

Ant Colony Optimization

Marco Dorigo and Mauro Birattari
Université Libre de Bruxelles, Brussels, Belgium

Synonyms

ACO

Definition

Ant colony optimization (ACO) is a population-based metaheuristic for the solution of difficult combinatorial optimization problems. In ACO, each individual of the population is an artificial agent that builds incrementally and stochastically a solution to the considered problem. Agents build solutions by moving on a graph-based representation of the problem. At each step their moves define which solution components are added to the solution under construction. A probabilistic model is associated with the graph and is used to bias the agents' choices. The probabilistic model is updated on-line by the agents so as to increase the probability that future agents will build good solutions.

Motivation and Background

Ant colony optimization is so called because of its original inspiration: the foraging behavior of some ant species. In particular, in Beckers et al. (1992) it was demonstrated experimentally that ants are able to find the shortest path between their nest and a food source by collectively exploiting the pheromone they deposit on the ground while walking. Similar to real ants, ACO's artificial agents, also called artificial ants, deposit artificial pheromone on the graph of the problem they are solving. The amount of pheromone each artificial ant deposits is proportional to the quality of the solution the artificial ant has built. These artificial pheromones are used to implement a probabilistic model that is exploited by the artificial ants to make decisions during their solution construction activity.

Structure of the Optimization System

Let us consider a minimization problem $(\mathcal{S}, f)$, where $\mathcal{S}$ is the *set of feasible solutions*, and f is the *objective function*, which assigns to each solution $s \in \mathcal{S}$ a cost value $f(s)$. The goal is to find an optimal solution s^*, that is, a feasible solution of minimum cost. The set of all optimal solutions is denoted by $\mathcal{S}^*$.

Ant colony optimization attempts to solve this minimization problem by repeating the following two steps:

- Candidate solutions are constructed using a parameterized probabilistic model, that is, a parameterized probability distribution over the solution space.
- The candidate solutions are used to modify the model in a way that is intended to bias future sampling toward low cost solutions.

The Ant Colony Optimization Probabilistic Model

We assume that the combinatorial optimization problem $(\mathcal{S}, f)$ is mapped on a problem that can be characterized by the following list of items:

- A finite set $\mathcal{C} = \{c_1, c_2, \ldots, c_{N_c}\}$ of *components*, where N_C is the number of components.
- A finite set $\mathcal{X}$ of *states* of the problem, where a state is a sequence $x = \langle c_i, c_j, \ldots, c_k, \ldots\rangle$ over the elements of $\mathcal{C}$. The length of a sequence x, that is, the number of components in the sequence, is expressed by $|x|$. The maximum length of a sequence is bounded by a positive constant $n < +\infty$.
- A set of (candidate) solutions $\mathcal{S}$, which is a subset of $\mathcal{X}$ (i.e., $\mathcal{S} \subseteq \mathcal{X}$).
- A set of feasible states $\tilde{\mathcal{X}}$, with $\tilde{\mathcal{X}} \subseteq \mathcal{X}$, defined via a set of *constraints* Ω.
- A nonempty set $\mathcal{S}^*$ of optimal solutions, with $\mathcal{S}^* \subseteq \tilde{\mathcal{X}}$ and $\mathcal{S}^* \subseteq \mathcal{S}$.

Given the above formulation (Note that, because this formulation is always possible, ACO can in principle be applied to any combinatorial optimization problem.) artificial ants build candidate solutions by performing randomized walks on the completely connected, weighted graph $\mathcal{G} = (\mathcal{C}, \mathcal{L}, \mathcal{T})$, where the vertices are the components $\mathcal{C}$, the set $\mathcal{L}$ fully connects the components $\mathcal{C}$, and $\mathcal{T}$ is a vector of so-called *pheromone trails* τ. Pheromone trails can be associated with components, connections, or both. Here we assume that the pheromone trails are associated with connections, so that $\tau(i, j)$ is the pheromone associated with the connection between components i and j. It is straightforward to extend the algorithm to the other cases. The graph $\mathcal{G}$ is called the *construction graph*.

To construct candidate solutions, each artificial ant is first put on a randomly chosen vertex of the graph. It then performs a randomized walk by moving at each step from vertex to vertex on the graph in such a way that the next vertex is chosen stochastically according to the strength of the pheromone currently on the arcs. While moving from one node to another of the graph $\mathcal{G}$, constraints Ω may be used to prevent ants from building infeasible solutions. Formally, the solution construction behavior of a generic ant can be described as follows:

ANT_SOLUTION_CONSTRUCTION

- For each ant:
  - Select a start node c_1 according to some problem dependent criterion.
  - Set $k = 1$ and $x_k = \langle c_1 \rangle$.
- While $x_k = \langle c_1, c_2, \ldots, c_k \rangle \in \mathcal{X}, x_k \notin \mathcal{S}$, and the set J_{x_k} of components that can be appended to x_k is not empty, select the next node (component) c_{k+1} randomly according to:

$$P_{\mathcal{T}}(c_{k+1} = c | x_k) = \begin{cases} \dfrac{F_{(c_k,c)}(\tau(c_k,c))}{\sum_{(c_k,y)\in J_{x_k}} F_{(c_k,y)(\tau(c_k,y))}} & \text{if } (c_k,c) \in J_{x_k}, \\ 0 & \text{otherwise,} \end{cases} \tag{1}$$

  where a connection (c_k, y) belongs to J_{x_k} if and only if the sequence $x_{k+1} = \langle c_1, c_2, \ldots, c_k, y \rangle$ satisfies the constraints Ω (that is, $x_{k+1} \in \tilde{\mathcal{X}}$) and $F_{(i,j)}(z)$ is some monotonic function – a common choice being $z^{\alpha}\eta(i,j)^{\beta}$, where α, $\beta > 0$, and $\eta(i,j)$'s are heuristic values measuring the desirability of adding component j after i. If at some stage $x_k \notin \mathcal{S}$ and $J_{x_k} = \emptyset$, that is, the construction process has reached a dead-end, the current state x_k is discarded. However, this situation may be prevented by allowing artificial ants to build infeasible solutions as well. In such a case, an infeasibility penalty term is usually added to the cost function. Nevertheless, in most of the settings in which ACO has been applied, the dead-end situation does not occur.

For certain problems, one may find it useful to use a more general scheme, where F depends on the pheromone values of several "related" connections rather than just a single one. Moreover, instead of the *random-proportional rule* above, different selection schemes, such as the *pseudo-random-proportional rule* (Dorigo and Gambardella 1997), may be used.

The Ant Colony Optimization Pheromone Update

Many different schemes for pheromone update have been proposed within the ACO framework. For an extensive overview, see Dorigo and Stützle (2004). Most pheromone updates can be described using the following generic scheme:

GENERIC_ACO_UPDATE

- $\forall s \in \hat{S}_t, \forall (i,j) \in s : \tau(i,j) \leftarrow \tau(i,j) + Q_F(s|S_1, \ldots, S_t)$
- $\forall (i,j) : \tau(i,j) \leftarrow (1-\rho) \cdot \tau(i,j)$,

where S_i is the sample in the ith iteration, $\rho, 0 \leq \rho < 1$, is the evaporation rate, and $Q_f(s|S_1, \ldots, S_t)$ is some "quality function," which is typically required to be non-increasing with respect to f and is defined over the "reference set" $\hat{S}_t$.

Different ACO algorithms may use different quality functions and reference sets. For example, in the very first ACO algorithm – Ant System (Dorigo et al. 1991, 1996) – the quality function is simply $1/f(s)$ and the reference set $\hat{S}_t = S_t$. In a subsequently proposed scheme, called *iteration best update* (Dorigo and Gambardella 1997), the reference set is a singleton containing the best solution within S_t (if there are several iteration-best solutions, one of them is chosen randomly). For the *global-best update* (Dorigo et al. 1996; Stützle and Hoos 1997), the reference set contains the best among all the iteration-best solutions (and if there are more than one global-best solution, the earliest one is chosen). In Dorigo et al. (1996) an *elitist* strategy was introduced, in which the update is a combination of the previous two.

In case a good lower bound on the optimal solution cost is available, one may use the following quality function (Maniezzo 1999):

$$Q_f(s|S_1,\ldots,S_t) = \tau_0\left(1 - \frac{f(s)-\mathrm{LB}}{\bar{f}-\mathrm{LB}}\right) = \tau_0\frac{\bar{f}-f(s)}{\bar{f}-\mathrm{LB}}, \tag{2}$$

where $\bar{f}$ is the average of the costs of the last k solutions and LB is the lower bound on the optimal solution cost. With this quality function, the solutions are evaluated by comparing their cost to the average cost of the other recent solutions, rather than by using the absolute cost values. In addition, the quality function is automatically scaled based on the proximity of the average cost to the lower bound.

A pheromone update that slightly differs from the generic update described above was used in *ant colony system* (ACS) (Dorigo and Gambardella 1997). There the pheromone is evaporated by the ants online during the solution construction, hence only the pheromone involved in the construction evaporates.

Another modification of the generic update was introduced in $\mathcal{MAX}-\mathcal{MIN}$ Ant System (Stützle and Hoos 1997, 2000), which uses maximum and minimum pheromone trail limits. With this modification, the probability of generating any particular solution is kept above some positive threshold. This helps to prevent search stagnation and premature convergence to suboptimal solutions.

Apriori Algorithm

Hannu Toivonen
University of Helsinki, Helsinki, Finland

Definition

Apriori algorithm (Agrawal et al. 1996) is a data mining method which outputs all ▶ frequent itemsets and ▶ association rules from given data.

Input: set $\mathcal{I}$ of items, multiset $\mathcal{D}$ of subsets of $\mathcal{I}$, frequency threshold min_fr, and confidence threshold min_conf.

Output: all frequent itemsets and all valid association rules in $\mathcal{D}$

Method:

```
1: level := 1; frequent_sets : = $\emptyset$;
2: candidate_sets : = $\{\{i\}|i \in \mathcal{I}\}$;
3: while candidate_sets $\neq \emptyset$
    3.1: scan data $\mathcal{D}$ to compute frequencies of all sets in candidate_sets;
    3.2: frequent_sets : = frequent_sets $\cup \{C \in$ candidate_sets $|$frequency$(C) \geq min\_fr\}$;
    3.3: level := level + 1;
    3.4: candidate_sets := $\{A \subset \mathcal{I} \,||\, A \,|=$ level and $B \in$ frequent_sets for all $B \subset A, | B |=$ level $- 1\}$;
4: output frequent_sets;
5: for each $F \in$ frequent_sets
    5.1: for each $E \subset F$, $E \neq \emptyset$, $E \neq F$
        5.1.1: if frequency$(F)$/frequency$(E) \geq min\_conf$ then output association rule $E \rightarrow (F \setminus E)$
```

The algorithm finds frequent itemsets (lines 1–4) by a breadth-first, general-to-specific search. It generates and tests candidate itemsets in batches, to reduce the overhead of database access. The search starts with the most general itemset patterns, the singletons, as candidate patterns (line 2). The algorithm then iteratively computes the frequencies of candidates (line 3.1) and saves those that are frequent (line 3.2). The crux of the algorithm is in the candidate generation (line 3.4): on the next level, those itemsets are pruned that have an infrequent subset. Obviously, such itemsets cannot be frequent. This allows Apriori to find all frequent itemset without spending too much time on infrequent itemsets. See ▶ frequent pattern and ▶ constraint-based mining for more details and extensions.

Finally, the algorithm tests all frequent association rules and outputs those that are also confident (lines 5–5.1.1).

Definition

The *area under curve* (AUC) statistic is an empirical measure of classification performance based on the area under an ROC curve. It evaluates the performance of a scoring classifier on a test set, but ignores the magnitude of the scores and only takes their rank order into account. AUC is expressed on a scale of 0 to 1, where 0 means that all negatives are ranked before all positives, and 1 means that all positives are ranked before all negatives. See ▶ ROC Analysis.

Artificial Immune Systems

Jon Timmis
University of York, Heslington, North Yorkshire, UK

Synonyms

AIS; Immune computing; Immune-inspired computing; Immunocomputing; Immunological computation

Definition

Artificial immune systems (AIS) have emerged as a computational intelligence approach that shows great promise. Inspired by the complexity of the immune system, computer scientists and engineers have created systems that in some way mimic or capture certain computationally appealing properties of the immune system, with the aim of building more robust and adaptable solutions. AIS have been defined by de Castro and Timmis (2002) as:

- adaptive systems, inspired by theoretical immunology and observed immune functions, principle and models, which are applied to problem solving

AIS are not limited to machine learning systems, there are a wide variety of other areas in which AIS are developed such as optimization, scheduling, fault tolerance, and robotics (Hart and Timmis 2008). Within the context of machine learning, both supervised and unsupervised approaches have been developed. Immune-inspired learning approaches typically develop a memory set of detectors that are capable of classifying unseen data items (in the case of supervised learning) or a memory set of detectors that represent clusters within the data (in the case of unsupervised learning). Both static and dynamic learning systems have been developed.

Motivation and Background

The immune system is a complex system that undertakes a myriad of tasks. The abilities of the immune system have helped to inspire computer scientists to build systems that *mimic*, in some way, various properties of the immune system. This field of research, AIS, has seen the application of immune-inspired algorithms to a wide variety of areas.

The origin of AIS has its roots in the early theoretical immunology work of Farmer, Perelson, and Varela (Farmer et al. 1986; Varela et al. 1988). These works investigated a number of theoretical ▸ immune network models proposed to describe the maintenance of immune memory in the absence of antigen. While controversial from an immunological perspective, these models began to give rise to an interest from the computing community. The most influential people at crossing the divide between computing and immunology in the early days were Bersini and Forrest. It is fair to say that some of the early work by Bersini (1991) was very well rooted in immunology, and this is also true of the early work by Forrest (1994). It was these works that formed the basis of a solid foundation for the area of AIS. In the case of Bersini, he concentrated on the immune network theory, examining how the immune system maintained its memory and how one might build models and algorithms mimicking that property. With regard to Forrest, her work was focused on computer security (in particular, network intrusion detection) and formed the basis of a great deal of further research by the community on the application of immune-inspired techniques to computer security.

At about the same time as Forrest was undertaking her work, other researchers began to investigate the nature of learning in the immune system and how that might by used to create *machine learning* algorithms (Cooke and Hunt 1995). They had the idea that it might be possible to exploit the mechanisms of the immune system (in particular, the immune network) in learning systems, so they set about doing a proof of concept (Cooke and Hunt 1995). Initial results were very encouraging, and they built on their success by applying the immune ideas to the classification of DNA sequences as either promoter or nonpromoter classes: this work was generalized in Timmis and Neal (2001).

Similar work was carried out by de Castro and Von Zuben (2001), who developed algorithms for use in function optimization and data clustering. Work in dynamic unsupervised machine learning algorithms was also undertaken, meeting with success in works such as Neal (2002). In the supervised learning domain, very little happened until the work by Watkins (2005) (later expanded in Watkins 2005) developed an immune-based classifier known as AIRS, and in the dynamic supervised domain, with the work in Secker et al. (2003) being one of a number of successes.

Structure of the Learning System

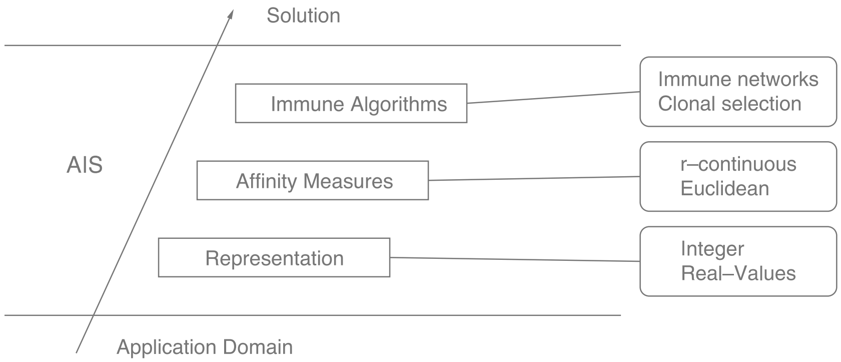
In an attempt to create a common basis for AIS, the work in de Castro and Timmis (2002) proposed the idea of a framework for engineering AIS. They argued that the case for such a framework as the existence of similar frameworks in other biologically inspired approaches, such as ▸ artificial neural networks (ANNs) and evolutionary algorithms (EAs), has helped considerably with the understanding and construction of such systems. For example, de Castro and Timmis (2002) consider a set of artificial neurons,which can be arranged together to form an ANN. In order to acquire knowledge, these neural networks undergo an adaptive process, known as learning or training, which alters (some of) the parameters within the network. Therefore, they argued that in a simplified form, a framework to design an ANN is composed of a set of artificial neurons, a pattern of interconnection for these neurons, and a learning algorithm. Similarly, they argued that in evolutionary algorithms, there is a set of artificial chromosomes representing a population of individuals that iteratively suffer a process of reproduction, genetic variation, and selection. As a result of this process, a population of evolved artificial individuals arises. A framework, in this case, would correspond to the genetic representation of the individuals of the population, plus the procedures for reproduction, genetic variation, and selection. Therefore, they proposed that a framework to design a biologically inspired algorithm requires, at least, the following basic elements:

- A representation for the components of the system
- A set of mechanisms to evaluate the interaction of individuals with the environment and each other. The environment is usually stimulated by a set of input stimuli, one or more fitness function(s), or other means
- Procedures of adaptation that govern the dynamics of the system, i.e., how its behavior varies over time

This framework can be thought of as a layered approach such as the specific framework for engineering AIS of de Castro and Timmis (2002) shown in Fig. 1. This framework follows the three basic elements for designing a biologically inspired algorithm just described, where the set of mechanisms for evaluation are the affinity measures and the procedures of adaptation are the immune algorithms. In order to build a system such as an AIS, one typically requires an application domain or target function. From this basis, the way in which the components of the system will be represented is considered. For example, the representation of network traffic may well be different from the representation of a real-time embedded system. In AIS, the way in which something is represented is known as *shape space*. There are many kinds of shape space, such as Hamming, real valued, and so on, each of which carries it own bias and should be selected with care (Freitas and Timmis 2003). Once the representation has been chosen, one or more affinity measures are used to quantify the interactions of the elements of the system. There are many possible affinity measures (which are partially dependent upon the representation adopted), such as Hamming and Euclidean distance metrics. Again, each of these has its own bias, and the affinity function must be selected with great care, as it can affect the overall performance (and ultimately the result) of the system (Freitas and Timmis 2003).

Supervised Immune-Inspired Learning

The artificial immune recognition system (AIRS) algorithm was introduced as one of the first immune-inspired supervised learning algorithms and has subsequently gone through a period of study and refinement (Watkins 2005). To use classifications from de Castro and Timmis (2002), for the procedures of adaptation, AIRS is a, ▸ clonal selection type of immune-inspired algorithm. The representation and affinity layers



Artificial Immune Systems, Fig. 1 AIS layered framework (Adapted from de Castro and Timmis 2002) of the system are standard in that any number of representations such as binary, real values, etc., can be used with the appropriate affinity function. AIRS has its origin in two other immune-inspired algorithms: CLONALG (CLONAL Selection alGorithm) and Artificial Immune NEtwork (AINE) (de Castro and Timmis 2002). AIRS resembles CLONALG in the sense that both the algorithms are concerned with developing a set of memory cells that give a representation of the learned environment.

AIRS is concerned with the development of a set of memory cells that can encapsulate the training data. This is done in a two-stage process of first evolving a candidate memory cell and then determining if this candidate cell should be added to the overall pool of memory cells. The learning process can be outlined as follows:

1. For each pattern to be recognized, do
   (a) Compare a training instance with all memory cells of the same class and find the memory cell with the best affinity for the training instance. This is referred to as a memory cell $\mathrm{mc}_{\mathrm{match}}$.
   (b) Clone and mutate $\mathrm{mc}_{\mathrm{match}}$ in proportion to its affinity to create a pool of abstract B-cells.
   (c) Calculate the affinity of each B-cell with the training instance.
   (d) Allocate resources to each B-cell based on its affinity.
   (e) Remove the weakest B-cells until the number of resources returns to a preset limit.
   (f) If the average affinity of the surviving B-cells is above a certain level, continue to step 1(g). Else, clone and mutate these surviving B-cells based on their affinity and return to step 1(c).
   (g) Choose the best B-cell as a candidate memory cell ($\mathrm{mc}_{\mathrm{cand}}$).
   (h) If the affinity of $\mathrm{mc}_{\mathrm{cand}}$ for the training instance is better than the affinity of $\mathrm{mc}_{\mathrm{match}}$, then add $\mathrm{mc}_{\mathrm{cand}}$ to the memory cell pool. If, in addition to this, the affinity between $\mathrm{mc}_{\mathrm{cand}}$ and $\mathrm{mc}_{\mathrm{match}}$ is within a certain threshold, then remove $\mathrm{mc}_{\mathrm{match}}$ from the memory cell pool.
2. Repeat from step 1(a) until all training instances have been presented.

Once this training routine is complete, AIRS classifies the instances using k-nearest neighbor with the developed set of memory cells.

Unsupervised Immune-Inspired Learning

The artificial immune network (aiNET) algorithm was introduced as one of the first immune-inspired unsupervised learning algorithms and has subsequently gone through a period of study and refinement (de Castro and Von Zuben 2001). To use classifications from de Castro and Timmis (2002), for the procedures of adaptation, aiNET is an immune network type of immune-inspired algorithm. The representation and affinity layers of the system are standard (the same as in AIRS). aiNET has its origin in another immune-inspired algorithms: CLONALG (the same forerunner to AIRS), and resembles CLONALG in the sense that both algorithms (again) are concerned with developing a set of memory cells that give a representation of the learnt environment. However, within aiNET there is no error feedback into the learning process. The learning process can be outlined as follows:

1. Randomly initialize a population P
2. For each pattern to be recognized, do
   (a) Calculate the affinity of each B-cell (b) in the network for an instance of the pattern being learnt
   (b) Select a number of elements from P into a clonal pool C
   (c) Mutate each element of C proportional to affinity to the pattern being learnt (the higher the affinity, the less mutation applied)
   (d) Select the highest affinity members of C to remain in the set C and remove the remaining elements
   (e) Calculate the affinity between all members of C and remove elements in C that have an affinity below a certain threshold (user defined)

(d) Combine the elements of C with the set P
(e) Introduce a random number of randomly created elements into P to maintain diversity

3. Repeat from 2(a) until stopping criteria is met

Once this training routine is complete, the minimum-spanning tree algorithm is applied to the network to extract the clusters from within the network.

Artificial Life

Artificial Life is an interdisciplinary research area trying to reveal and understand the principles and organization of living systems. Its main goal is to artificially synthesize life-like behavior from scratch in computers or other artificial media. Important topics in artificial life include the origin of life, growth and development, evolutionary and ecological dynamics, adaptive autonomous robots, emergence and self-organization, social organization, and cultural evolution.

Artificial Neural Networks

(ANNs) is a computational model based on biological neural networks. It consists of an interconnected group of artificial neurons and processes information using a connectionist approach to computation. In most cases an ANN is an adaptive system that changes its structure based on external or internal information that flows through the network during the learning phase.

Artificial Societies

Jürgen Branke
University of Warwick, Coventry, UK

Synonyms

Agent-based computational models; Agent-based modeling and simulation; Agent-based simulation models

Definition

An artificial society is an agent-based, computer-implemented simulation model of a society or group of people, usually restricted to their interaction in a particular situation. Artificial societies are used in economics and social sciences to explain, understand, and analyze socioeconomic phenomena. They provide scientists with a fully controllable virtual laboratory to test hypotheses and observe complex system behavior emerging as result of the ▶ agents' interaction. They allow formalizing and testing social theories by using computer code, and make it possible to use experimental methods with social phenomena, or at least with their computer representations, on a large scale. Because the designer is free to choose any desired ▶ agent behavior as long as it can be implemented, research based on artificial societies is not restricted by assumptions typical in classical economics, such as homogeneity and full rationality of agents. Overall, artificial societies have added an all new dimension to research in economics and social sciences and have resulted in a new research field called "agent-based computational economics."

Artificial societies should be distinguished from virtual worlds and ▶ artificial life. The term virtual world is usually used for virtual environments to interact with, as, e.g., in computer games. In artificial life, the goal is more to learn about biological principles, understand how life could emerge, and create life within a computer.

Motivation and Background

Classical economics can be roughly divided into analytical and empirical approaches. The former uses deduction to derive theorems from assumptions. Thereby, analytical models usually include a number of simplifying assumptions in order to keep the model tractable, the most typical being full rationality and homogeneity of agents. Also, analytical economics is often limited to equilibrium calculations. Classical empirical economics collects data from the real world, and derives patterns and regularities inductively. In recent years, the tremendous increase in available computational power gave rise to a new branch of economics and sociology which uses simulation of artificial societies as a tool to generate new insights.

Artificial societies are agent-based, computer-implemented simulation models of real societies or a group of people in a specific situation. They are built from the bottom up, by specifying the behavior of the agents in different situations. The simulation then reveals the emerging global behavior of the system, and thus provides a link between micro-level behavior of the agents and macro-level characteristics of the system. Using simulation, researchers can now carry out social experiments under fully controlled and reproducible laboratory conditions, trying out different configurations and observing the consequences.

Like deduction, simulation models are based on a set of clearly specified assumptions as written down in a computer program. This is then used to generate data, from which regularities and patterns are derived inductively. As such, research based on artificial societies stands somewhere between the classical analytical and empirical social sciences.

One of the main advantages of artificial societies is that they allow to consider very complex scenarios where agents are heterogeneous, boundedly rational, or have the ability to learn. Also, they allow to observe evolution over time, instead of just the equilibrium.

Artificial societies can be used for many purposes, e.g.:

1. Verification: Test a hypothesis or theory by examining its validity in relevant, clearly defined scenarios.
2. Explanation: Construct an artificial society which shows the same behavior as the real society. Then analyze the model to explain the emergent behavior.
3. Prediction: Run a model of an existing society into the future. Also, feed the model with different input parameters and use the result as a prediction on how the society would react.
4. Optimization: Test different strategies in the simulation environment, trying to find a best possible strategy.
5. Existence proof: Demonstrate that a specific simulation model is able to generate a certain global behavior.
6. Discovery: Play around with parameter settings, discovering new interdependencies and gaining new insights.
7. Training and education: Use simulation as demonstrator.

Structure of the Learning System

Using artificial societies requires the usual steps in model building and experimental science, including

1. Developing a conceptual model
2. Building the simulation model
3. Verification (making sure the model is correct)
4. Validation (making sure the model is suitable to answer the posed questions)
5. Simulation and analysis using an appropriate experimental design.

Artificial society is an interdisciplinary research area involving, among others, computer science, psychology, economics, sociology, and biology.

Important Aspects

The modeling, simulation, and analysis process described in the previous section is rather complex and only remotely connected to machine learning. Thus, instead of a detailed description of all steps, the following focuses on aspects particularly interesting from a machine learning point of view.

Modeling Learning

One of the main advantages of artificial societies is that they can account for boundedly rational and learning agents. For that, one has to specify (in form of a program) exactly how agents decide and learn.

In principle, all the learning algorithms developed in machine learning could be used, and many have been used successfully, including ▶ reinforcement learning, ▶ artificial neural networks, and ▶ evolutionary algorithms. However, note that the choice of a learning algorithm is not determined by its learning speed and efficiency (as usual in machine learning), but by how well it reflects human learning in the considered scenario, at least if the goal is to construct an artificial society which allows conclusions to be transferred to the real world. As a consequence, many learning models used in artificial societies are motivated by psychology. The idea of the most suitable model depends on the simulation context, e.g., on whether the simulated learning process is conscious or nonconscious, or on the time and effort an individual may be expected to spend on a particular decision.

Besides individual learning (i.e., learning from own past experience), artificial societies usually feature social learning (where one agent learns by observing others), and cultural learning (e.g., the evolution of norms). While the latter simply emerges from the interaction of the agents, the former has to be modeled explicitly. Several different models for learning in artificial societies are discussed in Brenner (2006).

One popular learning paradigm which can be used as a model for individual as well as social learning are ▸ evolutionary algorithms (EAs). Several studies suggest that EAs are indeed an appropriate model for learning in artificial societies, either based on comparisons of simulations with human subject experiments or based on comparisons with other learning mechanisms such as reinforcement learning (Duffy 2006). As EAs are successful search strategies, they seem particularly suitable if the space of possible actions or strategies is very large.

If used to model individual learning, each agent uses a separate EA to search for a better personal solution. In this case, the EA population represents the different alternative actions or strategies that an agent considers. The genetic operators crossover and mutation are clearly related to two major ingredients of human innovation: combination and variation. Crossover can be seen as deriving a new concept by combining two known concepts, and mutation corresponds to a small variation of an existing concept. So, the agent, in some sense, creatively tries out new possibilities. Selection, which favors the best solutions found so far, models the learning part. A solution's quality is usually assessed by evaluating it in a simulation assuming all other agents keep their behavior.

For modeling social learning, EAs can be used in two different ways. In both cases, the population represents the actions or strategies of the different agents in the population. From this it follows that the population size corresponds to the number of agents in the simulation. Fitness values are calculated by running the simulation and observing how the different agents perform. Crossover is now seen as a model for information exchange, or imitation, among agents. Mutation, as in the individual learning case, is seen as a small variation of an existing concept.

The first social learning model simply uses a standard EA, i.e., selection chooses agents to "reproduce," and the resulting new agent strategy replaces an old strategy in the population. While allowing to use standard EA libraries, this approach does not provide a direct link between agents in the simulation and individuals in the EA population. In the second social learning model, each agent directly corresponds to an individual in the EA. In every iteration, each agent creates and tests a new strategy as follows. First, it selects a "donor" individual, with preference to successful individuals. Then it performs a crossover of its own strategy and the donor's strategy, and mutates the result. This can be regarded as an agent observing other agents, and partially adopting the strategies of successful other agents. Then, the resulting new strategy is tested in a "thought experiment," by testing whether the agent would be better off with the new strategy compared with its current strategy, assuming all other agents keep their behavior. If the new strategy performs better, it replaces the current strategy in the next iteration. Otherwise, the new strategy is discarded and the agent again uses its old strategy in the next iteration. The testing of new strategies against their parents has been termed election operator in Arifovic (1994), and makes sure that some very bad and obviously implausible agent strategies never enter the artificial society.

Examples

One of the first forerunners of artificial societies was Schelling's segregation model, 1969. In this study, Schelling placed some artificial agents of two different colors on a simple grid. Each agent follows a simple rule: if less than a given percentage of agents in the neighborhood had the same color, the agent moves to a random free spot. Otherwise, it stays. As the simulation shows, in this model, segregation of agent colors could be observed even if every individual agent was satisfied to live in a neighborhood with only 50 % of its neighbors being of the same color. Thus, with this simple model, Schelling demonstrated that segregation of races in suburbs can occur even if each individual would be happy to live in a diverse neighborhood. Note that the simulations were actually not implemented on a computer but carried out by moving coins on a grid by hand.

Other milestones in artificial societies are certainly the work by Epstein and Axtell on their "sugarscape" model (Epstein and Axtell 1996), and the Santa Fe artificial stock market (Arthur et al. 1997). In the former, agents populate a simple grid world, with sugar growing as the only resource. The agents need the sugar for survival, and can move around to collect it. Axtell and Epstein have shown that even with agents following some very simple rules, the emerging behavior of the overall system can be quite complex and similar in many aspects to observations in the real world, e.g., showing a similar wealth distribution or population trajectories.

The latter is a simple model of a stock market with only a single stock and a risk-free fixed-interest alternative. This model has subsequently been refined and studied by many researchers. One remarkable result of the first model was to demonstrate that technical trading can actually be a viable strategy, something widely accepted in practice, but which classical analytical economics struggled to explain.

One of the most sophisticated artificial societies is perhaps the model of the Anasazi tribe, who left their dwellings in the Long House Valley in northeastern Arizona for so far unknown reasons around 1300 BC (Axtell et al. 2002). By building an artificial society of this tribe and the natural surroundings (climate etc.), it was possible to replicate macro behavior which is known to have occurred and provide a possible explanation for the sudden move.

The NewTies project (Gilbert et al. 2006) has a different and quite ambitious focus: it constructs artificial societies with the hope of an emerging artificial language and culture, which then might be studied to help explain how language and culture formed in human societies.

Software Systems

Agent-based simulations can be facilitated by using specialized software libraries such as Ascape, Netlogo, Repast, StarLogo, Mason, and Swarm. A comparison of different libraries can be found in Railsback (2006).

Applications

Artificial societies have many practical applications, from rather simple simulation models to very complex economic decision problems, examples include traffic simulation, market design, evaluation of vaccination programs, evacuation plans, or supermarket layout optimization. See, e.g., Bonabeau (2002) for a discussion of several such applications.

Future Directions, Challenges

The science on artificial societies is still at its infancy, but the field is burgeoning and has already produced some remarkable results. Major challenges lie in the model building, calibration, and validation of the artificial society simulation model. Despite several agent-based modeling toolkits available, there is a lot to be gained by making them more flexible, intuitive, and user-friendly, allowing to construct complex models simply by selecting and combining provided building blocks of agent behavior. ▶ Behavioral Cloning may be a suitable machine learning approach to generate representative agent models.

Association Rule

Hannu Toivonen
University of Helsinki, Helsinki, Finland

Definition

Association rules (Agrawal et al. 1993) can be extracted from data sets where each example consists of a set of items. An association rule has the form $X \rightarrow Y$, where X and Y are ▶ itemsets, and the interpretation is that if set X occurs in an example, then set Y is also likely to occur in the example.

Each association rule is usually associated with two statistics measured from the given data set. The *frequency* or *support* of a rule $X \rightarrow Y$, denoted $\mathrm{fr}(X \rightarrow Y)$, is the number (or alternatively the relative frequency) of examples in which $X \cup Y$ occurs. Its *confidence*, in turn, is the observed conditional probability $P(Y|X) = \mathrm{fr}(X \cup Y)/\mathrm{fr}(X)$.

The ▶ Apriori algorithm (Agrawal et al. 1996) finds all association rules, between any sets X and Y, which exceed user-specified support and confidence thresholds. In association rule mining, unlike in most other learning tasks, the result thus is a set of rules concerning different subsets of the feature space.

Association rules were originally motivated by supermarket ▶ basket analysis, but as a domain independent technique they have found applications in numerous fields. Association rule mining is part of the larger field of ▸ frequent itemset or ▸ frequent pattern mining.

Associative Bandit Problem

▸ Associative Reinforcement Learning

Associative Reinforcement Learning

Alexander L. Strehl
Rütgers University, New Brunswick, NJ, USA

Synonyms

Associative bandit problem; Bandit problem with side information; Bandit problem with side observations; One-step reinforcement learning

Definition

The *associative reinforcement-learning* problem is a specific instance of the ▸ *reinforcement learning* problem whose solution requires *generalization* and *exploration* but not *temporal credit assignment*. In associative reinforcement learning, an action (also called an arm) must be chosen from a fixed set of actions during successive timesteps and from this choice a real-valued reward or payoff results. On each timestep, an input vector is provided that along with the action determines, often probabilistically, the reward. The goal is to maximize the expected long-term reward over a finite or infinite horizon. It is typically assumed that the action choices do not affect the sequence of input vectors. However, even if this assumption is not asserted, learning algorithms are not required to infer or model the relationship between input vectors from one timestep to the next. Requiring a learning algorithm to discover and reason about this underlying process results in the full reinforcement learning problem.

Motivation and Background

The problem of associative reinforcement learning may be viewed as connecting the problems of ▸ supervised learning or ▸ classification, which is more specific, and reinforcement learning, which is more general. Its study is motivated by real-world applications such as choosing which internet advertisements to display based on information about the user or choosing which stock to buy based on current information related to the market. Both problems are distinguished from supervised learning by the absence of labeled training examples to learn from. For instance, in the advertisement problem, the learner is never told which ads would have resulted in the greatest expected reward (in this problem, reward is determined by whether an ad is clicked on or not). In the stock problem, the best choice is never revealed since the choice itself affects the future price of the stocks and therefore the payoff.

The Learning Setting

The learning problem consists of the following core objects:

- An input space $\mathcal{X}$, which is a set of objects (often a subset of the n-dimension Euclidean space $\mathbb{R}^n$).
- A set of actions or arms $\mathcal{A}$, which is often a finite set of size k.
- A distribution D over $\mathcal{X}$. In some cases, D is allowed to be time-dependent and may be denoted D_t on timestep t for $t = 1, 2, \ldots$.

A learning sequence proceeds as follows. During each timestep $t = 1, 2, \ldots$, an input vector $x_t \in \mathcal{X}$ is drawn according to the distribution D and is provided to the algorithm. The algorithm selects an aarm at $a_t \in \mathcal{A}$. This choice may be stochastic and depend on all previous inputs and rewards observed by the algorithm as well as all previous action choices made by the algorithm for timesteps $t = 1, 2, \ldots$. Then, the learner receives a payoff r_t generated according to some unknown stochastic process that depends only on the x_t and a_t. The informal goal is to maximize the expected long-term payoff. Let $\pi : \mathcal{X} \rightarrow \mathcal{A}$ be any policy that maps input vectors to actions. Let

$$V^{\pi}(T) := E\left[\sum_{i=1}^{T} r_i | a_i \right.$$

$$\left. = \pi(x_i) \text{ for } i = 1, 2, \ldots, T\right] \qquad (1)$$

denotes the expected total reward over T steps obtained by choosing arms according to policy π. The expectation is taken over any randomness in the generation of input vectors x_i and rewards r_i. The expected regret of a learning algorithm with respect to policy π is defined as $V^{\pi}(T) - E[\sum_{i=1}^{T} r_i]$ the expected difference between the return from following policy π and the actual obtained return.

Power of Side Information

Wang et al. (2005) studied the associative reinforcement learning problem from a statistical viewpoint. They considered the setting with two action and analyzed the *expected inferior sampling time*, which is the number of times that the lesser action, in terms of expected reward, is selected. The function mapping input vectors to conditional reward distributions belongs to a known parameterized class of functions, with the true parameters being unknown. They show that, under some mild conditions, an algorithm can achieve finite expected inferior sampling time. This demonstrates the power provided by the input vectors (also called *side observations* or *side information*), because such a result is not possible in the standard *multi-armed bandit problem*, which corresponds to the associative reinforcement-learning problem without input vectors x_i. Intuitively, this type of result is possible when the side information can be used to infer the payoff function of the optimal action.

Linear Payoff Functions

In its most general setting, the associative reinforcement learning problem is intractable. One way to rectify this problem is to assume that the payoff function is described by a linear system. For instance, Abe (1999) and Auer (2002) consider a model where during each timestep t, there is a vector $z_{t,i}$ associated with each arm i. The expected payoff of pulling arm i on this timestep is given by $\theta^T z_{t,i}$ where θ is an unknown parameter vector and θ^T denotes the transpose of f. This framework maps to the framework described above by taking $x_t = (z_{t,1}, z_{t,2}, \ldots, z_{t,k})$. They assume a time-dependent distribution D and focus on obtaining bounds on the regret against the optimal policy. Assuming that all rewards lie in the interval [0, 1], the worst possible regret of any learning algorithm is linear. When considering only the number of timesteps T, Auer (2002) shows that a regret (with respect to the optimal policy) of $O(\sqrt{T}\ln(T))$ can be obtained.

PAC Associative Reinforcement Learning

The previously mentioned works analyze the growth rate of the regret of a learning algorithm with respect to the optimal policy. Another way to approach the problem is to allow the learner some number of timesteps of *exploration*. After the exploration trials, the algorithm is required to output a policy. More specifically, given inputs $0 < \epsilon < 1$ and $0 < \delta < 1$, the algorithm is required to output an ϵ-optimal policy with probability at least $1 - \delta$. This type of analysis is based on the work by Valiant (1984), and learning algorithms satisfying the above condition are termed *probably approximately correct* (PAC).

Motivated by the work of Kaelbling (1994) and Fiechter (PAC associative reinforcement learning, unpublished manuscript, 1995), developed a PAC algorithm when the true payoff function can be described by a *decision list* over the action and input vector. Building on both works, Strehl et al. (2006) showed that a class of associative reinforcement learning problems can be solved efficiently, in a PAC sense, when given a learning algorithm for efficiently solving classification problems.

Attribute

Chris Drummond
National Research Council of Canada, Ottawa, ON, Canada

Synonyms

Characteristic; Feature; Property; Trait

Definition

Attributes are properties of things, ways that we, as humans, might describe them. If we were talking about the appearance of our friends, we might describe one of them as "sex female," "hair brown," "height 5 ft 7 in." Linguistically, this is rather terse, but this very terseness has the advantage of limiting ambiguity. The attributes are sex, hair color, and height. For each friend, we could give the appropriate values to go along with each attribute, some examples are shown in Table 1. Attribute-value pairs are a standard way of describing things within the machine learning community. Traditionally, values have come in one of three types: binary, sex has two values; nominal, hair color has many values; real, height has an ordered set of values. Ideally, the attribute-value pairs are sufficient to describe some things accurately and to tell them apart from others. What might be described is very varied, so the attributes themselves will vary widely.

Motivation and Background

For machine learning to be successful, we need a language to describe everyday things that is sufficiently powerful to capture the similarities and differences between them and yet is computationally easy to manage. The idea that a sufficient number of attribute-value pairs would meet this requirement is an intuitive one. It has also been studied extensively in philosophy and psychology, as a way that humans represent things mentally. In the early days of artificial intelligence research, the frame (Minsky 1974) became a common way of representing knowledge. We have, in many ways, inherited this representation, attribute-value pairs sharing much in common with the labeled slots for values used in frames. In addition, the data for many practical problems comes in this form. Popular methods of storing and manipulating data such as relational databases, and less formal structures such as spread sheets, have columns as attributes and cells as values. So, attribute-value pairs are a ubiquitous way of representing data.

Future Directions

The notion of an attribute-value pair is so well entrenched in machine learning that it is difficult to perceive what might replace it. As, in many practical applications, the data comes in this form, this representation will undoubtedly be around for some time. One change that is occurring is the growing complexity of attribute-values. Traditionally, we have used the simple value types, binary, nominal, and real, discussed earlier. But to effectively describe many things, we need to extend this simple language and use more complex values. For example, in ▸ data mining applied to multimedia, more new complex representations abound. Sound and video streams, images, and various properties of them, are just a few examples (Cord et al. 2005; Simoff and Djeraba 2000).

Attribute, Table 1 Some friends

Sex	Hair color	Height
Male	Black	6 ft 2 in.
Female	Brown	5 ft 7 in.
Female	Blond	5 ft 9 in.
Male	Brown	5 ft 10 in.

Perhaps, the most significant change is away from attributes, albeit with complex values, to structural forms where the relationship between things is included. As Quinlan (1996) states "Data may concern objects or observations with arbitrarily complex structure that cannot be captured by the values of a predetermined set of attributes." There is a large and growing community of researchers in ▸ relational learning. This is evidenced by the number, and growing frequency, of recent workshops at the International Conference for Machine Learning (Cord et al. 2005; De Raedt and Kramer 2000; Dietterich et al. 2004; Fern et al. 2006).

Limitations

In philosophy there is the idea of essence, the properties an object must have to be what it is. In machine learning, particularly in practical applications, we get what we are given and have little control in the choice of attributes and their range of values. If domain experts have chosen the attributes, we might hope that they are properties that can be readily ascertained and are relevant to the task at the hand. For example, when describing one of our friends, we would not say Fred is the one with the spleen. It is not only difficult to observe, it is also poor at discriminating between people. Data are collected for many reasons. In medical applications, all sorts of attribute-values would be collected on patients. Most are unlikely to be important to the current task. An important part of learning is ▸ feature extraction, determining which attributes are necessary for learning.

Whether or not attribute-value pairs are an essential representation for the type of learning required in the development, and functioning, of intelligent agents, remains to be seen. Attribute-values readily capture symbolic information, typically at the level of words that humans naturally use. But if our agents need to move around in their environment, recognizing what they encounter, we might need a different nonlinguistic representation. Certainly, other representations based on a much finer granularity of features, and more holistic in nature, have been central to areas such as ▸ neural networks for some time. In research into ▸ dynamic systems, attractors in a sensor space might be more realistic that attribute-values (See chapter on ▸ Classification).

Autonomous Helicopter Flight Using Reinforcement Learning

Adam Coates[1], Pieter Abbeel[2], and
Andrew Y. Ng[1,3]
[1]Stanford University, Stanford, CA, USA
[2]EECS Department, UC Berkeley, Stanford, CA, USA
[3]Computer Science Department, Stanford University, Stanford, CA, USA

Definition

Helicopter flight is a highly challenging control problem. While it is possible to obtain controllers for simple maneuvers (like hovering) by traditional manual design procedures, this approach is tedious and typically requires many hours of adjustments and flight testing, even for an experienced control engineer. For complex maneuvers, such as aerobatic routines, this approach is likely infeasible. In contrast, ▶ reinforcement learning (RL) algorithms enable faster and more automated design of controllers. Model-based RL algorithms have been used successfully for autonomous helicopter flight for hovering, forward flight, and using apprenticeship learning methods for expert-level aerobatics. In model-based RL, the first one builds a model of the helicopter dynamics and specifies the task using a reward function. Then, given the model and the reward function, the RL algorithm finds a controller that maximizes the expected sum of rewards accumulated over time.

Motivation and Background

Autonomous helicopter flight represents a challenging control problem and is widely regarded as being significantly harder than control of fixed-wing aircraft (see, e.g., Leishman 2000; Seddon 1990). At the same time, helicopters provide unique capabilities such as in-place hover, vertical takeoff and landing, and low-speed maneuvering. These capabilities make helicopter control an important research problem for many practical applications.

Building autonomous flight controllers for helicopters, however, is far from trivial. When done by hand, it can require many hours of tuning by experts with extensive prior knowledge about helicopter dynamics. Meanwhile, the automated development of helicopter controllers has been a major success story for RL methods. Controllers built using RL algorithms have established state-of-the-art performance for both basic flight maneuvers, such as hovering and forward flight (Bagnell and Schneider 2001; Ng et al. 2004b), as well as being among the only successful methods for advanced aerobatic stunts. Autonomous helicopter aerobatics has been successfully tackled using the innovation of "apprenticeship learning," where the algorithm learns by watching a human demonstrator (Abbeel and Ng 2004). These methods have enabled autonomous helicopters to fly aerobatics as well as an expert human pilot and often even better (Coates et al. 2008).

Developing autonomous flight controllers for helicopters is challenging for a number of reasons:

1. Helicopters have unstable, high-dimensional, asymmetric, noisy, nonlinear, non-minimum phase dynamics. As a consequence, all successful helicopter flight controllers (to date) have many parameters. Controllers with 10–100 gains are not atypical. Hand engineering the right setting for each of the parameters is difficult and time consuming, especially since their effects on performance are often highly coupled through the helicopter's complicated dynamics. Moreover, the unstable dynamics, especially in the low-speed flight regime, complicates flight testing.
2. Helicopters are underactuated: their position and orientation are representable using six parameters, but they have only four control inputs. Thus helicopter control requires significant planning and making trade-offs between errors in orientation and errors in desired position.
3. Helicopters have highly complex dynamics: even though we describe the helicopter as having a 12-dimensional state (position, velocity, orientation, and angular velocity), the true dynamics are significantly more complicated. To determine the precise effects of the inputs, one would have to consider the airflow in a large volume around the helicopter, as well as the parasitic coupling between the different inputs, the engine performance, and the non-rigidity of the rotor blades. Highly accurate simulators are thus difficult to create, and controllers developed in simulation must be sufficiently robust that they generalize to the real helicopter in spite of the simulator's imperfections.
4. Sensing capabilities are often poor: for small remotely controlled (RC) helicopters, sensing is limited because the onboard sensors must deal with a large amount of vibration caused by the helicopter blades rotating at about 30 Hz, as well as higher frequency noise from the engine. Although noise at these frequencies (which are well above the roughly

10 Hz at which the helicopter dynamics can be modeled reasonably) might be easily removed by low pass filtering, this introduces latency and damping effects that are detrimental to control performance. As a consequence, helicopter flight controllers have to be robust to noise and/or latency in the state estimates to work well in practice.

Typical Hardware Setup

A typical autonomous helicopter has several basic sensors on board. An inertial measurement unit (IMU) measures angular rates and linear accelerations for each of the helicopter's three axes. A 3-axis magnetometer senses the direction of the Earth's magnetic field, similar to a magnetic compass (Fig. 1).

Attitude-only sensing, as provided by the inertial and magnetic sensors, is insufficient for precise, stable hovering, and slow-speed maneuvers. These maneuvers require that the helicopter maintains relatively tight control over its position error, and hence high-quality position sensing is needed. GPS is often used to determine helicopter position (with carrier-phase GPS units achieving sub-decimeter accuracy), but vision-based solutions have also been employed (Abbeel et al. 2007; Coates et al. 2008; Saripalliz et al. 2003).

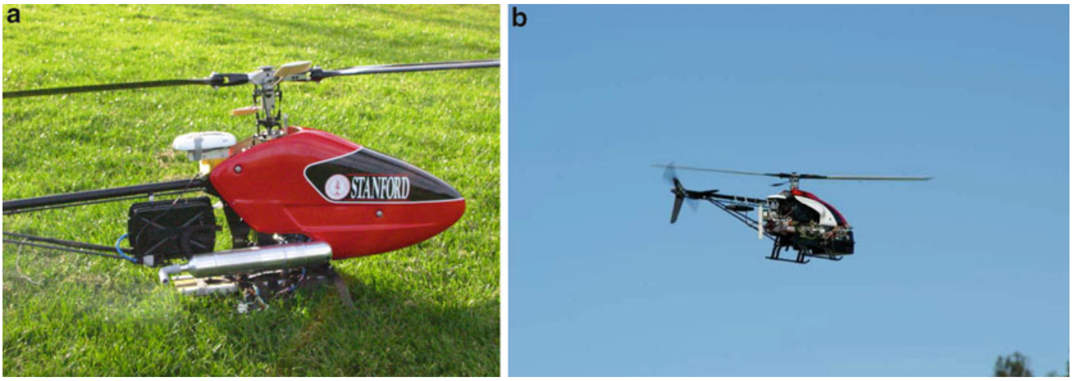
Vibration adds errors to the sensor measurements and may damage the sensors themselves; hence, significant effort may be required to mount the sensors on the airframe (Dunbabin et al. 2004). Provided there is no aliasing, sensor errors added by vibration can be removed by using a digital filter on the measurements (though, again, one must be careful to avoid adding too much latency).

Sensor data from the aircraft sensors is used to estimate the state of the helicopter for use by the control algorithm. This is usually done with an extended Kalman filter (EKF). A unimodal distribution (as computed by the EKF) suffices to represent the uncertainty in the state estimates, and it is common practice to use the mode of the distribution as the state estimate for feedback control. In general the accuracy obtained with this method is sufficiently high that one can treat the state as fully observed.

Most autonomous helicopters have an onboard computer that runs the EKF and the control algorithm (Gavrilets et al. 2002a; La Civita et al. 2006; Ng et al. 2004a). However, it is also possible to use ground-based computers by sending sensor data by wireless to the ground and then transmitting control signals back to the helicopter through the pilot's RC transmitter (Abbeel et al. 2007; Coates et al. 2008).

Helicopter State and Controls

The helicopter state s is defined by its position (p_x, p_y, p_z), orientation (which could be



Autonomous Helicopter Flight Using Reinforcement Learning, Fig. 1 (**a**) Stanford University's instrumented XCell Tempest autonomous helicopter. (**b**) A Bergen Industrial Twin autonomous helicopter with sensors and onboard computer expressed using a unit quaternion q), velocity (v_x, v_y, v_z), and angular velocity $(\omega_x, \omega_y, \omega_z)$.

The helicopter is controlled via a 4-dimensional action space:

1. u_1 and u_2: The lateral (left-right) and longitudinal (front-back) cyclic pitch controls (together referred to as the "cyclic" controls) cause the helicopter to roll left or right and pitch forward or backward, respectively.
2. u_3: The tail rotor pitch control affects tail rotor thrust and can be used to yaw (turn) the helicopter about its vertical axis. In analogy to airplane control, the tail rotor control is commonly referred to as "rudder."
3. u_4: The collective pitch control (often referred to simply as "collective") increases and decreases the pitch of the main rotor blades, thus increasing or decreasing the vertical thrust produced as the blades sweep through the air.

By using the cyclic and rudder controls, the pilot can rotate the helicopter into any orientation. This allows the pilot to direct the thrust of the main rotor in any particular direction, and thus fly in any direction, by rotating the helicopter appropriately.

Helicopter Flight as an RL Problem

Formulation

An RL problem can be described by a tuple $(S, \mathcal{A}, T, H, s(0), R)$, which is referred to as a ▶ Markov decision process (MDP). Here S is the set of states; $\mathcal{A}$ is the set of actions or inputs; T is the dynamics model, which is a set of probability distributions; $\{P^t_{su}\}$ ($P^t_{su}(s'|s,u)$ is the probability of being in state s' at time $t+1$, given the state and action at time t are s and u); H is the horizon or number of time steps of interest; $s(0) \in S$ is the initial state; $R : S \times \mathcal{A} \rightarrow \mathbb{R}$ is the reward function.

A policy $\pi = (\mu_0, \mu_1, \ldots, \mu_H)$ is a tuple of mappings from states S to actions $\mathcal{A}$, one mapping for each time $t = 0, \ldots, H$. The expected sum of rewards when acting according to a policy π is given by $U(\pi) = \mathrm{E}[\sum_{t=0}^{H} R(s(t), u(t))|\pi]$. The optimal policy π^* for an MDP $(S, \mathcal{A}, T, H, s(0), R)$ is the policy that maximizes the expected sum of rewards. In particular, the optimal policy is given by: $\pi^* = \arg\max_\pi U(\pi)$.

The common approach to finding a good policy for autonomous helicopter flight proceeds in two steps: First one collects data from manual helicopter flights to build a model. (One could also build a helicopter model by directly measuring physical parameters such as mass, rotor span, etc. However, even when this approach is pursued, one often resorts to collecting flight data to complete the model.) Then one solves the MDP comprised of the model and some chosen reward function. Although the controller obtained, in principle, is only optimal for the learned simulator model, it has been shown in various settings that optimal controllers perform well even when the model has some inaccuracies (see, e.g., Anderson and Moore 1989).

Modeling

One way to create a helicopter model is to use direct knowledge of aerodynamics to derive an explicit mathematical model. This model will depends on a number of parameters that are particular to the helicopter being flown. Many of the parameters may be measured directly (e.g., mass, rotational inertia), while others must be estimated from flight experiments. This approach has been used successfully on several systems (see, e.g., Gavrilets et al. 2001, 2002b; La Civita 2003). However, substantial expert aerodynamics knowledge is required for this modeling approach. Moreover, these models tend to cover only a limited fraction of the flight envelope.

Alternatively, one can learn a model of the dynamics directly from flight data, with only limited a priori knowledge of the helicopter's dynamics. Data is usually collected from a series of manually controlled flights. These flights involve the human sweeping the control sticks back and forth at varying frequencies to cover as much of the flight envelope as possible, while recording the helicopter's state and the pilot inputs at each instant.

Given a corpus of flight data, various different learning algorithms can be used to learn the underlying model of the helicopter dynamics.

If one is only interested in a single flight regime, one could learn a linear model that maps from the current state and action to the next state. Such a model can be easily estimated using ▶ linear regression. (While the methods presented here emphasize time domain estimation, frequency domain estimation is also possible for the special case of estimating linear models Tischler and Cauffman 1992.) Linear models are restricted to small flight regimes (e.g., hover or inverted hover) and do not immediately generalize to full-envelope flight. To cover a broader flight regime, nonparametric algorithms such as locally weighted linear regression have been used (Bagnell and Schneider 2001; Ng et al. 2004b). Nonparametric models that map from current state and action to next state can, in principle, cover the entire flight regime. Unfortunately, one must collect large amounts of data to obtain an accurate model, and the models are often quite slow to evaluate.

An alternative way to increase the expressiveness of the model, without resorting to nonparametric methods, is to consider a time-varying model where the dynamics are explicitly allowed to depend on time. One can then proceed to compute simpler (say, linear) parametric models for each choice of the time parameter. This method is effective when learning a model specific to a trajectory whose dynamics are repeatable but vary as the aircraft travels along the trajectory. Since this method can also require a great deal of data (similar to nonparametric methods) in practice, it is helpful to begin with a non-time-varying parametric model fit from a large amount of data and then augment it with a time-varying component that has fewer parameters (Abbeel et al. 2006; Coates et al. 2008).

One can also take advantage of symmetry in the helicopter dynamics to reduce the amount of data needed to fit a parametric model. Abbeel et al. (2006) observe that – in a coordinate frame attached to the helicopter – the helicopter dynamics are essentially the same for any orientation (or position) once the effect of gravity is removed. They learn a model that predicts (angular and linear) accelerations – except for the effects of gravity – in the helicopter frame as a function of the inputs and the (angular and linear) velocity in the helicopter frame. This leads to a lower-dimensional learning problem, which requires significantly less data. To simulate the helicopter dynamics over time, the predicted accelerations augmented with the effects of gravity are integrated over time to obtain velocity, angular rates, position, and orientation.

Abbeel et al. (2007) used this approach to learn a helicopter model that was later used for autonomous aerobatic helicopter flight maneuvers covering a large part of the flight envelope. Significantly less data is required to learn a model using the gravity-free parameterization compared to a parameterization that directly predicts the next state as a function of current state and actions (as was used in Bagnell and Schneider (2001) and Ng et al. (2004b)). Abbeel et al. evaluate their model by checking its simulation accuracy over longer time scales than just a one-step acceleration prediction. Such an evaluation criterion maps more directly to the reinforcement learning objective of maximizing the expected sum of rewards accumulated over time (see also Abbeel and Ng 2005b).

The models considered above are deterministic. This normally would allow us to drop the expectation when evaluating a policy according to $\mathrm{E}\left[\sum_{t=0}^{H} R(s(t), u(t))|\pi\right]$. However, it is common to add stochasticity to account for unmodeled effects. Abbeel et al. (2007) and Ng et al. (2004a) include additive process noise in their models. Bagnell and Schneider (2001) go further, learning a distribution over models. Their policy must then perform well, on expectation, for a (deterministic) model selected randomly from the distribution.

Control Problem Solution Methods

Given a model of the helicopter, we now seek a policy π that maximizes the expected sum of rewards $U(\pi) = \mathrm{E}\left[\sum_{t=0}^{H} R(s(t), u(t))|\pi\right]$ achieved when acting according to the policy π.

Policy Search

General policy search algorithms can be employed to search for optimal policies for the MDP based on the learned model. Given a policy π, we can directly try to optimize the objective $U(\pi)$. Unfortunately, $U(\pi)$ is an expectation over a complicated distribution making it impractical to evaluate the expectation exactly in general.

One solution is to approximate the expectation $U(\pi)$ by Monte Carlo sampling: under certain boundedness assumptions, the empirical average of the sum of rewards accumulated over time will give a good estimate $\hat{U}(\pi)$ of the expectation $U(\pi)$. Naively applying Monte Carlo sampling to accurately compute, e.g., the local gradient from the difference in function value at nearby points requires very large amounts of samples due to the stochasticity in the function evaluation.

To get around this hurdle, the PEGASUS algorithm (Ng and Jordan 2000) can be used to convert the stochastic optimization problem into a deterministic one. When evaluating by averaging over n simulations, PEGASUS initially fixes n random seeds. For each policy evaluation, the same n random seeds are used so that the simulator is now deterministic. In particular, multiple evaluations of the same policy will result in the same computed reward. A search algorithm can then be applied to the deterministic problem to find an optimum.

The PEGASUS algorithm coupled with a simple local policy search was used by Ng et al. (2004a) to develop a policy for their autonomous helicopter that successfully sustains inverted hover. Bagnell and Schneider (2001) proceed similarly, but use the "amoeba" search algorithm (Nelder and Mead 1964) for policy search.

Because of the searching involved, the policy class must generally have low dimension. Nonetheless, it is often possible to find good policies within these policy classes. The policy class of Ng et al. (2004a), for instance, is a decoupled, linear PD controller with a sparse dependence on the state variables. (For instance, the linear controller for the pitch axis is parametrized as $u_2 = c_0(p_x - p_x^*) + c_1(v_x - v_x^*) + c_2\theta$, which has just three parameters, while the entire state is nine dimensional. Here, $p_\cdot$, $v_\cdot$, and $p_\cdot^*$, $v_\cdot^*$, respectively, are the actual and desired position and velocity. θ denotes the pitch angle.) The sparsity reduces the policy class to just nine parameters. In Bagnell and Schneider (2001), two-layer neural network structures are used with a similar sparse dependence on the state variables. Two neural networks with five parameters each are learned for the cyclic controls.

Differential Dynamic Programming

Abbeel et al. (2007) use differential dynamic programming (DDP) for the task of aerobatic trajectory following. DDP (Jacobson and Mayne 1970) works by iteratively approximating the MDP as linear quadratic regulator (LQR) problems. The LQR control problem is a special class of MDPs, for which the optimal policy can be computed efficiently. In LQR the set of states is given by $S = \mathbb{R}^n$, the set of actions/inputs is given by $\mathcal{A} = \mathbb{R}^p$, and the dynamics model is given by

$$s(t+1) = A(t)s(t) + B(t)u(t) + w(t),$$

where for all $t = 0, \ldots, H$ we have that $A(t) \in \mathbb{R}^{n\times n}$, $B(t) \in \mathbb{R}^{n\times p}$, and $w(t)$ is a mean zero random variable (with finite variance). The reward for being in state $s(t)$ and taking action $u(t)$ is given by

$$-s(t)^\top Q(t)s(t) - u(t)^\top R(t)u(t).$$

Here $Q(t)$, $R(t)$ are positive semi-definite matrices which parameterize the reward function. It is well known that the optimal policy for the LQR control problem is a linear feedback controller which can be efficiently computed using dynamic programming (see, e.g., Anderson and Moore (1989), for details on linear quadratic methods).

DDP approximately solves general continuous state-space MDPs by iterating the following two steps until convergence:

1. Compute a linear approximation to the nonlinear dynamics and a quadratic approximation to the reward function around the trajectory obtained when executing the current policy in simulation.

2. Compute the optimal policy for the LQR problem obtained in Step 1, and set the current policy equal to the optimal policy for the LQR problem.

During the first iteration, the linearizations are performed around the target trajectory for the maneuver, since an initial policy is not available.

This method is used to perform autonomous flips, rolls, and "funnels" (high-speed sideways flight in a circle) in Abbeel et al. (2007) and autonomous autorotation (autorotation is an emergency maneuver that allows a skilled pilot to glide a helicopter to a safe landing in the event of an engine failure or tail-rotor failure) in Abbeel et al. (2008), Fig. 2.

While DDP computes a solution to the nonlinear optimization problem, it relies on the accuracy of the nonlinear model to correctly predict the trajectory that will be flown by the helicopter. This prediction is used in Step 1 above to linearize the dynamics. In practice, the helicopter will often not follow the predicted trajectory closely (due to stochasticity and modeling errors), and thus the linearization will become a highly inaccurate approximation of the nonlinear model. A common solution to this, applied by Coates et al. (2008), is to compute the DDP solution online, linearizing around a trajectory that begins at the current helicopter state. This ensures that the model is always linearized around a trajectory near the helicopter's actual flight path.

Apprenticeship Learning and Inverse RL

In computing a policy for an MDP, simply finding a solution (using any method) that performs well in simulation may not be enough. One may need to adjust both the model and reward function based on the results of flight testing. Modeling error may result in controllers that fly perfectly in simulation but perform poorly or fail entirely in reality. Because helicopter dynamics are difficult to model exactly, this problem is fairly common. Meanwhile, a poor reward function can result in a controller that is not robust to modeling errors or unpredicted perturbations (e.g., it may use large control inputs that are unsafe in practice). If a human "expert" is available to demonstrate the maneuver, this demonstration flight can be leveraged to obtain a better model and reward function.

The reward function encodes both the trajectory that the helicopter should follow and the trade-offs between different types of errors. If the desired trajectory is infeasible (either in the nonlinear simulation or in reality), this results in a significantly more difficult control problem. Also, if the trade-offs are not specified correctly, the helicopter may be unable to compensate for significant deviations from the desired trajectory. For instance, a typical reward function for hovering implicitly specifies a trade-off between position error and orientation error (it is possible to reduce one error, but usually at the cost of increasing the other). If this trade-off is incorrectly

Autonomous Helicopter Flight Using Reinforcement Learning, Fig. 2 Snapshots of an autonomous helicopter performing in-place flips and rolls chosen, the controller may be pushed off course by wind (if it tries too hard to keep the helicopter level) or, conversely, may tilt the helicopter to an unsafe attitude while trying to correct for a large position error.

We can use demonstrations from an expert pilot to recover both a good choice for the desired trajectory and good choices of reward weights for errors relative to this trajectory. In apprenticeship learning, we are given a set of N recorded state and control sequences, $\{s_k(t), u_k(t)\}_{t=0}^{H}$ for $k = 1, \ldots, N$, from demonstration flights by an expert pilot. Coates et al. (2008) note that these demonstrations may be suboptimal but are often suboptimal in different ways. They suggest that a large number of expert demonstrations may implicitly encode the optimal trajectory and propose a generative model that explains the expert demonstrations as stochastic instantiations of an "ideal" trajectory. This is the desired trajectory that the expert has in mind but is unable to demonstrate exactly. Using an Expectation-Maximization (Dempster et al. 1977) algorithm, they infer the desired trajectory and use this as the target trajectory in their reward function.

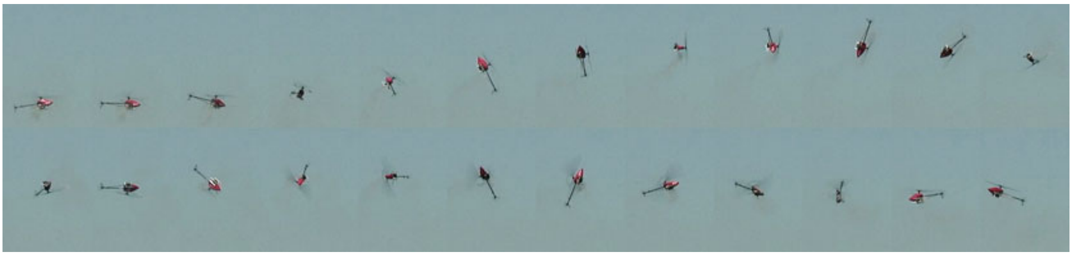
A good choice of reward weights (for errors relative to the desired trajectory) can be recovered using inverse reinforcement learning (Ng and Russell 2000; Abbeel and Ng 2004). Suppose the reward function is written as a linear combination of features as follows: $R(s,u) = c_0\phi_0(s,u) + c_1\phi_1(s,u) + \cdots$. For a single recorded demonstration, $\{s(t), u(t)\}_{t=0}^{H}$, the pilot's accumulated reward corresponding to each feature can be computed as $c_i\phi_i^* = c_i \sum_{t=0}^{H} \phi_i(s(t), u(t))$. If the pilot outperforms the autonomous flight controller with respect to a particular feature ϕ_i, this indicates that the pilot's own "reward function" places a higher value on that feature, and hence its weight c_i should be increased. Using this procedure, a good choice of reward function that makes trade-offs similar to that of a human pilot can be recovered. This method has been used to guide the choice of reward for many maneuvers during flight testing (Abbeel et al. 2007, 2008; Coates et al. 2008).

In addition to learning a better reward function from pilot demonstration, one can also use the pilot demonstration to improve the model directly and attempt to reduce modeling error. Coates et al. (2008), for instance, use errors observed in expert demonstrations to jointly infer an improved dynamics model along with the desired trajectory. Abbeel et al. (2007), however, have proposed the following alternating procedure that is broadly applicable (see also Abbeel and Ng (2005a) for details):

1. Collect data from a human pilot flying the desired maneuvers with the helicopter. Learn a model from the data.
2. Find a controller that works in simulation based on the current model.
3. Test the controller on the helicopter. If it works, we are done. Otherwise, use the data from the test flight to learn a new (improved) model and go back to Step 2.

This procedure has similarities with model-based RL and with the common approach in control to first perform system identification and then find a controller using the resulting model. However, the key insight from Abbeel and Ng (2005a) is that this procedure is guaranteed to converge to expert performance in a polynomial number of iterations. The authors report needing at most three iterations in practice. Importantly, unlike the E^3 family of algorithms (Kearns and Singh 2002), this procedure does not require explicit exploration policies. One only needs to test controllers that try to fly as much as possible (according to the current choice of dynamics model). (Indeed, the E^3-family of algorithms (Kearns and Singh 2002) and its extensions (Kearns and Koller 1999; Brafman and Tennenholtz 2002; Kakade et al. 2003) proceed by generating "exploration" policies, which try to visit inaccurately modeled parts of the state space. Unfortunately, such exploration policies do not even try to fly the helicopter well and thus would almost invariably lead to crashes.)

The apprenticeship learning algorithms described above have been used to fly the most advanced autonomous maneuvers to date. The apprenticeship learning algorithm of Coates et al. (2008), for example, has been used to attain ex-



Autonomous Helicopter Flight Using Reinforcement Learning, Fig. 3 Snapshot sequence of an autonomous helicopter flying a "chaos" maneuver using apprenticeship learning methods. Beginning from the top to left and proceeding left to right and top to bottom, the helicopter performs a flip while pirouetting counterclockwise about its vertical axis (this maneuver has been demonstrated continuously for as long as 15 cycles like the one shown here)

pert level performance on challenging aerobatic maneuvers as well as entire air shows composed of many maneuvers in rapid sequence. These maneuvers include in-place flips and rolls, tic-tocs ("tic-toc" is a maneuver where the helicopter pitches forward and backward with its nose pointed toward the sky (resembling an inverted clock pendulum)), and chaos. ("Chaos" is a maneuver where the helicopter flips in place but does so while continuously pirouetting at a high rate. Visually, the helicopter body appears to tumble chaotically while nevertheless remaining in roughly the same position.) (See Fig. 3.) These maneuvers are considered among the most challenging possible and can only be performed by advanced human pilots. In fact, Coates et al. (2008) show that their learned controller performance can even exceed the performance of the expert pilot providing the demonstrations, putting many of the maneuvers on par with professional pilots (Fig. 4).

A similar approach has been used in Abbeel et al. (2008) to perform the first successful autonomous autorotations. Their aircraft has performed more than 30 autonomous landings successfully without engine power.

Not only do apprenticeship methods achieve state-of-the-art performance, but they are among the fastest learning methods available, as they obviate the need for arduous hand tuning by engineers. Coates et al. (2008), for instance, report that entire air shows can be created from scratch with just 1 h of work. This is in stark contrast to previous approaches that may have required hours or even days of tuning for relatively simple maneuvers.

Conclusion

Helicopter control is a challenging control problem and has recently seen major successes with the application of learning algorithms. This entry has shown how each step of the control design process can be automated using machine learning algorithms for system identification and reinforcement learning algorithms for control. It has also shown how apprenticeship learning algorithms can be employed to achieve expert-level performance on challenging aerobatic maneuvers when an expert pilot can provide demonstrations. Autonomous helicopters with control systems developed using these methods are now capable of flying advanced aerobatic maneuvers (including flips, rolls, tic-tocs, chaos, and autorotation) at the level of expert human pilots.

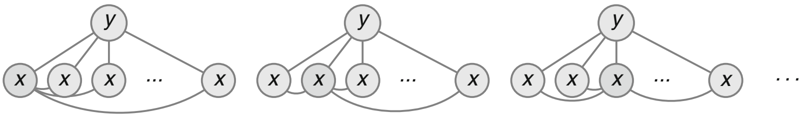
Definition

Averaged one-dependence estimators is a ▶ semi-naive Bayesian Learning method. It performs classification by aggregating the predictions of multiple one-dependence classifiers in which all attributes depend on the same single parent attribute as well as the class.

Classification with AODE

An effective approach to accommodating violations of naive Bayes' attribute independence assumption is to allow an attribute to depend on other non-class attributes. To maintain efficiency it can be desirable to utilize one-dependence classifiers, such as ▶ Tree Augmented Naive Bayes (TAN), in which each attribute depends upon the class and at most one other attribute. However, most approaches to learning with one-dependence classifiers perform model selection, a process that usually imposes substantial computational overheads and substantially increases variance relative to naive Bayes.



Averaged One-Dependence Estimators, Fig. 1 A Markov network representation of the SPODEs that comprise an example AODE

AODE avoids model selection by averaging the predictions of multiple one-dependence classifiers. In each one-dependence classifier, an attribute is selected as the parent of all the other attributes. This attribute is called the *SuperParent* and this type of one-dependence classifier is called a *SuperParent one-dependence estimator* (SPODE). Only those SPODEs with SuperParent x_i where the value of x_i occurs at least m times are used for predicting a class label y for the test instance $\mathbf{x} = \langle x_1, \ldots, x_n \rangle$. For any attribute value x_i,

$$P(y, \mathbf{x}) = P(y, x_i) P(\mathbf{x} | y, x_i).$$

This equality holds for every x_i. Therefore,

$$P(y, \mathbf{x}) = \frac{\sum_{1 \le i \le n \wedge F(x_i) \ge m} P(y, x_i) P(\mathbf{x} | y, x_i)}{|\{1 \le i \le n \wedge F(x_i) \ge m\}|}, \tag{1}$$

where $F(x_i)$ is the frequency of attribute value x_i in the training sample. Utilizing (1) and the assumption that attributes are independent given the class and the SuperParent x_i, AODE predicts the class for $\mathbf{x}$ by selecting

$$\operatorname*{argmax}_{y} \sum_{1 \le i \le n \wedge F(x_i) \ge m} \hat{P}(y, x_i) \prod_{1 \le j \le n, j \ne i} \hat{P}(x_j | y, x_i). \tag{2}$$

It averages over estimates of the terms in (1), rather than the true values, which has the effect of reducing the variance of these estimates.

Figure 1 shows a Markov network representation of an example AODE.

As AODE makes a weaker attribute conditional independence assumption than naive Bayes while still avoiding model selection, it has substantially lower ▶ bias with a very small increase in variance. A number of studies (Webb et al. 2005; Zheng and Webb 2005) have demonstrated that it often has considerably lower zero-one loss than naive Bayes with moderate time complexity. For comparisons with other semi-naive techniques, see ▶ semi-naive Bayesian learning. One study (Webb et al. 2005) found AODE to provide classification accuracy competitive to a state-of-the-art discriminative algorithm, boosted decision trees.

When a new instance is available, like naive Bayes, AODE only needs to update the probability estimates. Therefore, it is also suited to incremental learning.

In more recent work (Webb et al. 2012), AODE has been generalized to Averaged N-Dependence Estimators (ANDE) and it has been demonstrated that bias can be further decreased by introducing multiple SuperParents to each submodel.

ARL; Average-cost neuro-dynamic programming; Average-cost optimization; Average-payoff reinforcement learning

Definition

Average-reward reinforcement learning (ARL) refers to learning policies that optimize the average reward per time step by continually taking actions and observing the outcomes including the next state and the immediate reward.

Motivation and Background

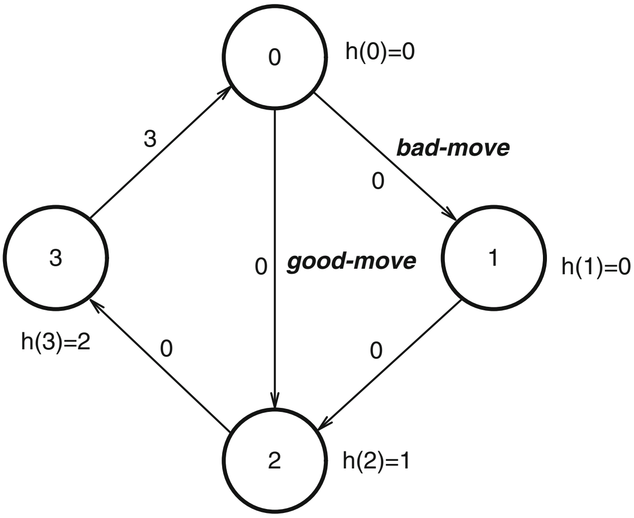
▸ Reinforcement learning (RL) is the study of programs that improve their performance at some task by receiving rewards and punishments from the environment (Sutton and Barto 1998). RL has been quite successful in the automatic learning of good procedures for complex tasks such as playing Backgammon and scheduling elevators (Tesauro 1992; Crites and Barto 1998). In episodic domains in which there is a natural termination condition such as the end of the game in Backgammon, the obvious performance measure to optimize is the expected total reward per episode. But some domains such as elevator scheduling are recurrent, i.e., do not have a natural termination condition. In such cases, total expected reward can be infinite, and we need a different optimization criterion.

In the discounted optimization framework, in each time step, the value of the reward is multiplied by a discount factor $\gamma < 1$, so that the total *discounted* reward is always finite. However, in many domains, there is no natural interpretation for the discount factor γ. A natural performance measure to optimize in such domains is the average reward received per time step. Although one could use a discount factor which is close to 1 to approximate average-reward optimization, an approach that directly optimizes the average reward avoids this additional parameter and often leads to faster convergence in practice.

There is a significant theory behind average-reward optimization based on ▸ Markov decision processes (MDPs) (Puterman 1994). An MDP is described by a 4-tuple $\langle S, A, P, r \rangle$, where S is a discrete set of states and A is a discrete set of actions. P is a conditional probability distribution over the next states, given the current state and action, and r gives the immediate reward for a given state and action. A *policy* π is a mapping from states to actions. Each policy π induces a Markov process over some set of states. In ergodic MDPs, every policy π forms a single closed set of states, and the average reward per time step of π in the limit of infinite horizon is independent of the starting state. We call it the "gain" of the policy π, denoted by $\rho(\pi)$, and consider the problem of finding a "gain-optimal policy," π^*, that maximizes $\rho(\pi)$.

Even though the gain $\rho(\pi)$ of a policy π is independent of the starting state s, the total expected reward in time t is not. It can be denoted by $\rho(\pi)t + h(s)$, where $h(s)$ is a state-dependent bias term. It is the bias values of states that determine which states and actions are preferred and

Average-Reward Reinforcement Learning, Fig. 1 A simple Markov decision process (MDP) that illustrates the Bellman equation



need to be learned for optimal performance. The following theorem gives the Bellman equation for the bias values of states.

Theorem 1 *For ergodic MDPs, there exist a scalar ρ and a real-valued bias function h over S that satisfy the recurrence relation*

$$\forall s \in S, h(s) = \max_{a \in A} \left\{ r(s,a) + \sum_{s' \in S} P(s'|s,a)h(s') \right\} - \rho. \quad (1)$$

Further, the gain-optimal policy μ^* attains the above maximum for each state s, and ρ is its gain.

Note that any one solution to (1) yields an infinite number of solutions by adding the same constant to all h-values. However, all these sets of h-values will result in the same set of optimal policies μ^*, since the optimal action in a state is determined only by the relative differences between the values of h.

For example, in Fig. 1, the agent has to select between the actions good-move and bad-move in state 0. If it stays in state 1, it gets an average reward of 1. If it stays in state 2, it gets an average reward of -1. For this domain, $\rho = 1$ for the optimal policy of choosing good-move in state 0. If we arbitrarily set $h(0)$ to 0, then $h(1) = 0, h(2) = 1$, and $h(3) = 2$ satisfy the recurrence relations in (1). For example, the difference between $h(3)$ and $h(1)$ is 2, which equals the difference between the immediate reward for the optimal action in state 3 and the optimal average reward 1.

Given the probability model P and the immediate rewards r, the above equations can be solved by White's relative value iteration method by setting the h-value of an arbitrarily chosen reference state to 0 and using synchronous successive approximation (Bertsekas 1995). There is also a policy iteration approach to determine the optimal policy starting with some arbitrary policy, solving for its values using the value iteration, and updating the policy using one step look-ahead search. The above iteration is repeated until the policy converges (Puterman 1994).

Model-Based Learning

If the probabilities and the immediate rewards are not known, the system needs to learn them before applying the above methods. A model-based approach called H-learning interleaves model learning with Bellman backups of the value function (Tadepalli and Ok 1998). This is an average-reward version of ▶ Adaptive real-time dynamic programming (Barto et al. 1995). The models are learned by collecting samples of state-action-next-state triples $\langle s, a, s' \rangle$

and computing $P(s'|s,a)$ using the maximum likelihood estimation. It then employs the "certainty equivalence principle" by using the current estimates as the true value while updating the h-value of the current state s according to the following update equation derived from the Bellman equation.

$$h(s) \leftarrow \max_{a \in A} \left\{ r(s,a) + \sum_{s' \in S} P(s'|s,a)h(s') \right\} - \rho. \tag{2}$$

One complication in ARL is the estimation of the average reward ρ in the update equations during learning. One could use the current estimate of the long-term average reward, but it is distorted by the exploratory actions that the agent needs to take to learn about the unexplored parts of the state space. Without the exploratory actions, ARL methods converge to a suboptimal policy. To take this into account, we have from (1), in any state s and a non-exploratory action a that maximizes the right-hand side, $\rho = r(s,a) - h(s) + \sum_{s' \in S} P(s'|S,a)h(s')$. Hence, ρ is estimated by cumulatively averaging $r - h(s) + h(s')$, whenever a greedy action a is executed in state s resulting in state s' and immediate reward r. ρ is updated using the following equation where α is the learning rate.

$$\rho \leftarrow \rho + \alpha(r - h(s) + h(s')). \tag{3}$$

One issue with model-based learning is that the models require too much space and time to learn as tables. In many cases, actions can be represented much more compactly. For example, Tadepalli and Ok (1998) uses dynamic Bayesian networks to represent and learn action models, resulting in significant savings in space and time for learning the models.

Model-Free Learning

One of the disadvantages of the model-based methods is the need to explicitly represent and learn action models. This is completely avoided in model-free methods such as ▶ Q-learning by learning value functions over state–action pairs. Schwartz's R-learning is an adaptation of Q-learning, which is a discounted reinforcement learning method, to optimize average reward (Schwartz 1993).

The state–action value $R(s,a)$ can be defined as the expected long-term advantage of executing action a in state s and from then on following the optimal average-reward policy. It can be defined using the bias values h and the optimal average reward ρ as follows.

$$R(s,a) = r(s,a) + \sum_{s' \in S} P(s'|s,a)h(s') - \rho. \tag{4}$$

The main difference with Q-values is that instead of discounting the expected total reward from the next state, we subtract the average reward ρ in each time step, which is the constant penalty for using up a time step. The h value of any state s can now be defined using the following equation:

$$h(s') = \max_u R(s',u). \tag{5}$$

Initially all the R-values are set to 0. When action a is executed in state s, the value of $R(s,a)$ is updated using the update equation

$$R(s,a) \leftarrow (1-\beta)R(s,a) + \beta(r + h(s') - \rho), \tag{6}$$

where β is the learning rate, r is the immediate reward received, s' is the next state, and ρ is the estimate of the average reward of the current greedy policy. In any state s, the greedy action a maximizes the value $R(s,a)$, so R-learning does not need to explicitly learn the immediate reward function $r(s,a)$ or the action models $P(s'|s,a)$, since it does not use them either for the action selection or for updating the R-values.

Both model-free and model-based ARL methods have been evaluated in several experimental domains (Mahadevan 1996; Tadepalli and Ok 1998). When there is a compact representation for models and can be learned quickly, the model-based method seems to perform better. It also has the advantage of fewer number of tunable parameters. However, model-free methods are more convenient to implement especially if the models are hard to learn or represent.

Scaling Average-Reward Reinforcement Learning

Just as for discounted reinforcement learning, scaling issues are paramount for ARL. Since the number of states is exponential to the number of relevant state variables, a table-based approach does not scale well. The problem is compounded in multi-agent domains where the number of joint actions is exponential in the number of agents. Several function approximation approaches, such as linear functions, multi-layer perceptrons (Marbach et al. 2000), local ▶ linear regression (Tadepalli and Ok 1998), and tile coding (Proper and Tadepalli 2006) were tried with varying degrees of success.

▶ Hierarchical reinforcement learning based on the MAXQ framework was also explored in the average-reward setting and was shown to lead to significantly faster convergence. In the MAXQ framework, we have a directed acyclic graph, where each node represents a task and stores the value function for that task. Usually, the value function for subtasks depends on fewer state variables than the overall value function and hence can be more compactly represented. The relevant variables for each subtask are fixed by the designer of the hierarchy, which makes it much easier to learn the value functions. One potential problem with the hierarchical approach is the loss due to the hierarchical constraint on the policy. Despite this limitation, both model-based (Seri and Tadepalli 2002) and model-free approaches (Ghavamzadeh and Mahadevan 2006) were shown to yield optimal policies in some domains that satisfy the assumptions of these methods.

Applications

A temporal difference method for average reward based on TD(0) was used to solve a call admission control and routing problem (Marbach et al. 2000). On a modestly sized network of 16 nodes, it was shown that the average-reward TD(0) outperforms the discounted version because it required more careful tuning of its parameters. Similar results were obtained in other domains such as automatic guided vehicle routing (Ghavamzadeh and Mahadevan 2006) and transfer line optimization (Wang and Mahadevan 1999).

Convergence Analysis

Unlike their discounted counterparts, both R-learning and H-learning lack convergence guarantees. This is because due to the lack of discounting, the updates can no longer be thought of as contraction mappings, and hence the standard theory of stochastic approximation does not apply. Simultaneous update of the average reward ρ and the value functions makes the analysis of these algorithms much more complicated. However, some ARL algorithms have been proved convergent in the limit using analysis based on ordinary differential equations (ODE) (Abounadi et al. 2002). The main idea is to turn to ordinary differential equations that are closely tracked by the update equations and use two-time-scale analysis to show convergence. In addition to the standard assumptions of stochastic approximation theory, the two-time-scale analysis requires that ρ is updated at a much slower time scale than the value function.

The previous convergence results are based on the limit of infinite exploration. One of the many challenges in reinforcement learning is that of efficient exploration of the MDP to learn the dynamics and the rewards. There are model-based algorithms that guarantee learning an approximately optimal average-reward policy in time polynomial in the numbers of states and actions of the MDP and its mixing time. These algorithms work by alternating between learning the action models of the MDP by taking actions in the environment and solving the learned MDP using offline value iteration.

In the "Explicit Explore and Exploit" or E^3 algorithm, the agent explicitly decides between exploiting the known part of the MDP and optimally trying to reach the unknown part of the MDP (exploration) (Kearns and Singh 2002). During exploration, it uses the idea of "balanced wandering," where the least executed action in the current state is preferred until all actions are executed a certain number of times. In contrast, the R-MAX algorithm implicitly chooses between exploration and exploitation by using the principle of "*optimism under uncertainty*" (Brafman and Tennenholtz 2002). The idea here is to initialize the model parameters optimistically so that all unexplored actions in all states are assumed to reach a fictitious state that yields maximum possible reward from then on regardless of which action is taken. The optimistic initialization of the model parameters automatically encourages the agent to execute unexplored actions, until the true models and values of more states and actions are gradually revealed to the agent. It has been shown that with a probability at least $1 - \delta$, both E^3 and R-MAX learn approximately correct models whose optimal policies have an average reward ϵ-close to the true optimal in time polynomial in the numbers of states and actions, the mixing time of the MDP, $\frac{1}{\epsilon}$, and $\frac{1}{\delta}$.

Unfortunately the convergence results do not apply when there is function approximation involved. In the presence of linear function approximation, the average-reward version of temporal difference learning, which learns a state-based value function for a fixed policy, is shown to converge in the limit (Tsitsiklis and Van Roy 1999). The transient behavior of this algorithm is similar to that of the corresponding discounted TD-learning with an appropriately scaled constant basis function (Van Roy and Tsitsiklis 2002). As in the discounted case, development of provably convergent optimal policy learning algorithms with function approximation is a challenging open problem.

University of Pittsburgh, Pittsburgh, PA, USA

Synonyms

Backprop; BP; Generalized delta rule

Definition

Backpropagation of error (henceforth *BP*) is a method for training feed-forward neural networks see ▶ Artificial Neural Networks. A specific implementation of BP is an iterative procedure that adjusts network weight parameters according to the gradient of an error measure. The procedure is implemented by computing an error value for each output unit, and by *backpropagating* the error values through the network.

Characteristics

Feed-Forward Networks

A feed-forward neural network is a mathematical function that is composed of constituent "semi-linear" functions constrained by a feed-forward network architecture, wherein the constituent functions correspond to nodes (often called *units* or *artificial neurons*) in a graph, as in Fig. 1. A feed-forward network architecture has a connectivity structure that is an *acyclic graph*; that is, there are no closed loops.

In most cases, the unit functions have a finite range such as [0, 1]. Thus, the network maps $\mathbb{R}^N$ to $[0, 1]^M$, where N is the number of input values and M is the number of output units. Let *FanIn*(k) refer to the set of units that provide input to unit k, and let *FanOut*(k) denote the set of units that receive input from unit k.

In an acyclic graph, at least one unit has a FanIn that is the null set. These are the *input units*; the activity of an input unit is not computed; rather it is set to a value external to the network (i.e., from the training data). Similarly, at least one unit has a null FanOut set. Such units typically represent the output of the network; i.e., this set of values is the result of the network computation. Intermediate units (often called *hidden units*) receive input from other units and project outputs to other computational units.

For the BP procedure, the activity of each unit is computed in two steps:

Linear step: the activities of the FanIn are each multiplied by an independent "weight" parameter, to which a "bias" parameter is added; each computational unit has a single bias parameter, independent of the other units. Let this sum be denoted x_k for unit k.

Backpropagation, Fig. 1 Two networks are shown. Input units are shown as simple squares at the bottom of each figure. Other units are computational (designated by a *horizontal line*). *Left*: A standard 3-layer network. Four input units project to five hidden units, which in turn project to a single output unit. Not all connections are shown. Such a network is commonly used for classification tasks. *Right*: An example of a feed-forward network with four inputs, three hidden units, and two outputs

Nonlinear step: The activity a_k of unit k is a differentiable nonlinear function of x_k. A favorite function is the logistic $a = 1/(1 + \exp(-x))$, because it maps the range $[-\infty, +\infty]$ to $[0, 1]$ and its derivative has properties conducive to the implementation of BP.

$$a_k = f_k(x_k); \quad \text{where } x_k = b_k + \sum_{j \varepsilon \text{FanIn}(k)} w_{kj} s_j$$

Gradient Descent

Derivation of BP is a direct application of the *gradient descent* approach to optimization and is dependent on a definition of network error, a function of the actual network response to a stimulus, $\mathbf{r}(\mathbf{s})$ and the target $\mathbf{T}(\mathbf{s})$. The two most common error functions are the summed squared error (SSE) and the cross entropy error (CE) (CE error as defined here is based on the presumption that the output values are in the range [0, 1]. Likewise for the target values; this is often used for classification tasks, wherein target values are set to the endpoints of the range, 0 and 1).

$$E^{SSE} \equiv \sum_{\substack{i \varepsilon \text{Outut} \\ s \varepsilon \text{Train}}} (T_i(\mathbf{s}) - r_i(\mathbf{s}))^2$$

$$E^{CE} \equiv \sum_{\substack{i \varepsilon \text{Outut} \\ s \varepsilon \text{Train}}} [T_i(\mathbf{s}) ln(r_i(\mathbf{s})) - 1 - (T_i(\mathbf{s})) ln(1 - r_i(\mathbf{s}))]$$

Each weight parameter, w_{ij} (the weight of the connection from j to i), is updated by an amount proportional to the negative gradient of the error measure with respect to that parameter:

$$\Delta w_{ij} = -\eta \frac{\partial W}{\partial w_{ij}},$$

where the *step size*, η, modulates the intrinsic tradeoff between smooth convergence of the weights and the speed of convergence; in the regime where η is small, the system is well-behaved and converges smoothly, but slowly, and for larger η, the system may learn some subsets of the training set faster at the expense of smooth convergence on all patterns in the set. Thus, η is also called the *learning rate*.

c Weights are updated

Backpropagation, Fig. 2 With each iteration of the backprop algorithm, (**a**) An activity value is computed for every unit in the network from the input to the output. (**b**) The network output is compared with the target. The error e_k for output unit k is defined as $(T_k - r_k)$. A value δ_k is computed for each output unit by multiplying e_k by the derivative of the activity function. For hidden units, the error is propagated backward using the weights. (**c**) The weight parameters w_{ij} are updated in proportion to the product of δ_i and a_j

Implementation

Several aspects of the feed-forward network must be defined prior to running a BP program, such as the configuration of the hidden units, the initial values of the weights, the functions they will compute, and the numerical representation of the input and target data. There are also parameters of the learning algorithm that must be chosen, such as the value of η and the form of the error function.

The weight and bias parameters are set to their initial values (these are usually random within specified limits). BP is implemented as an iterative process as follows:

1. A stimulus-target pair is drawn from the training set.
2. The activity values for the units in the network are computed for all the units in the network in a forward fashion from input to output (Fig. 2a).
3. The network output values are compared to the target and a *delta* (δ) value is computed for each output unit based on the difference between the target and the actual output response value.
4. The deltas are propagated backward through the network using the same weights that were used to compute the activity values (Fig. 2b).
5. Each weight is updated by an amount proportional to the product of the downstream delta value and the upstream activity (Fig. 2c).

The procedure can be run either in an *online* mode or *batch* mode. In the online mode, the network parameters are updated for each stimulus-target pair. In the batch mode, the weight changes are computed and accumulated over several iterations without updating the weights until a large number (B) of stimulus-target pairs have been processed (often, the entire training set), at which the weights are updated by the accumulated amounts.

$$\text{online:}\ \ \Delta w_{ij}(t) = \eta\delta_i(t)a_j(t) \quad \Delta b_i(t) = \eta\delta_i(t)$$

$$\text{batch:}\ \ \Delta w_{ij}(t+B) = \sum_{s=t-1}^{t+B} \eta\delta_i(s)a_j(s)$$

$$\Delta b_i(t+T) = \sum_{s=t+1}^{t-B} \eta\delta_i(s)$$

Classification Tasks with BP

The simplest and most common classification function returns a binary value, indicating membership in a particular class. The most common network architecture for a task of this kind is the three-layer network of Fig. 1 (left), with training values of 0 and 1. For classification tasks, the cross entropy error function generally gives significantly faster convergence. After training, the network is in test mode or production mode, and the responses are in the continuous range [0, 1]; the response must thus be interpreted. The value of the response could be interpreted as a probability or fuzzy Boolean value. Often, however, a single threshold is applied to give a binary answer. A double threshold is sometimes used, with the midrange defined as "uncertain."

Curve Fitting with BP

A feed-forward network can be trained to approximate any function, given the sufficient hidden units. The range of the output unit(s) must be capable of generating activity values in the required range. In order to accommodate an arbitrary range uniformly, a linear function is advisable for the output units, and the SSE function is the basis for gradient descent.

The Autoencoder Architecture

The autoencoder is a network design in which the target pattern is identical to the input pattern. The hidden units are configured such that there is a "bottleneck layer" of units that is smaller than the input layer, through which information flows; i.e., there are no connections bypassing the bottleneck. Thus, any information necessary to reconstruct the input pattern at the output layer must be represented at the bottleneck. This approach has been successfully applied as an approach to *nonlinear dimensionality reduction* (e.g., Demers and Cottrell 1993). It bears notable similarities and differences to linear techniques, such as ▸ *principal components analysis* (*PCA*).

Prediction with BP

The plain "vanilla" BP propagates input to output with no explicit representation of time. Several approaches to processing of temporal patterns have been put forward. Most prominent among these are:

Time delay neural network. In this approach, the input stimulus is simply a sample of a time varying signal. The input patterns are typically generated by a sliding window of samples over time or over a sequence.

▸ Simple recurrent network (Elman 1990). A sequence of stimulus patterns is presented as input for the network, which has a single hidden layer design. With each iteration, the input is augmented by a secondary set of input units whose activity is a copy of the hidden layer activity from the previous iteration. Thus, the network is able to maintain a representation of the recent history of network stimuli.

Backpropagation through time (Rumelhart et al. 1986). A recurrent network (i.e., a cyclic network) is "unfolded in time" by forming a large multilayer network, in which each layer is a copy of the entire network shifted in time. Thus, the number of layers limits the temporal window available to the network.

Recurrent backpropagation (Pineda 1989). An acyclic network is run with activity propagation and error propagation, until variables converge. Then the weights are updated.

Cognitive Modeling with BP

Interest in BP as a training technique for classifiers has waned somewhat since the introduction of ▸ *Support vector machines* (SVMs) in the mid 1990s. However, the influence of BP as an approach to modeling cognitive processes, including perception, concept learning, spatial cognition, and language learning, remains strong. Analysis of hidden unit representations (e.g., using clustering techniques) has given insight into plausible intermediate processes that may underlie cognitive phenomena. Also, many cognitive models trained with BP have exhibited time courses consistent with stages of human learning.

Biological Inspiration and Plausibility

The "connectionist" approach to modeling cognition is based on "neural network" models, which have been touted as "biologically inspired" since their inception. The similarities and differences between connectionist architectures and living brains have been exhaustively debated. Like the brain, the models consist of elements that are extremely limited, computationally. Computational power is derived by several units in network architecture. However, there are compelling differences as well. For example, the temporal dynamics in biological neurons is far more complex than the simple functions used in connectionist networks. It remains unclear what level of neurobiological detail is relevant to understand the cognitive functions.

Shortcomings of BP

The BP method is notorious for convergence problems. An inherent problem of gradient descent approaches to optimization is the issue of locally optimal values. Seeking a minimum value be heading downhill is like water running downhill. Not all water reaches the lowest point (sea level). Water that flows into a mountain lake has landed in a local minimum, a region that is bounded by higher ground.

Even when BP converges to a global minimum (or a local minimum that is "good enough"), it is sometimes very slow. The convergence properties of BP depend on the learning rate and random factors, such as the initial weight and bias values.

Another difficulty with BP is the selection of a network structure. The number of hidden units and the interconnectivity among them has a strong influence on both the generalization performance and the convergence time. Since the nature of this influence is poorly understood, the design of the network is left to guesswork. The standard approach is to use a single hidden layer (as in Fig. 1, left), which has the advantage of relatively fast convergence.

History

The idea of training a multilayered network using error propagation was originated by Frank Rosenblatt (1958, 1962). However, he was unable to apply gradient descent because he was using linear threshold functions that were not differentiable; therefore, the technique of gradient descent was unavailable. He developed a technique known as the perceptron learning rule that is only applicable to two layer networks (no hidden units). Without hidden units, the computational power of the network is severely reduced. Work in the field virtually stopped with the publication of *Perceptrons* (Minsky and Papert 1969). The backpropagation procedure was first published by Werbos (1974), but did not receive significant recognition until it was put forward by Rumelhart et al. (1986).

Synonyms

Market basket analysis

Definition

The goal of basket analysis is to utilize large volumes of electronic receipts, stored at the checkout terminals of supermarkets, for better understanding of customer behavior.

While many forms of learning and mining can be applied to market baskets, the term usually refers to some variant of ▶ association rule mining. In the basic setting, each market basket constitutes an example essentially defined by the set of purchased products. Association rules then identify sets of items that tend to be bought together. A classical, anecdotal discovery from supermarket data is that "if a basket contains diapers then it often also contains beer." This example illustrates several potential benefits of market basket analysis by association rules: simplicity and understandability of the results, actionability of the results, and a form of nonsupervised approach where the consequent of the rule has not been fixed by the user.

Association rules are often found with the ▶ Apriori algorithm, and are based on ▶ frequent itemsets.

Synonyms

Bayes' Theorem

Definition

Bayes' rule provides a decomposition of a conditional probability that is frequently used in a family of learning techniques collectively called *Bayesian learning*. Bayes' rule is the equality

$$P(z|w) = \frac{P(z)P(w|z)}{P(w)} \qquad (1)$$

P(w) is called the *prior probability*, P($w|z$) is called the *posterior probability*, and P($z|w$) is called the *likelihood*.

Discussion

Bayes' rule is used for two purposes. The first is *Bayesian update*. In this context z represents some new information that has become available since an estimate P(w) was formed of some hypothesis w. The application of Bayes' rule enables a new estimate of the probability of w (the posterior probability) to be calculated from estimates of the prior probability, the likelihood, and P(z).

The second common application of Bayes' rule is for estimating posterior probabilities in probabilistic learning, where it is the core of Bayesian networks, naïve Bayes, and semi-naïve Bayesian techniques.

While Bayes' rule may initially appear mysterious, it is readily derived from the basic principle of conditional probability that

$$P(w|z) = \frac{P(w,z)}{P(z)} \qquad (2)$$

As

$$P(w,z) = \frac{P(w)P(w,z)}{P(w)} \qquad (3)$$

and

$$\frac{P(w,z)}{P(w)} = P(z|w), \qquad (4)$$

Bayes' rule (Eq. 1) follows by simple substitution of Eq. 4 into Eq. 3 and then of the result into Eq. 2.

Definition

The two most important concepts used in Bayesian modeling are *probability* and *utility*. Probabilities are used to model our belief about the state of the world and utilities are used to model the *value* to us of different outcomes, thus to model costs and benefits. Probabilities are represented in the form of $p(x|C)$, where C is the current known context and x is some event(s) of interest from a space χ. The left and right arguments of the probability function are in general propositions (in the logical sense). Probabilities are updated based on new evidence or outcomes y using *Bayes rule*, which takes the form

$$p(x|C,y) = \frac{p(x|C)p(Y|x,C)}{p(y|C)},$$

where χ is the discrete domain of x. More generally, any measurable set can be used for the domain χ. An integral or mixed sum and integral can replace the sum. For a utility function $u(x)$ of some event x, for instance the benefit of a particular outcome, the *expected value* of $u()$ is

$$\mathcal{E}_{x|C}[u(x)] = \sum_{x\in\chi} p(x|C)u(x).$$

One then estimates the expected utility $\mathcal{E}_{x|c,y}[u(x)]$ based on different evidence, actions or outcomes y. An action is taken to maximize this expected utility, appealing to the principle of *maximum expected utility (MEU)*. A common application of this principle is recursive: one should take the action now that will maximize utility in the future, assuming all future actions are also taken to maximize utility.

Motivation and Background

In modeling a problem, primarily, one considers an interrelated space of *events* or *states, actions*, and *outcomes*. Events describe the state of the world, outcomes are also sometimes considered events but they are special in that one directly obtains from them costs or benefits. Actions allow one to influence the world. Some actions may instigate tests and thus also help measure the state of the world to reduce uncertainty. Some problems may be dynamic in that a sequence of actions and outcomes are considered and the resulting changes in states modeled.

The Bayesian approach is a modeling methodology that provides a principled approach of how to reason and act in the context of uncertainty and a dynamic environment. In the approach, probabilities are used to model all forms of belief or proportions about events and states, and then utilities are used to model the costs and benefits of any actions taken. An explicit assumption is that these probabilities and utilities can be adequately elicited and precisely modeled for the problem. An implicit assumption is that the computation required – recursive evaluation of possibly nested integrals and sums (over domain variables) – can be done quickly enough so that the computation itself does not become a significant factor in the costs considered.

The Bayesian approach is named after Rev. Thomas Bayes, whose work was contributed to the Royal Society in 1763 after his death, although it was independently more generally presented as a theory by Laplace in 1812. The field was subsequently developed into a field of statistics, inference and decision theory by a stream of authors in the 1900s including Jeffreys (Bernardo and Smith 1994). The field of statistics was dominated by the frequentist school during the 1990s, and for a time Bayesian methods were considered controversial. Like the different schools of theory in machine learning, these statistical approaches now coexist.

The Bayesian approach can be justified by axiomatic prescriptions of how a rational agent should reason and act, and by appeal to principles of consistency. In the context of learning, probabilities are used to infer models of the problem of interest, and then utilities are used to recommend predictions or analysis based on the models.

Theory

Basic Theory

First, consider definitions, the different kinds of probability, the process of reasoning (about probabilities), and making decisions.

Basic definitions: Probabilities are represented in the form of $p(x|C)$, where C is the current known context and x is some event(s) of interest. It is sufficient to place in C only terms relevant to x and ignore terms assumed by default. Moreover, both x and C must have well-defined events. For instance, x = "John is tall" is not considered a well-defined event since the word "tall" is not precise. One would instead replace it with something like x = "John is greater than 6 foot tall" or x = "Julie said John is tall."

An important functional used with probabilities is the *expected value*. For a function $f(x)$ of some event x from a space χ, the expected value of $f()$ is $\mathcal{E}_{x\in\chi[f(x)]}$.

Utility is used to measure value or relative satisfaction, and is usually represented as a function on outcomes. Costs are negative utility and benefits are positive. Utilities should be additive in worth, and are often practically interpreted in monetary units. Strictly speaking, the value of money is nonlinear (for most people, 2 billion dollars is not significantly better than 1 billion dollars), so it is not a correct utility measure. However, it is adequate when the range of financial transactions expected is reasonable.

Expected utility, which is the expected value of the utility function, is the fundamental quantity assessed with Bayesian methods. Some scenarios are the following:

Prediction: For prediction problems, the outcome is the "true" value, and the utility is sometimes the mean square error or the absolute error. In data mining, the choices are much richer, see ► Model Evaluation.

Diagnosis: The outcome is the "true" diagnosis, and utility is made up of the differing costs of treatment, mistreatment, and delay or nontreatment, as well as any benefit from correct diagnosis.

Game playing: The utility comes from the eventual outcome of the game, each player has their own utility and the state of the game constantly changes as plays are made.

In Bayesian machine learning, we usually take utilities as a given, and the majority of the work revolves around evaluating and estimating probabilities and maximizing of expected utility. In some ranking tasks and generalized agent learning, the utilities themselves may be poorly understood.

Belief and proportions: Some probabilities correspond to *proportions* that exist in the real world, such as the proportion of school children in the general population of a given state. These real proportions can be measured by counting or sampling, and they are governed by Kolmogorov's Axioms for probability, including the probability of certainty is 1 and the probability of a disjunction of mutually exclusive events is the sum of the probabilities of the individual events. This kind of probability is used in the *Frequentist School* that only considers long term average proportions obtained from a series of independent and identical experiments. These proportions can be model parameters one wishes to reason about.

Probabilities can also represent beliefs. For instance, in 2000, one could have had a belief about the event that George Bush would win the 2001 Presidential Election in the USA. This event is unique and has only one outcome, so the frequentist notion cannot be justified, i.e., there is no long-term sequence of different 2001 presidential elections with George Bush. Beliefs are usually considered to be *subjective*, in that they are specific to each agent, reflecting their sum of unique experiences, and the unique context in which the event in question occurs.

To better understand the role beliefs play in Bayesian methods, also see ▶ Prior Probability.

Reasoning: A stylized version of probabilistic reasoning considers an event of interest one is reasoning about, x, and evidence, y, one may obtain. Typical scenarios are

Learning: $x = (\boldsymbol{\Theta}, M)$ are parameters $\boldsymbol{\Theta}$ of a model from family M, and $y = \{\boldsymbol{D}\}$ is a set of data $\{\boldsymbol{D}\} = \{d_1, \ldots, d_N\}$. So one considers $p(\boldsymbol{\Theta}, M|\boldsymbol{D}, C)$ versus $p(\boldsymbol{\Theta}, M|C)$.

Diagnosis: x a disease or condition, and y is a set of observable symptoms or diagnostic tests. One might choose a test y that maximizes the expected utility.

Hypothesis testing: x is a hypothesis H and y is some sequence of evidence $E_1, E_2, \ldots, E_n$, so we consider $p(H|E_1, E_2, \ldots, E_n)$ and hope it is sufficiently high.

Different probabilities are then considered:

$p(x|C)$: *The prior probability* for event x, called the base-rate in some contexts.

$p(y|C)$: The *prior probability* for evidence y. Once the evidence has been seen, this is also used as a proxy for the quality of the model.

$p(x|y, C)$: The *posterior probability* for event x given evidence y.

$p(y|x, C)$: The *likelihood* for the event x based on evidence y.

In the case of diagnostic reasoning, the prior $p(x|C)$ is usually the base rate for the disease or condition, and can be got from the population base rate.

In the case of learning, however, the prior $p(\boldsymbol{\Theta}, M|C)$ represents a prior distribution on parameters about which we may well be largely ignorant, or at least may not be able to readily elicit from experts. For instance, the proportion θ_D might be the probability of a new drug slowing the onset of AIDS related diseases. At the moment of initial testing, θ_D is unknown so one places a probability distribution over θ_D, which represents one's belief about the proportion.

These priors are second-order probabilities, beliefs about proportions, and they are the most challenging quantity modeled with the Bayesian approach. They can be a function on thousands of parameters, and can be critical in the success of applications. They are also challenging from the philosophical perspective.

Decision theory: The term *Bayesian inference* is usually reserved for the process of manipulating priors and posteriors, computing probabilities, and computing expected values. *Bayesian decision theory* describes the process of formulating utilities and then evaluating the (sometimes) recursive maximum expected utility formula, such as in game playing, or interactive advertising.

In Bayesian theory one takes the action that maximizes expected utility (MEU) in the current context, sometimes referred to as the *expected utility hypothesis*. Decision theory places this in a dynamic context and says each action should be taken to maximize expected future utility. This is defined recursively, so taken to the limit this implies the optimal future actions need to be determined before the optimal current action can be got via MEU.

Justifications

This section covers basic mathematical justifications of the theory. The best general reference for this is Bernardo and Smith (1994). Additional discussion of prior probabilities appears in ▶ Prior Probability.

Note that Bayesian theory, with its acceptance as a branch of mainstream statistics, is widely accepted for the following reasons:

Application: It has extensive support through practical success, often times by clever combination of prior knowledge and statistical and computational finesse.

Explanation: It provides a convenient common language in which a variety of other theoretical approaches can be represented. For instance PAC, MDL methods, penalized likelihood methods, and the maximum margin approach all find good interpretations within the Bayesian framework.

Composition: It allows different reasoning tasks to be composed in a coherent way. With a probabilistic framework, the components can interoperate in a coherent manner, so that information may flow bidirectionally between components via probabilities.

Composition of processing steps in intelligent systems is a key application for Bayesian methods. For instance, natural language and vision recognition tasks can sometimes be broken down into a processing chain (for instance, doing a named entity recognition step before a dependency parsing step), but these components rarely work conclusively and unambiguously. By attaching probabilities to the output of components, and allowing probabilistic inputs, the uncertainty inherent in individual steps can be propagated and managed.

Theoretical justifications also exist to support each of the different components, probabilities, and utilities. These justifications are based on the concept of *normative* axioms, axioms that do not describe reasoning but rather prescribe basic principles it should follow. The axioms try to capture principles such as coherence and consistency in a quantitative manner. These various justifications have their reported shortcomings and a rich literature exists arguing about the details and postulating new variants. These axiomatic justifications are supportive of the Bayesian approach, but they are not irrefutable.

Justifying probabilities: In the Bayesian approach, beliefs and proportions are given the same mathematical treatment.

One set of arguably controversial justifications for this revolve around betting (Bernardo and Smith 1994, Sect. 2.8.3). Someone's subjective beliefs about specific events, such as significant economic and political events (or horse races), are claimed to be measurable by offering them a series of options or bets. Moreover, if their beliefs do not behave like proportions, then a clever bookmaker can use a so-called Dutch book to consistently profit from them.

An alternative scheme for justifying probability by Cox is based on normative axioms that beliefs should follow. For instance, one controversial axiom by Cox is that belief about a single event should be represented by a single real number. These axioms are presented by Jaynes as rules for a robot (Jaynes 2003), and as rules for intelligent systems by Horvitz et al. (1986).

Justifying decision theory: Another scheme again using normative axioms, by von Neumann and Morgenstern, is used to justify the use of utilities. This scheme assumes probabilities are the basis of inference about uncertainty. A different set of normative axiomatic schemes have been developed that justify the use of probabilities and utilities together under MEU, the best known is by Savage but others exist (Bernardo and Smith 1994).

Bayesian Computation

The first part of this article has been devoted to a brief overview of the Bayesian approach. Computation for Bayesian inference is an extensive field itself. Here we review the basic aspects as a pointer to the literature. This is an active area of research in machine learning, statistics, and a many applied artificial intelligence communities such as natural language processing, image analysis, and others.

In general, in Bayesian reasoning one wants to estimate posterior average parameter values, or their average variance, or some other averaged quantity, then general formulas are given by (in the case of continuous parameters)

$$\bar{\boldsymbol{\Theta}} = \mathcal{E}_{\boldsymbol{\Theta}|D,M,C}[\boldsymbol{\Theta}] = \int_{\boldsymbol{\Theta}} \boldsymbol{\Theta}\, p(\boldsymbol{\Theta}|D,M,C)\mathrm{d}\boldsymbol{\Theta}$$

$$\mathrm{var}(\boldsymbol{\Theta}) = \mathcal{E}_{\boldsymbol{\Theta}|D,M,C}[(\boldsymbol{\Theta} - \bar{\boldsymbol{\Theta}})^2]$$

Marginal likelihood: A useful quantity to assist in evaluating results, and a worthy score in its own right is the marginal likelihood, in the continuous parameter case found from the likelihood $p\,(\boldsymbol{D}|\boldsymbol{\Theta}, M, C)$ by taking an average

$$p(\mathbf{D}|M,C)=\int_{\mathbf{\Theta}} p(\mathbf{\Theta}|M,C)p(\boldsymbol{D}|\mathbf{\Theta},M,C)\mathrm{d}\mathbf{\Theta}$$

This is also called the *normalizing constant* due to its occurrence in the posterior formula

$$p(\mathbf{\Theta}|\boldsymbol{D},M,C) = \frac{p(\mathbf{\Theta}|M,C)p(D|\mathbf{\Theta},M,C)}{p(\mathbf{D}|M,C)}!.$$

It is generally difficult to estimate because of the multidimensional integrals and sums.

Exponential family distributions: Standard probability distributions covered in mathematical statistics, such as the ▶ Gaussian Distribution, the Poisson, Dirichlet, Gamma, and Wishart, have very convenient mathematical properties that make Bayesian estimation easier. With these distributions, one computes statistics, called *sufficient statistics*, such as a mean and sum of squares (for the Gaussian), and then parameter estimation follows with a function inverse on a concave function. This is the basis of ▶ linear regression, ▶ principal components analysis, and some ▶ decision tree learning methods, for instance. All good texts on mathematical statistics cover these in detail. Note the marginal likelihood is often computable in closed form for exponential family distributions.

Graphical models: ▶ Graphical Models are a general family of probabilistic models formed by composing graphs over variables. They work particularly well with exponential family distributions, and allow a rich variety of popular machine learning and data mining methods to be represented and manipulated. Graphical models allow complex models to be composed from simpler components and provide a family of algorithm schemes for developing inference and learning methods that operate on them. They have become the de facto standard for presenting (suitable decomposed) models and algorithms in the machine learning community.

Maximum a posterior estimation: known as MAP, is usually the simplest form of parameter estimation that could be called Bayesian. It also corresponds to a penalized or regularized maximum likelihood method. Given the posterior for a stylized learning problem of the previous section, one finds the parameters $\mathbf{\Theta}$ that maximizes the posterior $p(\mathbf{\Theta},M|\boldsymbol{D},C)$, which can be conveniently done without computing the marginal likelihood above, so

$$\widehat{\mathbf{\Theta}_{MP}} = \underset{\mathbf{\Theta}}{\text{armugmax}}\ \log\ p(\mathbf{\Theta},\boldsymbol{D}|M,C)$$

where the log probability can be broken down as a prior and a likelihood term

$$\log p(\mathbf{\Theta},\boldsymbol{D}|M,C) = \log p(\mathbf{\Theta}|M,C) + \log p(\boldsymbol{D}|\mathbf{\Theta},M,C).$$

The Laplace approximation: When the posterior is well behaved, and there is a large amount of data, the posterior is focused around a vanishing small region in parameter space of diameter $O(1/\sqrt{(N)})$. If this occurs away from the boundary of the parameter space, then one can make a second-order Taylor expansion of the log. posterior at the MAP point and the result is a Gaussian approximation to the posterior.

$$\log p(\boldsymbol{D},\mathbf{\Theta}|M,C) \approx \log p(\boldsymbol{D},\widehat{\mathbf{\Theta}_{MP}}|M,C) + \frac{1}{2}(\widehat{\mathbf{\Theta}_{MP}}-\mathbf{\Theta})^T \left.\frac{\mathrm{d}^2\log p(\boldsymbol{D},\mathbf{\Theta}|M,C)}{\mathrm{d}\mathbf{\Theta}\mathrm{d}\mathbf{\Theta}^T}\right|_{\mathbf{\Theta}=\widehat{\mathbf{\Theta}_{MP}}} (\widehat{\mathbf{\Theta}_{MP}}-\mathbf{\Theta}).$$

From this, one can approximate integrals such as the marginal likelihood $p(\boldsymbol{D}|M,C)$. This is known as the *Laplace approximation*, the name of the corresponding general method used for the asymptotic expansion of integrals. In general, this is a poor approximation, but it serves to aid our understanding of parameter estimation (MacKay 2003, Chaps. 27 and 28), and is the approximate basis for some model selection criteria.

Latent variable models: Latent variables are data that are hidden and thus never observed in the evidence. However, their existence is postulated as a significant component of the model. For instance, in ▶ Clustering (an unsupervised method) and finite mixture models generally, one assumes each data point has a hidden class label, thus the Bayesian model of clustering is a simple kind of latent variable model.

▶ *Markov chain Monte Carlo* methods: The most general form of reasoning and estimation available are the *Markov chain Monte Carlo* (MCMC) methods. The MCMC methods couple two processes: first, they use *Monte Carlo* or simulation methods to estimate the integral, and second they use a *Markov Chain* to sample, so sampling is sequentially (Markovian) based, and samples are not independent.

Simulation methods generally use the functional form of $p(\boldsymbol{\Theta}, \boldsymbol{D}|M, C)$ so we do not need to compute the marginal likelihood. Hence, given a set of I samples $\{\boldsymbol{\Theta}_1, \ldots, \boldsymbol{\Theta}_I\}$ the expected value is approximated with a weighted average

$$\bar{\boldsymbol{\Theta}} \approx \frac{1}{I}\sum_{i=1}^{I} w_i \boldsymbol{\Theta}_i .$$

The simplest case is where the samples are made independently according to the posterior itself and then the weights $w_i = 1$, This is called the ordinary Monte Carlo (OMC) method, but it is not often usable in practice because efficient multidimensional posterior samplers rarely exist. Alternatively, one can sample according to a Markov Chain, $\boldsymbol{\Theta}_{i+1} \sim q(\boldsymbol{\Theta}_{i+1}|\boldsymbol{\Theta}_i)$, so each $\boldsymbol{\Theta}_{i+1}$ is conditionally dependent on $\boldsymbol{\Theta}i$. So while samples are not independent, as long as the long run distribution of the Markov chain is the same as the posterior, the same approximation formula holds. There are a rich variety of MCMC methods, and this forms one of the key areas of current research.

Gibbs sampling: The simplest kind of MCMC method samples each dimension (or sub-vector) in turn. Suppose the parameter vector has K real components, $\boldsymbol{\Theta} = (\theta_1, \ldots, \theta_K)$. Sampling a complete $\boldsymbol{\Theta}$ in one go is not generally possible given just a functional form of the posterior $p(\boldsymbol{\Theta}|\boldsymbol{D}, M, C)$ but given no computable form for the normalizing constant. Gibbs sampling works in the one-dimensional case where normalizing bounds can be obtained and sampling tricks used. The conditional posterior of θ_k is given by

$$p(\theta_k|(\theta_1, \ldots, \theta_{k-1}, \theta_{k+1}, \ldots, \theta k), \boldsymbol{D}, M, C),$$

and this is usually easier to sample from.

The Gibbs (and MCMC) sample $\boldsymbol{\Theta}_{i+1}$ can be drawn given the previous sample $\boldsymbol{\Theta}_i$ by progressively resampling each dimension in turn and so slowly updating the full vector:

1. Sample $\theta_{i+1,1}$ according to $p(\theta_1|\theta_{i,2}, \ldots, \theta_{i,K}, \mathbf{D}, M, C)$. ...

k. Sample $\theta_{i+1,k}$ according to $p(\theta_2|\theta i_{+1,1}, \ldots, \theta_{i+1,k-1}, \theta_{i,k+1}, \ldots, \theta_{i,K}, \mathbf{D}, M, C)$.

...

k. Sample $\theta_{i+1,k}$ according to $p(\theta_K|\theta_{i+1,1}, \ldots, \theta_{i+1,K-1}, \mathbf{D}, M, C)$.

In samping terms, this method is no more successful than coordinate-wise ascent is as a primitive greedy search method: it is supported by theoretical results but can be very slow to converge.

Variational approximations: When the function you seek to optimize or average over presents difficulty, perhaps it is highly multimodal, then one option is to change the function itself, and replace it with a more readily approximated function. Variational methods provide a general principle for doing this safely. The general principle uses variational calculus, which is the calculus over functions, not just variables. Variational methods are a very general approach that can be used to develop a broad range of algorithms (Wainwright and Jordan 2008).

Nonparametric models: The above discussion implicitly assumed the model has a fixed finite parameter vector $\boldsymbol{\Theta}$. If one is attempting to model a regression function, or a language grammar, or image model of unknown a priori structural complexity, then one cannot know the dimension ahead of time. Moreover, as in the case of functions, the dimension cannot always be finite. The ▶ Bayesian Nonparametric Models address this situation, and are perhaps the most important family of techniques for general machine learning.

Recommended Reading

A good introduction to the problems of uncertainty and philosophical issues behind the Bayesian treatment of probability is in Lindley (2006). From the statistical machine learning perspective, a good introductory text is by MacKay (2003) who carefully covers information theory, probability, and inference but not so much statistical machine learning. Another alternative introduction to probabilities is the posthumously completed and published work of Jaynes (2003).

Discussions from the frequentist versus Bayesian battlefront can be found in works such as Rosenkrantz (1983), and in the approximate artificial intelligence versus probabilistic battlefront in discussion articles such as Cheeseman's (1988) and the many responses and rebuttals. It should be noted that it is the continued success in applications that have really led these methods into the mainstream, not the entertaining polemics.

Good mathematical statistics text books, such as Casella and Berger (2001) cover the breadth of statistical methods and therefore handle basic Bayesian theory. A more comprehensive treatment is given in Bayesian texts such as Gelman et al. (2003).

Most advanced statistical machine learning text books cover Bayesian methods, but to fully understand the subtleties of prior beliefs and Bayesian methodology one needs to view more advanced Bayesian literature. A detailed theoretical reference for Bayesian methods is Bernardo and Smith (1994).

Bayesian Network

Synonyms

Bayes net

Definition

A Bayesian network is a form of directed ▶ graphical model for representing multivariate probability distributions.

The nodes of the network represent a set of random variables, and the directed arcs represent causal relationships between variables. The *Markov property* is usually required: every direct dependency between a possible cause and a possible effect has to be shown with an arc. Bayesian networks with the Markov property are called *I-maps* (independence maps). If all arcs in the network correspond to a direct dependence on the system being modeled, then the network is said to be a *D-map* (dependence-map). Each node is associated with a conditional probability distribution, that quantifies the effects the parents of the node, if any, have on it. Bayesian support various forms of reasoning: *diagnosis*, to derive causes from symptoms, *prediction*, to derive effects from causes, and *intercausal reasoning*, to discover the mutual causes of a common effect.

Definition

A Bayesian nonparametric model is a Bayesian model on an infinite-dimensional parameter space. The parameter space is typically chosen as the set of all possible solutions for a given learning problem. For example, in a regression problem, the parameter space can be the set of continuous functions, and in a density estimation problem, the space can consist of all densities. A Bayesian nonparametric model uses only a finite subset of the available parameter dimensions to explain a finite sample of observations, with the set of dimensions chosen depending on the sample such that the effective complexity of the model (as measured by the number of dimensions used) adapts to the data. Classical adaptive problems, such as nonparametric estimation and model selection, can thus be formulated as Bayesian inference problems. Popular examples of Bayesian nonparametric models include Gaussian process regression, in which the correlation structure is refined with growing sample size, and Dirichlet process mixture models for clustering, which adapt the number of clusters to the complexity of the data. Bayesian nonparametric models have recently been applied to a variety of machine learning problems, including regression, classification, clustering, latent variable modeling, sequential modeling, image segmentation, source separation, and grammar induction.

Motivation and Background

Most of machine learning is concerned with learning an appropriate set of parameters within a model class from ▸ training data. The meta-level problems of determining appropriate model classes are referred to as model selection or model adaptation. These constitute important concerns for machine learning practitioners, not only for avoidance of over-fitting and under-fitting, but also for discovery of the causes and structures underlying data. Examples of model selection and adaptation include selecting the number of clusters in a clustering problem, the number of hidden states in a hidden Markov model, the number of latent variables in a latent variable model, or the complexity of features used in nonlinear regression.

Nonparametric models constitute an approach to model selection and adaptation where the sizes of models are allowed to grow with data size. This is as opposed to *parametric models*, which use a fixed number of parameters. For example, a parametric approach to density estimation would be to fit a Gaussian or a mixture of a fixed number of Gaussians by maximum likelihood. A nonparametric approach would be a Parzen window estimator, which centers a Gaussian at each observation (and hence uses one mean parameter per observation). Another example is the support vector machine with a Gaussian kernel. The representer theorem shows that the decision function is a linear combination of Gaussian radial basis functions centered at every input vector, and thus has a complexity that grows with more observations. Nonparametric methods have long been popular in classical (non-Bayesian) statistics (Wasserman 2006). They often perform impressively in applications and, though theoretical results for such models are typically harder to prove than for parametric models, appealing theoretical properties have been established for a wide range of models.

Bayesian nonparametric methods provide a Bayesian framework for model selection and adaptation using nonparametric models. A Bayesian formulation of nonparametric problems is nontrivial, since a Bayesian model defines prior and posterior distributions on a single fixed parameter space, but the dimension of the parameter space in a nonparametric approach should change with sample size. The Bayesian nonparametric solution to this problem is to use an infinite-dimensional parameter space, and to invoke only a finite subset of the available parameters on any given finite data set. This subset generally grows with the data set. In the context of Bayesian nonparametric models, "infinite-dimensional" can therefore be interpreted as "of finite but unbounded dimension." More precisely, a Bayesian nonparametric model is a model that (1) constitutes a Bayesian model on an infinite-dimensional parameter space and (2) can be evaluated on a finite sample in a manner that uses only a finite subset of the available parameters to explain the sample.

We make the above description more concrete in the next section when we describe a number of standard machine learning problems and the corresponding Bayesian nonparametric solutions. As we will see, the parameter space in (1) typically consists of functions or of measures, while (2) is usually achieved by marginalizing out surplus dimensions over the prior. Random functions and measures and, more generally, probability distributions on infinite-dimensional random objects are called *stochastic processes*; examples that we will encounter include Gaussian processes, Dirichlet processes, and beta processes. Bayesian nonparametric models are often named after the stochastic processes they contain. The examples are then followed by theoretical considerations, including formal constructions and representations of the stochastic processes used in Bayesian nonparametric models, exchangeability, and issues of consistency and convergence rate. We conclude this chapter with future directions and a list of literature available for reading.

Examples

Clustering with mixture models. Bayesian nonparametric generalizations of finite mixture models provide an approach for estimating both the number of components in a mixture model and the parameters of the individual mixture components simultaneously from data. Finite mixture models define a density function over data items x of the form $p(x) = \sum_{k=1}^{K} \pi_k p(x|\theta_k)$, where π_k is the mixing proportion and θ_k are parameters associated with component k. The density can be written in a non-standard manner as an integral: $p(x) = \int p(x|\theta)G(\theta)d\theta$, where $G = \sum_{k=1}^{K} \pi_k \delta_{\theta_k}$ is a discrete mixing distribution encapsulating all the parameters of the mixture model and δ_θ is a dirac distribution (atom) centered at θ. Bayesian nonparametric mixtures use mixing distributions consisting of a *countably infinite* number of atoms instead:

$$G = \sum_{k=1}^{\infty} \pi_k \delta_{\theta_k}. \quad (1)$$

This gives rise to mixture models with an infinite number of components. When applied to a finite training set, only a finite (but varying) number of components will be used to model the data, since each data item is associated with exactly one component but each component can be associated with multiple data items. Inference in the model then automatically recovers both the number of components to use and the parameters of the components. Being Bayesian, we need a prior over the mixing distribution G, and the most common prior to use is a *Dirichlet process* (DP). The resulting mixture model is called a DP mixture.

Formally, a Dirichlet process $DP(\alpha, H)$ parametrized by a concentration paramter $\alpha > 0$ and a base distribution H is a prior over distributions (probability measures) G such that, for any finite partition $A_1, \ldots, A_m$ of the parameter space, the induced random vector $(G(A_1), \ldots, G(A_m))$ is Dirichlet distributed with parameters $(\alpha H(A_1), \ldots, \alpha H(A_m))$ (see entitled Section "Theory" for a discussion of subtleties involved in this definition). It can be shown that draws from a DP will be discrete distributions as given in (1). The DP also induces a distribution over partitions of integers called the *Chinese restaurant process* (CRP), which directly describes the prior over how data items are clustered under the DP mixture. For more details on the DP and the CRP, see ▸ Dirichlet Process.

Nonlinear regression. The aim of regression is to infer a continuous function from a training set consisting of input–output pairs $\{(t_i, x_i)\}i_{=1}^{n}$. Parametric approaches parametrize the function using a finite number of parameters and attempt to infer these parameters from data. The prototypical Bayesian nonparametric approach to this problem is to define a prior distribution over continuous functions directly by means of a *Gaussian process* (GP). As explained in the Chapter ▸ Gaussian Process, a GP is a distribution on an infinite collection of random variables X_t, such that the joint distribution of each finite subset $X_{t_1}, \ldots, X_{t_m}$ is a multivariate Gaussian. A value x_t taken by the variable X_t can be regarded as the value of a continuous function f at t, that is, $f(t) = x_t$. Given the training set, the Gaussian process posterior is again a distribution on functions, conditional on these functions taking values $f(t_1) = x_1, \ldots, f(t_n) = x_n$.

Latent feature models. These models represent a set of objects in terms of a set of latent features, each of which represents an independent degree of variation exhibited by the data. Such a representation of data is sometimes referred to as a distributed representation. In analogy to nonparametric mixture models with an unknown number of clusters, a Bayesian nonparametric approach to latent feature modeling allows for an unknown number of latent features. The stochastic processes involved here are known as the *Indian buffet process* (IBP) and the *beta process* (BP). Draws from BPs are random discrete measures, where each of an infinite number of atoms has a mass in (0, 1) but the masses of atoms need not sum to 1. Each atom corresponds to a feature, with the mass corresponding to the probability that the feature is present for an object. We can visualize the occurrences of features among objects using a binary matrix, where the (i, k) entry is 1 if object i has feature k and 0 otherwise. The distribution over binary matrices induced by the BP is called the IBP.

▸ *Hidden Markov Models* (*HMMs*). HMMs are popular models for sequential or temporal data, where each time step is associated with a state, with state transitions dependent on the previous state. An *infinite HMM* is a Bayesian nonparametric approach to HMMs, where the number of states is unbounded and allowed to grow with the sequence length. It is defined using one DP prior for the transition probabilities going out from each state. To ensure that the set of states reachable from each outgoing state is the same, the base distributions of the DPs are shared and given a DP prior recursively. The construction is called a *hierarchical Dirichlet process* (HDP); see below.

▸ *Density Estimation*. A nonparametric Bayesian approach to density estimation requires a prior on densities or distributions. However, the DP is not useful in this context, since it generates discrete distributions. A useful density estimator should smooth the empirical density (such as a Parzen window estimator), which requires a prior that can generate smooth distributions. Priors applicable in density estimation problems include DP mixture models and Pólya trees.

If $p(x|\theta)$ is a smooth density function, the density $\sum_{k=1}^{\infty} \pi_k p(x|\theta_k)$ induced by a DP mixture model is a smooth random density, such that DP mixtures can be used as prior in density estimation problems.

Pólya trees are priors on probability distributions that can generate both discrete and piecewise continuous distributions, depending on the choice of parameters. Pólya trees are defined by a recursive infinitely deep binary subdivision of the domain of the generated random measure. Each subdivision is associated with a beta random variable which describes the relative amount of mass on each side of the subdivision. The DP is a special case of a Pólya tree corresponding to a particular parametrization. For other parametrizations the resulting random distribution can be smooth, so it is suitable for density estimation.

Power-law Phenomena. Many naturally occurring phenomena exhibit power-law behavior. Examples include natural languages, images, and social and genetic networks. An interesting generalization of the DP, called the *Pitman-Yor process*, PYP(α, d, H), has recently been successfully used to model power-law data. The Pitman-Yor process augments the DP by a third parameter $d \in [0, 1)$. When $d = 0$ the PYP is a $DP(\alpha, H)$, while when $\alpha = 0$ it is a so called *normalized stable process*.

Sequential modeling. HMMs model sequential data using latent variables representing the underlying state of the system, and assuming that each state only depends on the previous state (the so called Markov property). In some applications, for example language modeling and text compression, we are interested in directly modeling sequences without using latent variables, and without making any Markov assumptions, i.e., modeling each observation conditional on all previous observations in the sequence. Since the set of potential sequences of previous observations is unbounded, this calls for nonparametric models. A *hierarchical Pitman-Yor process* can be used to construct a Bayesian nonparametric solution whereby the conditional probabilities are coupled hierarchically.

Dependent and hierarchical models. Most of the Bayesian nonparametric models described so far are applied in settings where observations are homogeneous or exchangeable. In many real world settings observations are not homogeneous, and in fact are often structured in interesting ways. For example, the data generating process might change over time thus observations at different times are not exchangeable, or observations might come in distinct groups with those in the same group being more similar than across groups.

Significant recent efforts in Bayesian nonparametrics research have been placed in developing extensions that can handle these non-homogeneous settings. Dependent Dirichlet processes are stochastic processes, typically over a spatial or temporal domain, which define a Dirichlet process (or a related random measure) at each point with neighboring DPs being more dependent. These are used for spatial modeling, nonparametric regression, as well as for modeling temporal changes. Alternatively, hierarchical Bayesian nonparametric models like the hierarchical DP aim to couple multiple Bayesian nonparametric models within a hierarchical Bayesian framework. The idea is to allow sharing of statistical strength across multiple groups of observations. Among other applications, these have been used in the infinite HMM, topic modeling, language modeling, word segmentation, image segmentation, and grammar induction. For an overview of various dependent Bayesian nonparametric models and their applications in biostatistics please refer to Dunson (2010). Teh and Jordan (2010) is an overview of hierarchical Bayesian nonparametric models as well as a variety of applications in machine learning.

Theory

As we saw in the preceding examples, Bayesian nonparametric models often make use of priors over functions and measures. Because these spaces typically have uncountable number of dimensions, extra care has to be taken to define the priors properly and to study the asymptotic properties of estimation in the resulting models. In this section we give an overview of the basic concepts involved in the theory of Bayesian nonparametric models. We start with a discussion of the importance of exchangeability in Bayesian parametric and nonparametric statistics. This is followed by representations of the priors and issues of convergence.

Exchangeability

The underlying assumption of all Bayesian methods is that the parameter specifying the observation model is a random variable. This assumption is subject to much criticism, and at the heart of the Bayesian versus non-Bayesian debate that has long divided the statistics community. However, there is a very general type of observation for which the existence of such a random variable can be derived mathematically: For so-called *exchangeable* observations, the Bayesian assumption that a randomly distributed parameter exists is not a modeling assumption, but a mathematical consequence of the data's properties.

Formally, a sequence of variables X_1, $X_2, \ldots, X_n$ over the same probability space (χ, Ω) is *exchangeable* if their joint distribution is invariant to permuting the variables. That is, if P is the joint distribution and σ any permutation of $\{1, \ldots, n\}$, then

$$P(X_1 = x_1, X_2 = x_2 \ldots X_n = x_n) \\ = P(X_1 = x_{\sigma(1)}, X_2 = x_{\sigma(2)} \ldots X_n = x_{\sigma(n)}). \tag{2}$$

An infinite sequence X_1, X_2, ...is *infinitely exchangeable* if X_1, ..., X_n is exchangeable for *everyn* $\geqslant$ 1. In this chapter, we mean infinite exchangeability whenever we write exchangeability. Exchangeability reflects the assumption that the variables do not depend on their indices although they may be dependent among themselves. This is typically a reasonable assumption in machine learning and statistical applications, even if the variables are not themselves independently and identically distributed (iid).

Exchangeability is a much weaker assumption than iid since iid variables are automatically exchangeable.

If θ parametrizes the underlying distribution, and one assumes a prior distribution over θ, then the resulting marginal distribution over X_1, X_2,...with θ marginalized out will still be exchangeable. A fundamental result credited to de Finetti (1931) states that the converse is also true. That is, if X_1, X_2, ...is (infinitely) exchangeable, then there is a random θ such that:

$$P(X_1, \ldots, X_n) = \int P(\theta) \prod_{i=1}^{n} P(X_i|\theta) d\theta \tag{3}$$

for every $n \geqslant 1$. In other words, the seemingly innocuous assumption of exchangeability automatically implies the existence of a hierarchical Bayesian model with θ being the random latent parameter. This the crux of the fundamental importance of exchangeability to Bayesian statistics.

In de Finetti's Theorem it is important to stress that θ can be infinite dimensional (it is typically a random measure), thus the hierarchical Bayesian model (3) is typically a nonparametric one. For an example, the Blackwell–MacQueen urn scheme (related to the CRP) is exchangeable and thus implicitly defines a random measure, namely the DP (see ▸ Dirichlet Processes for more details). In this sense, we will see below that de Finetti's theorem is an alternative route to Kolmogorov's extension theorem, which implicitly defines the stochastic processes underlying Bayesian nonparametric models.

Model Representations

In finite dimensions, a probability model is usually defined by a density function or probability mass function. In infinite dimensional spaces, this approach is not generally feasible, for reasons explained below. To define or work with a Bayesian nonparametric model, we have to choose alternative mathematical representations.

Weak distributions. A weak distribution is a representation for the distribution of a stochastic process, that is, for a probability distribution on an infinite-dimensional sample space. If we assume that the dimensions of the space are indexed by $t \in T$, the stochastic process can be regarded as the joint distribution P of an infinite set of random variables $\{Xt\}_{t \in T}$. For any finite subset $S \subset T$ of dimensions, the joint distribution P_S of the corresponding subset $\{X_t\}_{t \in S}$ of random variables is a finite-dimensional marginal of P. The *weak distribution* of a stochastic process is the set of all its finite-dimensional marginals, that is, the set $\{P_S : S \subset T, |S| < \infty\}$. For example, the customary definition of the Gaussian process as an infinite collection of random variables, each finite subset of which has a joint Gaussian distribution, is an example of a weak distribution representation. In contrast to the explicit representations to be described below, this representation is generally not generative, because it represents the distribution rather than a random draw, but is more widely applicable.

Apparently, just defining a weak distribution in this manner need not imply that it is a valid representation of a stochastic process. A given collection of finite-dimensional distributions represents a stochastic process only (1) if a process with these distributions as its marginals actually exists, and (2) if it is uniquely defined by the marginals. The mathematical result which guarantees that weak distribution representations are valid is the *Kolmogorov extension theorem* (also known as the Daniell–Kolmogorov theorem or the Kolmogorov consistency theorem). Suppose that a collection $\{P_S : S \subset T, |S| < \infty\}$ of distributions is given. If all distributions in the collection are marginals of each other, that is, if P_{s_1} is a marginal of P_{s_2} whenever $S_1 \subset S_2$, the set of distributions is called a *projective family*. The Kolmogorov extension theorem states that, if the set T is countable, and if the distributions P_S form a projective family, then there exists a uniquely defined stochastic process with the collection $\{P_S\}$ as its marginal distributions. In other words, any projective family for a countable set T of dimensions is the weak distribution of a stochastic process. Conversely, any stochastic process can be represented in this manner, by computing its set of finite-dimensional marginals.

The weak distribution representation assumes that all individual random variable X_t of the stochastic process take values in the same sample space Ω. The stochastic process P defined by the weak distribution is then a probability distribution on the sample space Ω^T, which can be interpreted as the set of all functions $f : T \to \Omega$. For example, to construct a GP we might choose $T = \mathbb{Q}$ and $\Omega = \mathbb{R}$ to obtain real-valued functions on the countable space of rational numbers. Since $\mathbb{Q}$ is dense in $\mathbb{R}$, the function f can then be extended to all of $\mathbb{R}$ by continuity. To define the DP as a distribution over probability measures on $\mathbb{R}$, we note that a probability measure is a set function that maps "random events," i.e., elements of the Borel σ-algebra $\mathcal{B}(\mathbb{R})$ of $\mathbb{R}$, into probabilities in [0, 1]. We could therefore choose a weak distribution consisting of Dirichlet distributions, and set $T = \mathcal{B}(\mathbb{R})$ and $\Omega = [0, 1]$. However, this approach raises a new problem because the set $\mathcal{B}(\mathbb{R})$ is not countable. As in the GP, we can first define the DP on a countable "base" for $\mathcal{B}(\mathbb{R})$ then extend to all random events by continuity of measures. More precise descriptions are unfortunately beyond the scope of this chapter.

Explicit representations. Explicit representations directly describe a random draw from a stochastic process, rather than its distribution. A prominent example of an explicit representation is the so-called *stick-breaking representation* of the Dirichlet process. The discrete random measure G in (1) is completely determined by the two infinite sequences $\{\pi_k\}_{k\in\mathbb{N}}$ and $\{\theta_k\}_{k\in\mathbb{N}}$. The stick-breaking representation of the DP generates these two sequences by drawing $\theta k \sim H$ iid and $v_k \sim Beta(1, \alpha)$ for $k = 1, 2, \ldots$. The coefficients πk are then computed as $\pi_k = v_k \prod_{j=1}^{k-1}(1 - v_k)$. The measure G so obtained can be shown to be distributed according to a $DP(\alpha, G_0)$. Similar representations can be derived for the Pitman–Yor process and the beta process as well. Explicit representations, if they exist for a given model, are typically of great practical importance for the derivation of algorithms.

Implicit Representations. A third representation of infinite dimensional models is based on de Finetti's Theorem. Any exchangeable sequence $X_1, \ldots, X_n$ uniquely defines a stochastic process θ, called the de Finetti measure, making the X_i's iid. If the X_i's are sufficient to define the rest of the model and their conditional distributions are easily specified, then it is sufficient to work directly with the X_i's and have the underlying stochastic process implicitly defined. Examples include the Chinese restaurant process (an exchangeable distribution over partitions) with the DP as the de Finetti measure, and the Indian buffet process (an exchangeable distribution over binary matrices) with the BP being the corresponding de Finetti measure. These implicit representations are useful in practice as they can lead to simple and efficient inference algorithms.

Finite representations. A fourth representation of Bayesian nonparametric models is as the infinite limit of finite (parametric) Bayesian models. For example, DP mixtures can be derived as the infinite limit of finite mixture models with particular Dirichlet priors on mixing proportions, GPs can be derived as the infinite limit of particular Bayesian regression models with Gaussian priors, while BPs can be derived as from the limit of an infinite number of independent beta variables. These representations are sometimes more intuitive for practitioners familiar with parametric models. However, not all Bayesian nonparametric models can be expressed in this fashion, and they do not necessarily make clear the mathematical subtleties involved.

Consistency and Convergence Rates

A recent series of works in mathematical statistics examines the convergence properties of Bayesian nonparametric models, and in particular the questions of *consistency* and *convergence rates*. In this context, a Bayesian model is called consistent if, given that an infinite amount of data is available, the model posterior will concentrate in a neighborhood of the true solution (e.g., true function or density). A rate of convergence specifies, for a finite sample, how rapidly the posterior concentrates depending on the sample size. In their pioneering article Diaconis and Freedman (1986) showed, to the great surprise of much of the Bayesian community, that models such as the Dirichlet process can be inconsistent, and may converge to arbitrary solutions even for an infinite amount of data.

More recent results, notably by van der Vaart and Ghosal, apply modern methods of mathematical statistics to study the convergence properties of Bayesian nonparametric models (see e.g., Gho (2010) and references therein). Consistency has been shown for a number of models, including Gaussian processes and Dirichlet process mixtures. However, a particularly interesting aspect of this line of work are results on convergence rates, which specify the rate of concentration of the posterior depending on sample size, on the complexity of the model, and on how much probability mass the prior places around the true solution. To make such results quantitative requires a measure for the complexity of a Bayesian nonparametric model. This is done by means of complexity measures developed in empirical process theory and statistical learning theory, such as metric entropies, covering numbers and bracketing, some of which are well-known in theoretical machine learning.

Inference

There are two aspects to inference from Bayesian nonparametric models: the analytic tractability of posteriors for the stochastic processes embedded in Bayesian nonparametric models, and practical inference algorithms for the overall models. Bayesian nonparametric models typically include stochastic processes such as the Gaussian process and the Dirichlet process. These processes have an infinite number of dimensions, hence naïve algorithmic approaches to computing posteriors are generally infeasible. Fortunately, these processes typically have analytically tractable posteriors, so all but finitely many of the dimensions can be analytically integrated out efficiently. The remaining dimensions, along with the parametric parts of the models, can then be handled by the usual inference techniques employed in parametric Bayesian modeling, including Markov chain Monte Carlo, sequential Monte Carlo, variational inference, and message-passing algorithms like expectation propagation. The precise choice of approximations to use will depend on the specific models under consideration, with speed/accuracy trade-offs between different techniques generally following those for parametric models. In the following, we will give two examples to illustrate the above points, and discuss a few theoretical issues associated with the analytic tractability of stochastic processes.

Examples

In Gaussian process regression, we model the relationship between an input x and an output y using a function f, so that $y \sim f(x) + \varepsilon$, where ε is iid Gaussian noise. Given a GP prior over f and a finite training data set $\{(x_i, y_i)\}_{i=1}^{n}$ we wish to compute the posterior over f. Here we can use the weak representation of f and note that $\{f(xi)\}_{i=1}^{n}$ is simply a finite-dimensional Gaussian with mean and covariance given by the mean and covariance functions of the GP. Inference for $\{f(x_i)\}_{i=1}^{n}$ is then straightforward. The approach can be thought of equivalently as marginalizing out the whole function except its values on the training inputs. Note that although we only have the posterior over $\{f(x_i)\}_{i=1}^{n}$, this is sufficient to reconstruct the function evaluated at any other point x_0 (say the test input), since $f(x_0)$ is Gaussian and independent of the training data $\{(x_i, y_i)\}_{i=1}^{n}$ given $\{f(x_i)\}_{i=1}^{n}$. In GP regression the posterior over $\{f(x_i)\}_{i=1}^{n}$ can be computed exactly. In GP classification or other regression settings with nonlinear likelihood functions, the typical approach is to use sparse methods based on variational approximations or expectation propagation; see Chapter ▶ Gaussian Process for details.

Our second example involves Dirichlet process mixture models. Recall that the DP induces a clustering structure on the data items. If our training set consists of n data items, since each item can only belong to one cluster, there are at most n clusters represented in the training set. Even though the DP mixture itself has an infinite number of potential clusters, all but finitely many of these are not associated with data, thus the associated variables need not be explicitly represented at all. This can be understood either as marginalizing out these variables, or as an implicit representation which can be made explicit whenever required by sampling from the prior. This idea is applicable for DP mixtures using both the Chinese restaurant process and the stick-breaking representations. In the CRP representation, each data item x_i is associated with a cluster index z_i, and each cluster k with a parameter θ_k^* (these parameters can be marginalized out if H is conjugate to F), and these are the only latent variables that need be represented in memory. In the stick-breaking representation, clusters are ordered by decreasing prior expected size, with cluster k associated with a parameter θ_k^* and a size π_k. Each data item is again associated with a cluster index z_i, and only the clusters up to $K = \max(z_1, \ldots, zn)$ need to be represented. All clusters with index $> K$ need not be represented since their posterior conditioning on $\{(x_i, z_i)\}_{i=1}^{n}$ is just the prior.

On Bayes Equations and Conjugacy

It is worth noting that the posterior of a Bayesian model is, in abstract terms, defined as the conditional distribution of the parameter given the data and the hyperparameters, and this definition does not require the existence of a Bayes equation. If a Bayes equation exists for the model, the posterior can equivalently be defined as the left-hand side of the Bayes equation. However, for some stochastic processes, notably the DP on an uncountable space such as $\mathbb{R}$, it is not possible to define a Bayes equation even though the posterior is still a well-defined mathematical object. Technically speaking, existence of a Bayes equation requires the family of all possible posteriors to be dominated by the prior, but this is not the case for the DP. That posteriors of these stochastic processes can be evaluated at all is solely due to the fact that they admit an analytic representation.

The particular form of tractability exhibited by many stochastic processes in the literature is that of a *conjugate* posterior, that is, the posterior belongs to the same model family as the prior, and the posterior parameters can be computed as a function of the prior hyperparameters and the observed data. For example, the posterior of a $DP(\alpha, G_0)$ under observations $\theta_1, \ldots, \theta n$ is again a Dirichlet process, $DP(\alpha + n, \frac{1}{\alpha+n}(\alpha G_0 + \sum \delta_{\theta_i}))$. Similarly the posterior of a GP under observations of $f(x_1), \ldots, f(x_n)$ is still a GP. It is this conjugacy that allows practical inference in the examples above. A Bayesian nonparametric model is conjugate if and only if the elements of its weak distribution, i.e., its finite-dimensional marginals, have a conjugate structure as well (Orbanz 2010). In particular, this characterizes a class of conjugate Bayesian nonparametric models whose weak distributions consist of exponential family models. Note however, that lack of conjugacy does not imply intractable posteriors. An example is given by the Pitman–Yor process in which the posterior is given by a sum of a finite number of atoms and a Pitman-Yor process independent from the atoms.

Future Directions

Since MCMC (see ▸ Markov Chain Monte Carlo) sampling algorithms for Dirichlet process mixtures became available in the 1990s and made latent variable models with nonparametric Bayesian components applicable to practical problems, the development of Bayesian nonparametrics has experienced explosive growth (Escobar and West 1995; Neal 2000). Arguably, though, the results available so far have only scratched the surface. The repertoire of available models is still mostly limited to using the Gaussian process, the Dirichlet process, the beta process, and generalizations derived from those. In principle, Bayesian nonparametric models may be defined on any infinite-dimensional mathematical object of possible interest to machine learning and statistics. Possible examples are kernels, infinite graphs, special classes of functions (e.g., piece-wise continuous or Sobolev functions), and permutations.

Aside from the obvious modeling questions, two major future directions are to make Bayesian nonparametric methods available to a larger audience of researchers and practitioners through the development of software packages, and to understand and quantify the theoretical properties of available methods.

General-Purpose Software Package

There is currently significant growth in the application of Bayesian nonparametric models across a variety of application domains both in machine learning and in statistics. However significant hurdles still exist, especially the expense and expertise needed to develop computer programs for inference in these complex models. One future direction is thus the development of software packages that can compile efficient inference algorithms automatically given model specifications, thus allowing a much wider range of modeler to make use of these models. Current developments include the R DPpackage (http://cran.r-project.org/web/packages/DPpackage), the hierarchical Bayesian compiler (http://www.cs.utah.edu/hal/HBC), adaptor grammars (http://www.cog.brown.edu/mj/Software.htm), the MIT-Church project (http://projects.csail.mit.edu/church/wiki/Church), as well as efforts to add Bayesian nonparametric models to the repertoire of current Bayesian modeling environments like OpenBugs (http://mathstat.helsinki.fi/openbugs) and infer.NET (http://research.microsoft.com/en-us/um/cambridge/projects/infernet).

Statistical Properties of Models

Recent work in mathematical statistics provides some insight into the quantitative behavior of Bayesian nonparametric models (cf theory section). The elegant, methodical approach underlying these results, which quantifies model complexity by means of empirical process theory and then derives convergence rates as a function of the complexity, should be applicable to a wide range of models. So far, however, only results for Gaussian processes and Dirichlet process mixtures have been proven, and it will be of great interest to establish properties for other priors. Some models developed in machine learning, such as the infinite HMM, may pose new challenges to theoretical methodology, since their study will probably have to draw on both the theory of algorithms and mathematical statistics. Once a wider range of results is available, they may in turn serve to guide the development of new models, if it is possible to establish how different methods of model construction affect the statistical properties of the constructed model.

In addition to the references embedded in the text above, we recommend the books Hjort et al. (2010) and Ghosh and Ramamoorthi (2002), and the review articles Walker et al. (1999) and Müller and Quintana (2004) on Bayesian nonparametrics. Further references can be found in the chapter by they Teh and Jordan (2010) of the book Hjort et al. (2010).

Definition

Bayesian reinforcement learning refers to ▸ reinforcement learning modeled as a Bayesian learning problem (see ▸ Bayesian Methods). More specifically, following Bayesian learning theory, reinforcement learning is performed by computing a posterior distribution on the unknowns (e.g., any combination of the transition probabilities, reward probabilities, value function, value gradient, or policy) based on the evidence received (e.g., history of past state–action pairs).

Motivation and Background

Bayesian reinforcement learning can be traced back to the 1950s and 1960s in the work of Bellman (1961), Fel'Dbaum (1965), and several of Howard's students (Martin 1967). Shortly after ▸ Markov decision processes were formalized, the above researchers (and several others) in Operations Research considered the problem of controlling a Markov process with uncertain transition and reward probabilities, which is equivalent to reinforcement learning. They considered Bayesian techniques since Bayesian learning is performed by probabilistic inference, which naturally combines with decision theory. In general, Bayesian reinforcement learning distinguishes itself from other reinforcement learning approaches by the use of probability distributions (instead of point estimates) to fully capture the uncertainty. This enables the learner to make more informed decisions, with the potential of learning faster with less data. In particular, the exploration/exploitation tradeoff can be naturally optimized. The use of a prior distribution also facilitates the encoding of domain knowledge, which is exploited in a natural and principled way by the learning process.

Structure of Learning Approach

A Markov decision process (MDP) (Puterman 1994) can be formalized by a tuple $\langle S, A, T \rangle$

where S is the set of states s, A is the set of actions a, $T(s,\ a,\ s') = \Pr(s'|s, a)$ is the transition distribution indicating the probability of reaching s' when executing a in s. Let s_r denote the reward feature of a state and $\Pr(s'_r|s, a)$ be the probability of earning r when executing a in s. A policy $\pi : S \rightarrow A$ consists of a mapping from states to actions. For a given discount factor $0 \leq \gamma \leq 1$ and horizon h, the value V^{π} of a policy π is the expected discounted total reward earned while executing this policy: $V^{\pi}(s) = \sum_{t=o}^{h} \gamma^t E_{s|\pi}[s_r^t]$. The value function V^{π} can be written in a recursive form as the expected sum of the immediate reward s'_r with the discounted future rewards: $V^{\pi}(s) = \sum_{s'} \Pr(s'|s, \pi(s))[s'_r + \gamma V \pi(s')]$. The goal is to find an optimal policy π^*, that is, a policy with the highest value V^* in all states (i.e., $V^*(s) \geq V^{\pi}(s) \forall \pi, s$). Many algorithms exploit the fact that the optimal value function V^* satisfies Bellman's equation:

$$V^*(s) = \max_a \sum_{s'} \Pr(s'|s, a)[s'_r + \gamma V^*(s)] \quad (1)$$

Reinforcement learning (Sutton and Barto 1998) is concerned with the problem of finding an optimal policy when the transition (and reward) probabilities T are unknown (or uncertain). Bayesian learning is a learning approach in which unknowns are modeled as random variables X over which distributions encode the uncertainty. The process of learning consists of updating the prior distribution $\Pr(X)$ based on some evidence e to obtain a posterior distribution $\Pr(X|e)$ according to Bayes theorem: $\Pr(X|e) = k\Pr(X)\Pr(e|X)$. (Here $k = 1/\Pr(e)$ is a normalization constant.) Hence, *Bayesian reinforcement learning* consists of using Bayesian learning for reinforcement learning. The unknowns are the transition (and reward) probabilities T, the optimal value function V^*, and the optimal policy π^*. Techniques that maintain a distribution on T are known as *model-based* Bayesian reinforcement learning since they explicitly learn the underlying model T. In contrast, techniques that maintain a distribution on V^* or π^* are known as *model-free* Bayesian reinforcement learning since they directly learn the optimal value function or policy without learning a model.

Model-Based Bayesian Learning

In model-based Bayesian reinforcement learning, the learner starts with a prior distribution over the parameters of T, which we denote by θ. For instance, let $\theta_{sas'} = \Pr(s'|s,\ a,\ \theta)$ be the unknown probability of reaching s$'$ when executing a in s. In general, we denote by θ the set of all $\theta_{sas'}$. Then, the prior $b(\theta)$ represents the initial *belief* of the learner regarding the underlying model. The learner updates its belief after every s, a, s' triple observed by computing a posterior $b_{sas'}(\theta) = b(\theta|s, a, s')$ according to Bayes theorem:

$$b_{sas'}(\theta) = kb(\theta) \Pr(s'|s, a, \theta) = kb(\theta)\theta_{sas'}. \quad (2)$$

In order to facilitate belief updates, it is convenient to pick the prior from a family of distributions that is closed under Bayes updates. This ensures that beliefs are always parameterized in the same way. Such families are called *conjugate priors*. In the case of a discrete model (i.e., $\Pr(s'|s, a, \theta)$ is a discrete distribution), Dirichlets are conjugate priors and form a family of distributions corresponding to monomials over the simplex of discrete distributions (DeGroot 1970). They are parameterized as follows: $Dir(\theta; n) = k \prod_i \theta_i^{n_i - 1}$. Here θ is an unknown discrete distribution such that $\sum_i \theta_i = 1$ and n is a vector of strictly positive real numbers n_i (known as the hyperparameters) such that $n_i - 1$ can be interpreted as the number of times that the θ_i-probability event has been observed. Since the unknown transition model θ is made up of one unknown distribution θ_a^s per s, a pair, let the prior be $b(\theta) = \prod_{s,a} Dir\ (\theta_a^s;\ n_a^s)$ such that n_a^s is a vector of hyperparameters $n_a^{s,s'}$. The posterior obtained after transition $\hat{s}, \hat{a}, \hat{s}'$ is

$$\begin{aligned} b_a^{s,s'}(\theta) &= k\theta_a^{s,s'} \prod_{s,a} Dir(\theta_a^s; n_a^s) \\ &= \prod_{s,a} Dir(\theta_a^s; n_a^s + \delta_{\hat{s},\hat{a},\hat{s}'}(s, a, s')) \end{aligned} \quad (3)$$

where $\delta_{\hat{s},\hat{a},\hat{s}'}(s, a, s')$ is a Kronecker delta that returns 1 when $s = \hat{s}, a = \hat{a}, s' = \hat{s}'$ and 0 otherwise. In practice, belief monitoring is as simple as incrementing the hyperparameter corresponding to the observed transition.

Belief MDP Equivalence

At any point in time, the belief b provides an explicit representation of the uncertainty of the learner about the underlying model. This information is very useful to decide whether future actions should focus on exploring or exploiting. Hence, in Bayesian reinforcement learning, policies π are mappings from state-belief pairs $\langle s, b \rangle$ to actions. Equivalently, the problem of Bayesian reinforcement learning can be thought as one of planning with a belief MDP (or a partially observable MDP). More precisely, every Bayesian reinforcement learning problem has an equivalent belief MDP formulation $\langle S_{bel},\ A_{bel},\ T_{bel} \rangle$ where $S_{bel} = S \times B$ (B is the space of beliefs b), $A_{bel} = A$, and $T_{bel}(s_{bel}, a_{bel}, b'_{bel}) = \Pr(b'_{bel} | b_{bel}, a_{bel}) = \Pr(s', b' | s, b, a) = \Pr(b' | s, b, a, s')\Pr(s' | s, b, a)$. The decomposition of the transition dynamics is particularly interesting since $\Pr(b' | s,\ b,\ a,\ s')$ equals 1 when $b' = b_a^{s,s'}$ (as defined in Eq. 3) and 0 otherwise. Furthermore, $\Pr(s' | s,\ b,\ a) = \int_\theta b(\theta) \Pr(s' | s, \theta, a) d\theta$, which can be computed in closed form when b is a Dirichlet. As a result, the transition dynamics of the belief MDP are fully known. This is a remarkable fact since it means that Bayesian reinforcement learning problems, which by definition have unknown/uncertain transition dynamics, can be recast as belief MDPs with known transition dynamics. While this doesn't make the problem any easier since the belief MDP has a hybrid state space (discrete s with continuous b), it allows us to treat policy optimization as a problem of planning and in particular to adapt algorithms originally designed for belief MDPs (also known as partially observable MDPs).

Optimal Value Function Parameterization

Many planning techniques compute the optimal value function V^*, from which an optimal policy π^* can easily be extracted. Despite the hybrid nature of the state space, the optimal value function (for a finite horizon) has a simple parameterization corresponding to the upper envelope of a set of polynomials (Poupart et al. 2006). Recall that the optimal value function satisfies Bellman's equation, which can be adapted as follows for a belief MDP:

$$V^*(s, b) = \max_a \sum_{s'} \Pr(s', b' | s, b, a)$$

$$[s'_r + \gamma V^*(s', b')]. \tag{4}$$

Using the fact that b' must be $b_a^{s,s'}$ (otherwise $\Pr(s',\ b' | s, b, a) = 0$) allows us to rewrite Bellman's equation as follows:

$$V^*(s, b) = \max_a \sum_{s'} \Pr(s' | s, b, a)$$

$$[s'_r + \gamma V^*(s', b_a^{s,s'})] \tag{5}$$

Let Γ^n be a set of polynomials in θ such that the optimal value function V^n with n steps to go is $V^n(s, b) = \int_\theta b(\theta) poly_{s,b}(\theta) d\theta$ where $poly_{s,b} = \operatorname{argmax}_{poly \in \Gamma_s^n} \int_\theta b(\theta) poly(\theta) d\theta$. It suffices to replace $\Pr(s' | s,\ b, a), b_a^{s,s'}$ and V^n by their definitions in Bellman's equation

$$V^{n+1}(s, b) = \max_a \sum_{s'} \int_\theta b(\theta) \Pr(s' | s, \theta, a)$$

$$[r'_s + \gamma poly_{s', b_a^{s,s'}}(\theta)] d\theta \tag{6}$$

$$= \max_a \int_\theta b(\theta) \sum_{s'} \theta_a^{s,s'}$$

$$[r'_s + \gamma poly_{s', b_a^{s,s'}}(\theta)] d\theta \tag{7}$$

to obtain a similar set of polynomials $\Gamma_s^{n+1} = \left\{ \sum_{s'} \theta_a^{s,s'} [r'_s + \gamma\ poly'_s] | a \in A, poly_{s'} \in \Gamma_{s'}^n \right\}$ that represents V^{n+1}.

The fact that the optimal value function has a closed form with a simple parameterization is quite useful for planning algorithms based on value iteration. Instead of using an arbitrary function approximator to fit the value function, one can take advantage of the fact that the value function can be represented by a set of polynomials to choose a good representation. For instance, the Beetle algorithm (Poupart et al. 2006) performs point-based value iteration and approximates the value function with a bounded set of polynomials that each consists of a linear combination of monomial basis functions.

Exploration/Exploitation Tradeoff

Since the underlying model is unknown in reinforcement learning, it is not clear whether actions should be chosen to explore (gain more information about the model) or exploit (maximize immediate rewards based on information gathered so far). Bayesian reinforcement learning provides a principled solution to the exploration/exploitation tradeoff. Despite the appearance of multiple objectives induced by exploration and exploitation, there is a single objective in reinforcement learning: maximize total discounted rewards. Hence, an optimal policy (which maximizes total discounted rewards) must naturally optimize the exploration/exploitation tradeoff. In order for a policy to be optimal, it must use all the information available. The information available to the learner consists of the history of past states and actions. One can show that state–belief pairs $\langle s, b\rangle$ are sufficient statistics of the history. Hence, by searching for the mapping from state–belief pairs to actions that maximizes total discounted rewards, Bayesian reinforcement learning implicitly seeks an optimal tradeoff between exploration and exploitation. In contrast, traditional reinforcement learning approaches search in the space of mappings from states to actions. As a result, such techniques typically focus on asymptotic convergence (i.e., convergence to a policy that is optimal in the limit), but do not effectively balance exploration and exploitation since they do not use histories or beliefs to quantify the uncertainty about the underlying model.

Related Work

Michael Duff's PhD thesis (Duff 2002) provides an excellent survey of Bayesian reinforcement learning up until 2002. The above text pertains mostly to model-based Bayesian reinforcement learning applied to discrete, fully observable, single agent domains. Bayesian learning has also been explored in model-free reinforcement learning (Dearden et al. 1998; Engel et al. 2005; Ghavamzadeh and Engel 2006) continuous-valued state spaces (Ross et al. 2008), partially observable domains (Poupart and Vlassis 2008; Ross et al. 2007), and multi-agent systems (Chalkiadakis and Boutilier 2003, 2004; Gmytrasiewicz and Doshi 2005).

Beam Search

Claude Sammut
The University of New South Wales, Sydney, NSW, Australia

A beam search is a heuristic search technique that combines elements of breadth-first and best-first searches. Like a breadth-first search, the beam search maintains a list of nodes that represent a frontier in the search space. Whereas the breadth-first adds all neighbors to the list, the beam search orders the neighboring nodes according to some heuristic and only keeps the n best, where n is the *beam size*. This can significantly reduce the processing and storage requirements for the search.

In machine learning, the beam search has been used in algorithms, such as Dietterich and Michalski (1977).

Apprenticeship learning; Learning by demonstration; Learning by imitation; Learning control rules

Definition

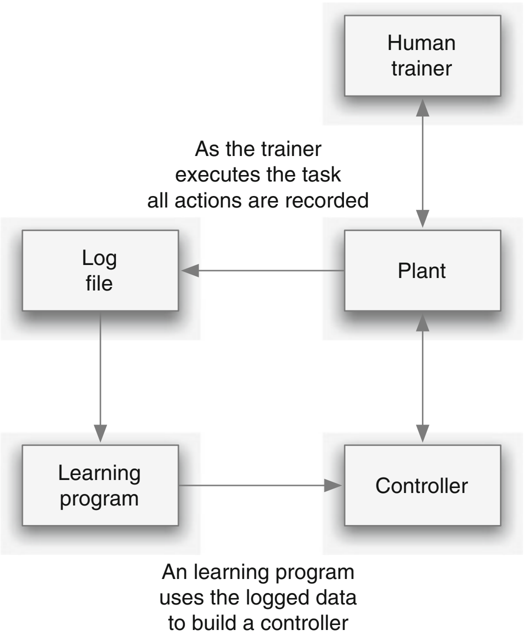
Behavioral cloning is a method by which human subcognitive skills can be captured and reproduced in a computer program. As the human subject performs the skill, his or her actions are recorded along with the situation that gave rise to the action. A log of these records is used as input to a learning program. The learning program outputs a set of rules that reproduce the skilled behavior. This method can be used to construct automatic control systems for complex tasks for which classical control theory is inadequate. It can also be used for training.

Motivation and Background

Behavioral cloning (Michie et al. 1990) is a form of *learning by imitation* whose main motivation is to build a model of the behavior of a human when performing a complex skill. Preferably, the model should be in a readable form. It is related to other forms of learning by imitation, such as ▸ inverse reinforcement learning (Abbeel and Ng 2004; Amit and Matariæ 2002; Hayes and Demiris 1994; Kuniyoshi et al. 1994; Pomerleau 1989) and methods that use data from human performances to model the system being controlled (Atkeson and Schaal 1997; Bagnell and Schneider 2001).

Experts might be defined as people who know what they are doing not what they are talking about. That is, once a person becomes highly skilled in some task, the skill becomes sub-cognitive and is no longer available to introspection. So when the person is asked to explain why certain decisions were made, the explanation is a post hoc justification rather than a true explanation.

Michie et al. (1990) used an induction program to learn rules for balancing a pole (in simulation) and earlier work by Donaldson (1960), Widrow and Smith (1964), and Chambers and Michie (1969) demonstrated the feasibility of learning by imitation, also for pole-balancing.



As the trainer executes the task all actions are recorded

An learning program uses the logged data to build a controller

Behavioral Cloning, Fig. 1 Structure of learning system

Structure of the Learning System

Behavioral cloning assumes that there is a plant of some kind that is under the control of a human operator. The plant may be a physical system or a simulation. In either case, the plant must be instrumented so that it is possible to capture the state of the system, including all the control settings. Thus, whenever the operator performs an action, that is, changes a control setting, we can associate that action with a particular state.

Let us use a simple example of a system that has only one control action. A *pole balancer* has four state variables: the angle of the pole, θ, and its angular velocity, $\dot{\theta}$ and the position, x, and velocity $\dot{x}$, of the cart on the track. The only action available to the controller is to apply a fixed positive of negative force, F, to accelerate the cart left or right (Fig. 1).

We can create an experimental setup where a human can control a pole and cart system (either real or in simulation) by applying a left push or a right push at the appropriate time. Whenever a control action is performed, we record the action as well as values of the four state variables at the time of the action. Each of these records can be viewed as an example of a mapping from state to action.

Michie et al. (1990) demonstrated that it is possible to construct a controller by learning from these examples. The learning task is to predict the appropriate action, given the state. They used a ▸ decision tree learning program to produce a classifier that, given the values of the four state variables, would output an action. A decision tree is easily convertible into an executable code as a nested **if** statement. The quality of the controller can be tested by inserting the decision tree into the simulator, replacing the human operator.

If the goal of learning is simply to produce an operational controller then any program capable of building a classifier could be used. The reason that Michie et al. (1990) chose a symbolic learner was their desire to produce a controller whose decision making was transparent as well as operational. That is, it should be possible to extract an explanation of the behavior that is meaningful to an expert in the task.

Learning Direct (Situation–Action) Controllers

A controller such as the one described above is referred to as a *direct controller* because it maps situations to actions. Other examples of learning a direct controller are building an autopilot from behavioral traces of human pilots flying aircraft in a flight simulator (Sammut et al. 1992) and building a control system for a container crane

(Urbani and Bratko 1994). These systems extended the earlier work by operating in domains in which there is more than one control variable and the task is sufficiently complex that it must be decomposed into several subtasks.

An operator of a container crane can control the speed of the cart and the length of the rope. A pilot of a fixed-wing aircraft can control the ailerons, elevators, rudder, throttle, and flaps. To build an autopilot, the learner must build a system that can set each of the control variables. Sammut et al. (1992), viewed this as a multitask learning problem.

Each training example is a feature vector that includes the position, orientation, and velocities of the aircraft as well as the values of each of the control settings: ailerons, elevator, throttle, and flaps. The rudder is ignored. A separate decision tree is built for each control variable. For example, the aileron setting is treated as the dependent variable and all the other variables, including the other controls, are treated as the attributes of the training example. A decision tree is built for ailerons, then the process is repeated for the elevators, etc. The result is a decision tree for each control variable.

The autopilot code executes each decision tree in each cycle of the control loop. This method treats the setting of each control as a separate task. It may be surprising that this method works since it is often necessary to adjust more than one control simultaneously to achieve the desired result. For example, to turn, it is normal to use the ailerons to roll the aircraft while adjusting the elevators to pull it around. This kind of multivariable control does result from multiple decision trees. When, say, the aileron decision tree initiates a roll, the elevator's decision tree detects the roll and causes the aircraft to pitch up and execute a turn.

Limitations

Direct controllers work quite well for systems that have a relatively small state space. However, for complex systems, behavioral cloning of direct situation–action rules tends to produce very brittle controllers. That is, they cannot tolerate large disturbances. For example, when air turbulence is introduced into the flight simulator, the performance of the clone degrades very rapidly. This is because the examples provided by logging the performance of a human only cover a very small part of the state space of a complex system such as an aircraft in flight. Thus, the"expertise" of the controller is very limited. If the system strays outside the controller's region of expertise, it has no method for recovering and failure is usually catastrophic.

More robust control is possible but only with a significant change in approach. The more successful methods decompose the learning task into two stages: learning goals and learning the actions to achieve those goals.

Learning Indirect (Goal-Directed) Controllers

The problem of learning in a large search space can partially be addressed by decomposing the learning into subtasks. A controller built in this way is said to be an *indirect controller*. A control is "indirect" if it does not compute the next action directly from the system's current state but uses, in addition, some intermediate information. An example of such intermediate information is a subgoal to be attained before achieving the final goal.

Subgoals often feature in an operator's control strategies and can be automatically detected from a trace of the operator's behavior (Šuc and Bratko 1997). The problem of subgoal identification can be treated as the inverse of the usual problem of controller design, that is, given the actions in an operator's trace, find the goal that these actions achieve. The limitation of this approach is that it only works well for cases in which there are just a few subgoals, not when the operator's trajectory contains many subgoals. In these cases, a better approach is to generalize the operator's trajectory. The generalized trajectory can be viewed as defining a continuously changing subgoal (Bratko and Šuc 2002; Šuc and Bratko 1999a) (see also the use of flow tubes in dynamic plan execution Hofmann and Williams 2006).

Subgoals and generalized trajectories are not sufficient to define a controller. A model of the systems dynamics is also required. Therefore, in addition to inducing subgoals or a generalized trajectory, this approach also requires learning approximate system dynamics, that is a model of the controlled system. Bratko and Šuc (2003) and use a combination of the Goldhorn (Križman and Džeroski 1995) discovery program and locally weighted regression to build the model of the system's dynamics. The next action is then computed "indirectly" by (1) computing the desired next state (e.g., next subgoal) and (2) determining an action that brings the system to the desired next state. Bratko and Šuc also investigated building qualitative control strategies from operator traces (Bratko and Šuc 2002).

An analog to this approach is ▸ inverse reinforcement learning (Abbeel and Ng 2004; Atkeson and Schaal 1997; Ng and Russell 2000) where the reward function is learned. Here, the learning the reward function corresponds to learning the human operator's goals.

Isaac and Sammut (2003) uses an approach that is similar in spirit to Šuc and Bratko but incorporates classical control theory. Learned skills are represented by a two-level hierarchical decomposition with an anticipatory goal level and a reactive control level. The goal level models how the operator chooses goal settings for the control strategy and the control level models the operator's reaction to any error between the goal setting and actual state of the system. For example, in flying, the pilot can achieve goal values for the desired heading, altitude, and airspeed by choosing appropriate values of turn rate, climb rate, and acceleration. The controls can be set to correct errors between the current state and the desired state of these goal-directing quantities. Goal models map system states to a goal setting. Control actions are based on the error between the output of each of the goal models and the current system state.

The control level is modeled as a set of proportional integral derivative (PID) controllers, one for each control variable. A PID controller determines a control value as a linear function proportional to the error on a goal variable, the integral of the error, and the derivative of the error.

Goal setting and control models are learned separately. The process begins be deciding which variables are to be used for the goal settings. For example, trainee pilots will learn to execute a "constant-rate turn," that is, their goal is to maintain a given turn rate. A separate goal rule is constructed for each goal variable using a ▸ model tree learner (Potts and Sammut 2005).

A goal rule gives the setting for a goal variable and therefore, we can find the difference (error) between the current state value and the goal setting. The integral and derivative of the error can also be calculated. For example, if the set turn rate is 180° min, then the error on the turn rate is calculated as the actual turn rate minus 180. The integral is then the running sum of the error multiplied by the time interval between time samples, starting from the first time sample of the behavioral trace, and the derivative is calculated as the difference between the error and previous error all divided by the time interval.

For each control available to the operator, a model tree learner is used to predict the appropriate control setting. ▸ Linear regression is used in the leaf nodes of the model tree to produce linear equations whose coefficients are the P, I, and D of values of the PID controller. Thus the learner produces a collection of PID controllers that are selected according to the conditions in the internal nodes of the tree. In control theory, this is known as *piecewise linear control*.

Another indirect method is to learn a model of the dynamics of the system and use this to learn, in simulation, a controller for the system (Bagnell and Schneider 2001; Ng et al. 2003). This approach does not seek to directly model the behavior of a human operator. A behavioral trace may be used to generate data for modeling the system but then a reinforcement learning algorithm is used to generate a policy for controlling the simulated system. The learned policy can then be transferred to the physical system. ▸ Locally weighted regression is typically used for system modeling, although ▸ model trees can also be used.

Belief State Markov Decision Processes

▸ Partially Observable Markov Decision Processes

Bellman Equation

The *Bellman Equation* is a recursive formula that forms the basis for ▸ dynamic programming. It computes the expected total reward of taking an action from a state in a ▸ Markov decision process by breaking it into the immediate reward and the total future expected reward. See ▸ dynamic programming.

Bias

Bias has two meanings, ▸ inductive bias, and *statistical bias* see ▸ bias variance decomposition.

Bias Specification Language

Hendrik Blockeel
Katholieke Universiteit Leuven, Heverlee,
Leuven, Belgium
Leiden Institute of Advanced Computer Science,
Heverlee, Belgium

Definition

A *bias specification language* is a language in which a user can specify a ▸ Language Bias. The language bias of a learner is the set of hypotheses (or hypothesis descriptions) that this learner may return.

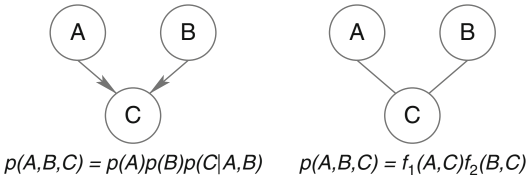
In contrast to the ▸ hypothesis language, the bias specification language allows us to describe not single hypotheses but sets (languages) of hypotheses.

Examples

In learning approaches based on ▸ graphical models or ▸ artificial neural networks, whenever the user provides the graph structure of the model, he or she is specifying a bias. The "language" used to specify this bias, in this case, consists of graphs. Figure 1 shows examples of such graphs. Not every kind of bias can necessarily be expressed by some bias specification language; for instance, the bias defined by the ▸ Bayesian network structure in Fig. 1 cannot be expressed using a ▸ Markov network. Bayesian networks and Markov networks have a different expressiveness, when viewed as bias specification languages.

Also certain parameters of decision tree learners or rule set learners effectively restrict the hypothesis language (for instance, an upper bound on the rule length or the size of the decision tree).

A combination of parameter values can hardly be called a language, and even the "language" of graphs is a relatively simple kind of language. More elaborate types of bias specification languages are typically found in the field of ▸ inductive logic programming (ILP).



Bias Specification Language, Fig. 1 Graphs defining a bias for learning joint distributions. The Bayesian network structure to the left constrains the form of the joint distribution in a particular way (shown as the equation below the graph). Notably, it guarantees that only distributions can be learned in which the variables A and B are (unconditionally) independent. The Markov network structure to the right constrains the form of the joint distribution in a different way: it states that it must be possible to write the distribution as a product of a function of A and C and a function of B and C. These two biases are different. In fact, no Markov network structure over the variables A, B, and C exists that expresses the bias specified by the Bayesian network structure

Bias Specification Languages in Inductive Logic Programming

In ILP, the hypotheses returned by the learning algorithm are typically written as first-order logic clauses. As the set of all possible clauses is too large to handle, a subset of these clauses is typically defined; this subset is called the language bias. Several formalisms (“bias specification languages”) have been proposed for specifying such subsets. We here focus on a few representative ones.

DLAB

In the DLAB bias specification language (Dehaspe and De Raedt 1996), the language bias is defined in a declarative way, by defining a syntax that clauses must fulfill. In its simplest form, a DLAB specification simply gives a set of possible head and body literals out of which the system can build a clause.

Example 1 The actual syntax of the DLAB specification language is relatively complicated (see Dehaspe and De Raedt 1996), but in essence, one can write down a specification such as:

```
{ parent({X,Y,Z},{X,Y,Z}),
   grandparent({X,Y,Z},
      {X,Y,Z})}
:-
{ parent({X,Y,Z},{X,Y,Z}),
   parent({X,Y,Z},{X,Y,Z}),
   grandparent({X,Y,Z},{X,Y,Z}),
   grandparent({X,Y,Z}, {X,Y,Z}) }
```

which states that the hypothesis language consists of all clauses that have at most one parent and at most one grandparent literal in the head, and at most two of these literals in the body; the arguments of these literals may be variables X,Y,Z. Thus, the following clauses are in the hypothesis language:

```
grandparent(X, Y)
:- parent(X, Z), parent(Z,Y)
:- parent(X,Y), parent(Y,X)
:- parent(X,X)
```

These express the usual definition of grandparent as well as the fact that there can be no cycles in the parent relation.

Note that for each argument of each literal, all the variables and constants that may occur have to be enumerated explicitly. This can make a DLAB specification quite complex. While DLAB contains advanced constructs to alleviate this problem, it remains the case that often very elaborate bias specifications are needed in practical situations.

Type-and Mode-Based Biases

A more flexible bias specification language is used by Progol (Muggleton 1995) and many other ILP systems. It is based on the notions of types and modes. In Progol, arguments of a predicate can be typed, and a variable can never occur in two locations with different types. Similarly, arguments of a predicate have an input (+) or output (−) mode; each variable that occurs as an input argument of some literal must occur elsewhere as an output argument, or must occur as input argument in the head literal of a clause.

Example 2 In Progol, the specifications

```
type(parent(human,human)).
type(grandparent(human,human)).
modeh(grandparent(+,+)).
   % modeh: specifies a head
literal modeb(grandparent(+,-)).
   % modeb: specifies a body
literal modeb(parent(+,-)).
```

allow the system to construct a clause such as

```
grandparent(X,Y) :- parent(X,Z),
     parent(Z,Y)
```

but not the following clause:

```
grandparent(X,Y) :- parent(Z,Y)
```

because Z occurs as an input parameter for parent without occurring elsewhere as an output parameter (i.e., it is being used without having been given a value first).

FLIPPER's Bias Specification Language

The FLIPPER system (Cohen 1996) employs a powerful, but somewhat more procedural, bias specification formalism. The user does not specify a set of valid hypotheses directly, but rather, specifies a Refinement Operator. The language bias is the set of all clauses that can be obtained from one or more starting clauses through repeated application of this refinement operator. The operator itself is defined by specifying under which conditions certain literals can be added to a clause.

Rules defining the operator have one of the following forms:

- $A \leftarrow B$ where *Pre* asserting *Post*
- L where *Pre* asserting *Post*

The first form defines a set of "starting clauses," and the second form defines when a literal L can be added to a clause. Each rule can only be applied when its preconditions *Pre* are fulfilled, and upon application will assert a set of literals *Post*. As an example (Cohen 1996), the rules

$illegal(A, B, C, D, E, F) \leftarrow$

`where` *true*
`asserting` $\{linked(A), linked(B), \ldots,$ $linked(F)\}$

$R(X, Y)$ where $rel(R)$, $linked(X)$, $linked(Y)$
`asserting` Ø

state that any clause of the form

illegal (A, B,C,D, E, F)←

can be used as a starting point for the refinement operator, and the variables in this clause are all *linked*. Further, any literal of the form $R(X, Y)$ with R a relation symbol (as defined by the *Rel* predicate) and X and Y linked variables can be added.

Other Approaches

Grammars or term rewriting systems have been proposed several times as a means of defining the hypothesis language. A relatively recent approach along these lines was given by Lloyd, who uses a rewriting system to define the tests that can occur in the nodes of a decision tree built by the Alkemy system (Lloyd 2003).

Boström and Idestam-Almquist (1999) present an approach where the language bias is implicitly defined through the Background Knowledge given to the learner.

Knobbe et al. (2000) propose the use of UML as a "common" bias specification language, specifications in which could be translated automatically to languages specific to a particular learner.

Further Reading

An overview of bias specification formalisms in ILP is given by Nédellec et al. (1996). The bias specification languages discussed above are discussed in more detail in Dehaspe and De Raedt (1996), Muggleton (1995), and Cohen (1996). De Raedt (1992) discusses language bias and the concept of bias shift (learners weakening their bias, i.e., extending the set of hypotheses that can be represented, when a given language bias turns out to be too restrictive). A more recent approach to learning declarative bias is presented by Bridewell and Todorovski (2008).

Bias Variance Decomposition

Definition

The bias-variance decomposition is a useful theoretical tool to understand the performance characteristics of a learning algorithm. The following discussion is restricted to the use of *squared loss* as the performance measure, although similar analyses have been undertaken for other loss functions. The case receiving most attention is the zero-one loss (i.e., classification problems), in which case the decomposition is nonunique and a topic of active research. See Domingos (1992) for details.

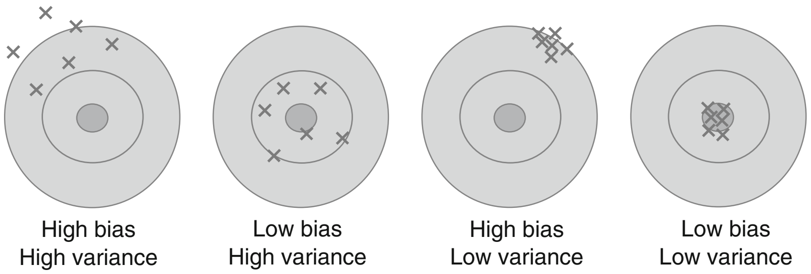
The decomposition allows us to see that the mean squared error of a model (generated by a particular learning algorithm) is in fact made up of two components. The *bias* component tells us how accurate the model is, on average across different possible training sets. The *variance* component tells us how sensitive the learning algorithm is to small changes in the training set (Fig. 1).

Mathematically, this can be quantified as a decomposition of the mean squared error function. For a testing example $\{\mathbf{x}, d\}$, the decomposition is:

$$\mathcal{E}_{\mathcal{D}}\{(f(\mathbf{x})-d)^2\} = (\mathcal{E}_{\mathcal{D}}\{f(\mathbf{x})\}-d)^2 + \mathcal{E}_{\mathcal{D}}\{(f(\mathbf{x})-\mathcal{E}_{\mathcal{D}}\{f(\mathbf{x})\})^2\},$$

$$\text{MSE} = \text{bias}^2 + \text{variance},$$

where the expectations are with respect to all possible training sets. In practice, this can be estimated by cross-validation over a single finite training set, enabling a deeper understanding of the algorithm characteristics. For example, efforts to reduce variance often cause increases in bias, and vice versa. A large bias and low variance is an indicator that a learning algorithm is prone to ▶ overfitting the model.



Bias Variance Decomposition, Fig. 1 The bias-variance decomposition is like trying to hit the bullseye on a dartboard. Each dart is thrown after training our "dart-throwing" model in a slightly different manner. If the darts vary wildly, the learner is *high variance*. If they are far from the bullseye, the learner is *high bias*. The ideal is clearly to have both low bias and low variance; however this is often difficult, giving an alternative terminology as the bias-variance "dilemma" (*Dartboard analogy*, Moore and McCabe 2002)

Bias-Variance Trade-Offs: Novel Applications

Definition

Consider a given random variable $\underline{F}$ and a random variable that we can modify, $\hat{\underline{F}}$. We wish to use a sample of $\hat{\underline{F}}$ as an estimate of a sample of $\underline{F}$. The mean squared error (MSE) between such a pair of samples is a sum of four terms. The first term reflects the statistical coupling between $\underline{F}$ and $\hat{\underline{F}}$ and is conventionally ignored in bias-variance analysis. The second term reflects the inherent noise in $\underline{F}$ and is independent of the estimator $\hat{\underline{F}}$. Accordingly, we cannot affect this term. In contrast, the third and fourth terms depend on $\hat{\underline{F}}$. The third term, called the bias, is independent of the precise samples of both $\underline{F}$ and $\hat{\underline{F}}$ and reflects the difference between the means of $\underline{F}$ and $\hat{\underline{F}}$. The fourth term, called the variance, is independent of the precise sample of $\underline{F}$ and reflects the inherent noise in the estimator as one samples it. These last two terms can be modified by changing the choice of the estimator. In particular, on small sample sets, we can often decrease our mean squared error by, for instance, introducing a small bias that causes a large reduction the variance. While most commonly used in machine learning, this article shows that such bias-variance trade-offs are applicable in a much broader context and in a variety of situations. We also show, using experiments, how existing bias-variance trade-offs can be applied in novel circumstances to improve the performance of a class of optimization algorithms.

Motivation and Background

In its simplest form, the bias-variance decomposition is based on the following idea. Say we have a random variable $\underline{F}$ taking on values F distributed according to a density function $p(F)$. We want to estimate the value of a sample from $p(F)$. To form our estimate, we sample a different random variable $\hat{\underline{F}}$ taking on values $\hat{F}$ distributed according to $p(\hat{F})$. Assuming a quadratic loss function, the quality of our estimate is measured by its MSE:

$$\mathrm{MSE}(\hat{\underline{F}}) \equiv \int p(\hat{F}, F)\,(\hat{F} - F)^2 \mathrm{d}\hat{F}\,\mathrm{d}F.$$

In many situations, $\underline{F}$ and $\hat{\underline{F}}$ are dependent variables. For example, in supervised machine learning, $\underline{F}$ is a "target" conditional distribution, stochastically mapping elements of an input space X into a space Y of output variables. The associated distribution $p(F)$ is the "prior" of $\underline{F}$. A random sample $\mathcal{D}$ of $\underline{F}$, called "the training set," is generated, and $\mathcal{D}$ is used in a "learning algorithm" to produce $\hat{\underline{F}}$, which is our estimate of $\underline{F}$. Clearly, this $\underline{F}$ and $\hat{\underline{F}}$ are statistically dependent, via $\mathcal{D}$. Indeed, intuitively speaking, the goal in designing a learning algorithm is that the $\hat{\underline{F}}$'s it produces are positively correlated with $\underline{F}$'s.

In practice this coupling is simply ignored in analyses of bias plus variance, without any justification (one such justification could be that the coupling has little effect on the value of the MSE). We shall follow that practice here. Accordingly, our equation for MSE reduces to

$$\mathrm{MSE}(\underline{\hat{F}}) = \int p(\hat{F})p(F)\,(\hat{F}-F)^2 \mathrm{d}\hat{F}\,\mathrm{d}F. \tag{1}$$

If we were to account for the coupling of $\hat{F}$ and $\underline{\hat{F}}$, an additive correction term would need to be added to the right-hand side. For instance, see Wolpert (1997).

Using simple algebra, the right-hand side of (1) can be written as the sum of three terms. The first is the variance of $\underline{F}$. Since this is beyond our control in designing the estimator $\underline{\hat{F}}$, we ignore it for the rest of this article. The second term involves a mean that describes the deterministic component of the error. This term depends on both the distribution of $\underline{F}$ and that of $\underline{\hat{F}}$ and quantifies how close the means of those distributions are. The third term is a variance that describes stochastic variations from one sample to the next. This term is independent of the random variable being estimated. Formally, up to an overall additive constant, we can write

$$\begin{aligned}
\mathrm{MSE}(\hat{F}) &= \int p(\hat{F})(\hat{F}^2 - 2F\hat{F} + F^2)\,\mathrm{d}\hat{F} \\
&= \int p(\hat{F})\hat{F}^2\,\mathrm{d}\hat{F} \\
&\quad -2F\int p(\hat{F})\hat{F}\,\mathrm{d}\hat{F} + F^2 \\
&= \overbrace{\mathbb{V}(\hat{F}) + [\mathbb{E}(\hat{F})]^2} - 2F\,\mathbb{E}(\hat{F}) + F^2 \\
&= \mathbb{V}(\hat{F}) + \underbrace{[F - \mathbb{E}(\hat{F})]^2} \\
&= \text{variance} + \text{bias}^2.
\end{aligned} \tag{2}$$

In light of (2), one way to try to reduce expected quadratic error is to modify an estimator to trade-off bias and variance. Some of the most famous applications of such bias-variance trade-offs occur in parametric machine learning, where many techniques have been developed to exploit the trade-off. Nonetheless, the trade-off also arises in many other fields, including integral estimation and optimization. In the rest of this paper, we present a few novel applications of bias-variance trade-off and describe some interesting features in each case. A recurring theme is the following: whenever a bias-variance trade-off arises in a particular field, we can use many techniques from parametric machine learning that have been developed for exploiting this trade-off. See Wolpert and Rajnarayan (2007) for further details of many of these applications.

Applications

In this section, we describe some applications of the bias-variance trade-off. First, we describe Monte Carlo (MC) techniques for the estimation of integrals and provide a brief analysis of bias-variance trade-offs in this context. Next, we introduce the field of Monte Carlo optimization (MCO) and illustrate that there are more subtleties involved than in simple MC. Then, we describe the field of parametric machine learning, which, as will show, is formally identical to MCO. Finally, we describe the application of parametric learning (PL) techniques to improve the performance of MCO algorithms. We do this in the context of an MCO problem that addresses black-box optimization.

Monte Carlo Estimation of Integrals Using Importance Sampling

Monte Carlo methods are often the method of choice for estimating difficult high-dimensional integrals. Consider a function $f : X \to \mathbb{R}$, which we want to integrate over some region $\mathcal{X} \subseteq X$, yielding the value F, as given by

$$F = \int_{\mathcal{X}} \mathrm{d}x\; f(x).$$

We can view this as a random variable $\underline{F}$, with density function given by a Dirac delta function centered on F. Therefore, the variance of $\underline{F}$ is 0, and (2) is exact.

A popular MC method to estimate this integral is importance sampling (see Robert and Casella 2004). This exploits the law of large numbers as follows: i.i.d. samples $x^{(i)}, i = 1, \ldots, m$ are generated from a so-called importance distribution $h(x)$ that we control, and the associated values of the integrand $f(x^{(i)})$ are computed. Denote these "data" by

$$\mathcal{D} = \left\{(x^{(i)}, f(x^{(i)}), \; i = 1, \ldots, m\right\}. \qquad (3)$$

Now,

$$\begin{aligned} F &= \int_{\mathcal{X}} \mathrm{d}x \, h(x) \frac{f(x)}{h(x)} \\ &= \lim_{m\to\infty} \frac{1}{m} \sum_{i=1}^{m} \frac{f\left(x^{(i)}\right)}{h\left(x^{(i)}\right)} \quad \text{with probability 1.} \end{aligned}$$

Denote by $\underline{\hat{F}}$ the random variable with value given by the sample average for $\mathcal{D}$:

$$\hat{F} = \frac{1}{m} \sum_{i=1}^{m} \frac{f\left(x^{(i)}\right)}{h\left(x^{(i)}\right)}.$$

We use $\underline{\hat{F}}$ as our statistical estimator for $\underline{F}$, as we broadly described in the introductory section. Assuming a quadratic loss function, $L(\hat{F}, F) = (F - \hat{F})^2$, the bias-variance decomposition described in (2) applies *exactly*. It can be shown that the estimator $\underline{\hat{F}}$ is unbiased, that is, $\mathbb{E}(\underline{\hat{F}}) = F$, where the mean is over samples of h. Consequently, the MSE of this estimator is just its variance. The choice of sampling distribution h that minimizes this variance is given by (see Robert and Casella 2004)

$$h^{\star}(x) = \frac{|f(x)|}{\int_{\mathcal{X}} |f(x')| \, \mathrm{d}x'}.$$

By itself, this result is not very helpful, since the equation for the optimal importance distribution contains a similar integral to the one we are trying to estimate. For nonnegative integrands $f(x)$, the VEGAS algorithm (Lepage 1978) describes an adaptive method to find successively better importance distributions, by iteratively estimating $\underline{F}$ and then using that estimate to generate the next importance distribution h. In the case of these unbiased estimators, there is no trade-off between bias and variance, and minimizing MSE is achieved by minimizing variance.

Monte Carlo Optimization

Instead of a *fixed* integral to evaluate, consider a parametrized integral

$$F(\theta) = \int_{\mathcal{X}} \mathrm{d}x \; f_{\theta}(x).$$

Further, suppose we are interested in finding the value of the parameter $\theta \in \Theta$ that minimizes $F(\theta)$:

$$\theta^{\star} = \arg\min_{\theta\in\Theta} F(\theta).$$

In the case where the functional form of f_{θ} is not explicitly known, one approach to solve this problem is a technique called MCO (see Ermoliev and Norkin 1998), involving repeated MC estimation of the integral in question with adaptive modification of the parameter θ.

We proceed by analogy to the case with MC. First, we introduce the θ-indexed random variable $\underline{F}(\theta)$, all of whose components have delta-function distributions about the associated values $F(\theta)$. Next, we introduce a θ-indexed vector random variable $\underline{\hat{F}}$ with values

$$\hat{F} \equiv \left\{\hat{F}(\theta) \; \forall\, \theta \in \Theta\right\}. \qquad (4)$$

Each real-valued component $\underline{\hat{F}}(\theta)$ can be sampled and viewed as an estimate of $\underline{F}(\theta)$.

For example, let $\mathcal{D}$ be a data set as described in (3). Then for every θ, any sample of $\mathcal{D}$ provides an associated estimate

$$\hat{F}(\theta) = \frac{1}{m} \sum_{i=1}^{m} \frac{f_{\theta}\left(x^{(i)}\right)}{h\left(x^{(i)}\right)}.$$

That average serves as an estimate of $\underline{F}(\theta)$. Formally, $\underline{\hat{F}}$ is a function of the random variable $\mathcal{D}$ and is given by such averaging over the elements of $\mathcal{D}$. So, a sample of $\mathcal{D}$ provides a sample of $\underline{\hat{F}}$. A priori, we make no restrictions on $\underline{\hat{F}}$, and so, in general, its components may be statistically coupled with one another. Note that this coupling arises even though we are, for simplicity, treating each function $\underline{F}(\theta)$ as having a delta-function distribution rather than as having a nonzero variance that would reflect our lack of knowledge of the $f(\theta)$ functions.

However $\underline{\hat{F}}$ is defined, given a sample of $\hat{F}$, one way to estimate $\theta^\star$ is

$$\hat{\theta}^\star = \arg\min_{\theta\in\Theta} \hat{F}(\theta).$$

We call this approach "natural" MCO. As an example, say that $\mathcal{D}$ is a set of m samples of h, and let

$$\hat{F}(\theta) \triangleq \frac{1}{m}\sum_{i=1}^{m} \frac{f_\theta\left(x^{(i)}\right)}{h\left(x^{(i)}\right)},$$

as above. Under this choice for $\underline{\hat{F}}$,

$$\hat{\theta}^\star = \arg\min_{\theta\in\Theta} \frac{1}{m}\sum_{i=1}^{m} \frac{f_\theta\left(x^{(i)}\right)}{h\left(x^{(i)}\right)}. \qquad (5)$$

We call this approach "naive" MCO.

Consider *any* algorithm that estimates $\theta^\star$ as a single-valued function of $\hat{F}$. The estimate of $\theta^\star$ produced by that algorithm is itself a random variable, since it is a function of the random variable $\underline{\hat{F}}$. Call this random variable $\underline{\hat{\theta}}^\star$, taking on values $\hat{\theta}^\star$. Any MCO algorithm is defined by $\underline{\hat{\theta}}^\star$; that random variable encapsulates the output estimate made by the algorithm.

To analyze the error of such an algorithm, consider the associated random variable given by the true parametrized integral $F(\underline{\hat{\theta}}^\star)$. The difference between a sample of $F(\underline{\hat{\theta}}^\star)$ and the true minimal value of the integral, $F(\theta^\star) = \min_\theta F(\theta)$, is the error introduced by our estimating that optimal θ as a sample of $\underline{\hat{\theta}}^\star$. Since our aim in MCO is to minimize $F(\theta)$, we adopt the loss function $L(\underline{\hat{\theta}}^\star, \theta^\star) \triangleq F(\underline{\hat{\theta}}^\star) - F(\theta^\star)$. This is in contrast to our discussion on MC integration, which involved quadratic loss. The current loss function just equals $F(\underline{\hat{\theta}}^\star)$ up to an additive constant $F(\theta^\star)$ that is fixed by the MCO problem at hand and is beyond our control. Up to that additive constant, the associated expected loss is

$$\mathbb{E}(L) = \int d\hat{\theta}^\star p(\hat{\theta}^\star) F(\hat{\theta}^\star). \qquad (6)$$

Now change coordinates in this integral from the values of the scalar random variable $\underline{\hat{\theta}}^\star$ to the values of the underlying vector random variable $\underline{\hat{F}}$. The expected loss now becomes

$$\mathbb{E}(L) = \int \mathrm{d}\hat{F}\; p(\hat{F}) F(\hat{\theta}^\star(\hat{F})).$$

The natural MCO algorithm provides some insight into these results. For that algorithm,

$$\begin{aligned}\mathbb{E}(L) &= \int \mathrm{d}\hat{F}\;\, p(\hat{F}) F\left(\arg\min_\theta \hat{F}(\theta)\right)\\ &= \int \mathrm{d}\hat{F}(\theta_1)\, \mathrm{d}\hat{F}(\theta_2)\ldots p(\hat{F}(\theta_1), \hat{F}(\theta_2), \ldots)\\ &\quad F\left(\arg\min_\theta \hat{F}(\theta)\right). \end{aligned} \qquad (7)$$

For any fixed θ, there is an error between samples of $\hat{F}(\theta)$ and the true value $F(\theta)$. Bias-variance considerations apply to this error, exactly as in the discussion of MC above. We are not, however, concerned with $\hat{F}$ for a single component θ but rather for a set Θ of θs.

The simplest such case is where the components of $\hat{F}(\Theta)$ are independent. Even so, $\arg\min_\theta \hat{F}(\theta)$ is distributed according to the laws for extrema of multiple independent random variables, and this distribution depends on higher-order moments of each random variable $\hat{F}(\theta)$. This means that $\mathbb{E}[L]$ also depends on such higher-order moments. Only the first two moments, however, arise in the bias and variance for any single θ. Thus, even in the simplest possible case, the bias-variance considerations for the individual θ do not provide a complete analysis.

In most cases, the components of $\hat{F}$ are *not* independent. Therefore, in order to analyze $\mathbb{E}[L]$, in addition to higher moments of the distribution for each θ, we must now also consider higher-order moments coupling the estimates $\hat{F}(\theta)$ for different θ.

Due to these effects, it may be quite acceptable for all the components $\hat{F}(\theta)$ to have both a large bias and a large variance, as long as they still order the θ's correctly with respect to the true $F(\theta)$. In such a situation, large covariances could ensure that if some $\hat{F}(\theta)$ were incorrectly large, then $\hat{F}(\theta'), \theta' \neq \theta$ would also be incorrectly large. This coupling between the components of $\hat{F}$ would preserve the ordering of θ's under $\underline{F}$. So, even with large bias and variance for each θ, the estimator as a whole would still work well.

Nevertheless, it *is* sufficient to design estimators $\hat{F}(\theta)$ with sufficiently small bias plus variance for each single θ. More precisely, suppose that those terms are very small on the scale of differences $F(\theta) - F(\theta')$ for any θ and θ'. Then by Chebychev's inequality, we know that the density functions of the random variables $\hat{\underline{F}}(\theta)$ and $\hat{\underline{F}}(\theta')$ have almost no overlap. Accordingly, the probability that a sample of $\hat{\underline{F}}(\theta) - \hat{\underline{F}}(\theta')$ has the opposite sign of $F(\theta) - F(\theta')$ is almost zero.

Evidently, $\mathbb{E}[L]$ is generally determined by a complicated relationship involving bias, variance, covariance, and higher moments. Natural MCO in general, and naive MCO in particular, ignore all of these effects and, consequently, often perform quite poorly in practice. In the next section, we discuss some ways of addressing this problem.

Parametric Machine Learning

There are many versions of the basic MCO problem described in the previous section. Some of the best-explored arise in parametric density estimation and parametric supervised learning, which together comprise the field of parametric machine learning (PL).

In particular, parametric supervised learning attempts to solve

$$\arg\min_{\theta \in \Theta} \int \mathrm{d}x \; p(x) \int \mathrm{d}y \; p(y \mid x) \, f_\theta(x).$$

Here, the values x represent inputs, and the values y represent corresponding outputs, generated according to some stochastic process defined by a set of conditional distributions $\{p(y \mid x),\; x \in \mathcal{X}\}$. Typically, one tries to solve this problem by casting it as an MCO problem. For instance, say we adopt a quadratic loss between a predictor $z_\theta(x)$ and the true value of y. Using MCO notation, we can express the associated supervised learning problem as finding $\arg\min_\theta F(\theta)$, where

$$\begin{aligned} l_\theta(x) &= \int \mathrm{d}y \; p(y \mid x) \, (z_\theta(x) - y)^2, \\ f_\theta(x) &= p(x) \, l_\theta(x), \\ F(\theta) &= \int \mathrm{d}x \; f_\theta(x). \end{aligned} \tag{8}$$

Next, the argmin is estimated by minimizing a sample-based estimate of the $F(\theta)$s. More precisely, we are given a "training set" of samples of $p(y \mid x)\, p(x)$, $\{(x^{(i)}, y^i)\; i = 1, \ldots, m\}$. This training set provides a set of associated estimates of $F(\theta)$:

$$\hat{F}(\theta) = \frac{1}{m} \sum_{i=1}^{m} l_\theta\left(x^{(i)}\right).$$

These are used to estimate $\arg\min_\theta F(\theta)$, exactly as in MCO. In particular, one could estimate the minimizer of $F(\theta)$ by finding the minimum of $\hat{F}(\theta)$, just as in natural MCO. As mentioned above, this MCO algorithm can perform very poorly in practice. In PL, this poor performance is called "overfitting the data."

There are several formal approaches that have been explored in PL to try to address this "overfitting the data." Interestingly, none are based on direct consideration of the random variable $F(\hat{\theta}^\star(\hat{\underline{F}}))$ and the ramifications of its distribution for expected loss (cf. (7)). In particular, no work has applied the mathematics of extrema of multiple random variables to analyze the bias-variance-covariance trade-offs encapsulated in (7).

The PL approach that perhaps comes closest to such direct consideration of the distribution of $F(\hat{\underline{\theta}}^\star)$ is uniform convergence theory, which is a central part of computational learning theory (see Angluin 1992). Uniform convergence theory starts by crudely encapsulating the quadratic loss formula for expected loss under natural MCO (7). It does this by considering the worst-case bound, over possible $p(x)$ and $p(y \mid x)$, of the probability that $F(\underline{\theta}^\star)$ exceeds $\min_\theta F(\theta)$ by more than κ. It then examines how that bound varies with κ.

In particular, it relates such variation to characteristics of the set of functions $\{f_\theta : \theta \in \Theta\}$, e.g., the "VC dimension" of that set (see Vapnik 1982, 1995).

Another, historically earlier approach, is to apply bias-plus-variance considerations to the *entire* PL algorithm $\underline{\hat{\theta}}^\star$ rather than to each $\underline{\hat{F}}(\theta)$ separately. This approach is applicable for algorithms that do not use natural MCO and even for nonparametric supervised learning. As formulated for parametric supervised learning, this approach combines the formulas in (8) to write

$$F(\theta) = \int \mathrm{d}x\, \mathrm{d}y\;\; p(x)p(y \mid x)(z_\theta(x) - y)^2.$$

This is then substituted into (6), giving

$$\begin{aligned}\mathbb{E}[L] &= \int \mathrm{d}\hat{\theta}^\star \mathrm{d}x\, \mathrm{d}y\;\; p(x)\, p(y \mid x)\, p(\hat{\theta}^\star)\\ &\qquad (z_{\hat{\theta}^\star}(x) - y)^2\\ &= \int \mathrm{d}x\, p(x) \Bigg[\int \mathrm{d}\hat{\theta}^\star \mathrm{d}y\;\; p(x)p(y\,|\,x)p(\hat{\theta}^\star)\\ &\qquad (z_{\hat{\theta}^\star}(x) - y)^2\Bigg]. \qquad (9)\end{aligned}$$

The term in square brackets is an x-parameterized expected quadratic loss, which can be decomposed into a bias, variance, etc., in the usual way. This formulation eliminates any direct concern for issues like the distribution of extrema of multiple random variables, covariances between $\underline{\hat{F}}(\theta)$ and $\underline{\hat{F}}(\theta')$ for different values of θ, and so on.

There are numerous other approaches for addressing the problems of natural MCO that have been explored in PL. Particularly important among these are Bayesian approaches, e.g., Buntine and Weigend (1991), Berger (1985), and Mackay (2003). Based on these approaches, as well as on intuition, many powerful techniques for addressing data-overfitting have been explored in PL, including regularization, cross-validation, stacking, bagging, etc. Essentially all of these techniques can be applied to *any* MCO problem, not just PL problems. Since many of these techniques can be justified using (9), they provide a way to exploit the bias-variance tradeoff in other domains besides PL.

PLMCO

In this section, we illustrate how PL techniques that exploit the bias-variance decomposition of (9) can be used to improve an MCO algorithm used in a domain outside of PL. This MCO algorithm is a version of adaptive importance sampling, somewhat similar to the CE method (Rubinstein and Kroese 2004), and is related to function smoothing on continuous spaces. The PL techniques described are applicable to any other MCO problem, and this particular one is chosen just as an example.

MCO Problem Description

The problem is to find the θ-parameterized distribution q_θ that minimizes the associated expected value of a function $G\colon \mathbb{R}^n \to \mathbb{R}$, i.e., find

$$\arg\min_\theta \mathbb{E}_{q_\theta}[G].$$

We are interested in versions of this problem where we do not know the functional form of G, but can obtain its value $G(x)$ at any $x \in \mathcal{X}$. Similarly we cannot assume that G is smooth, nor can we evaluate its derivatives directly. This scenario arises in many fields, including black-box optimization (see Wolpert et al. 2006) and risk minimization (see Ermoliev and Norkin 1998).

We begin by expressing this minimization problem as an MCO problem. We know that

$$\mathbb{E}_{q_\theta}[G] = \int_{\mathcal{X}} \mathrm{d}x\, q_\theta(x)G(x)$$

Using MCO terminology, $f_\theta(x) = q_\theta(x)G(x)$ and $F(\theta) = \mathbb{E}_{q_\theta}[G]$. To apply MCO, we must define a vector-valued random variable $\underline{\hat{F}}$ with components indexed by θ and then use a sample of $\underline{\hat{F}}$ to estimate $\arg\min_\theta \mathbb{E}_{q_\theta}[G]$. In particular, to apply naive MCO to estimate $\arg\min_\theta \mathbb{E}_{q_\theta}(G)$, we first i.i.d. sample a density function $h(x)$. By evaluating the associated values of $G(x)$, we get a data set

$$\begin{aligned}\mathcal{D} &\equiv (\mathcal{D}_{\mathcal{X}}, \mathcal{D}_G)\\ &= \Big(\{x^{(i)} : i = 1, \ldots, m\},\\ &\qquad \{G(x^{(i)}) : i = 1, \ldots, m\}\Big).\end{aligned}$$

The associated estimates of $F(\theta)$ for each θ are

$$\hat{F}(\theta) \triangleq \frac{1}{m}\sum_{i=1}^{m}\frac{q_\theta\left(x^{(i)}\right)G\left(x^{(i)}\right)}{h\left(x^{(i)}\right)}. \qquad (10)$$

The associated naive MCO estimate of $\arg\min_\theta \mathbb{E}_{q_\theta}[G]$ is

$$\hat{\theta}^\star \equiv \arg\min_\theta \hat{F}(\theta).$$

Suppose Θ includes all possible density functions over x's. Then the q_θ minimizing our estimate is a delta function about the $x^{(i)} \in \mathcal{D}_\mathcal{X}$ with the lowest associated value of $G(x^{(i)})/h(x^{(i)})$. This is clearly a poor estimate in general; it suffers from "data-overfitting." Proceeding as in PL, one way to address this data-overfitting is to use regularization. In particular, we can use the entropic regularizer, given by the negative of the Shannon entropy $S(q_\theta)$. So we now want to find the minimizer of $\mathbb{E}_{q_\theta}[G(x)]-TS(q_\theta)$, where T is the regularization parameter. Equivalently, we can minimize $\beta\mathbb{E}_{q_\theta}[G(x)] - S(q_\theta)$, where $\beta = 1/T$. This changes the definition of $\hat{F}$ from the function given in (10) to

$$\hat{F}(\theta) \triangleq \frac{1}{m}\sum_{i=1}^{m}\frac{\beta\, q_\theta\left(x^{(i)}\right)G\left(x^{(i)}\right)}{h\left(x^{(i)}\right)} - S(q_\theta).$$

Solution Methodology

Unfortunately, it can be difficult to find the θ globally minimizing this new $\hat{F}$ for an arbitrary $\mathcal{D}$. An alternative is to find a close approximation to that optimal θ. One way to do this is as follows. First, we find minimizer of

$$\frac{1}{m}\sum_{i=1}^{m}\frac{\beta\, p\left(x^{(i)}\right)G\left(x^{(i)}\right)}{h\left(x^{(i)}\right)} - S(p) \qquad (11)$$

over the set of all possible distributions $p(x)$ with domain $\mathcal{X}$. We then find the q_θ that has minimal Kullback–Leibler (KL) divergence from this p, evaluated over $\mathcal{D}_\mathcal{X}$. That serves as our approximation to $\arg\min_\theta \hat{F}(\theta)$ and therefore as our estimate of the θ that minimizes $\mathbb{E}_{q_\theta}(G)$.

The minimizer p of (11) can be found in closed form; over $\mathcal{D}_\mathcal{X}$, it is the Boltzmann distribution $p^\beta\left(x^{(i)}\right) \propto \exp\left(-\beta\, G\left(x^{(i)}\right)\right)$. The KL divergence in $\mathcal{D}_\mathcal{X}$ from this Boltzmann distribution to q_θ is

$$\begin{aligned} F(\theta) &= \mathrm{KL}\left(p^\beta \| q_\theta\right) \\ &= \int_\mathcal{X} \mathrm{d}x\, p^\beta(x)\log\left(\frac{p^\beta(x)}{q_\theta(x)}\right). \end{aligned}$$

The minimizer of this KL divergence is given by

$$\theta^\dagger = \arg\min_\theta - \sum_{i=1}^{m}\frac{\exp\left(-\beta G\left(x^{(i)}\right)\right)}{h\left(x^{(i)}\right)}\log\left(q_\theta\left(x^{(i)}\right)\right). \qquad (12)$$

This approach is an approximation to a regularized version of the naive MCO estimate of the θ that minimizes $\mathbb{E}_{q_\theta}(G)$. The application of the technique of regularization in this context has the same motivation as it does in PL: to reduce bias plus variance.

Log-Concave Densities

If q_θ is log-concave in its parameters θ, then the minimization problem in (12) is a convex optimization problem, and the optimal parameters can be found closed-form. Denote the likelihood ratios by $s^{(i)} = \exp(-\beta G(x^{(i)}))/h(x^{(i)})$. Differentiating (12) with respect to the parameters μ and Σ^{-1} and setting them to zero yields

$$\mu^\star = \frac{\sum_\mathcal{D} s^{(i)} x^{(i)}}{\sum_\mathcal{D} s^{(i)}}$$

$$\Sigma^\star = \frac{\sum_\mathcal{D} s^{(i)}\left(x^{(i)}-\mu^\star\right)\left(x^{(i)}-\mu^\star\right)^T}{\sum_\mathcal{D} s^{(i)}}$$

Mixture Models

The single Gaussian is a fairly restrictive class of models. Mixture models (see ▶ Mixture Modeling) can significantly improve flexibility, but at the cost of convexity of the KL distance minimization problem. However, a plethora of techniques from supervised learning, in particular the expectation maximization (EM) algorithm, can be applied with minor modifications.

Suppose q_θ is a mixture of M Gaussians, that is, $\theta = (\mu, \Sigma, \phi)$ where ϕ is the mixing p.m.f, we can view the problem as one where a hidden variable z decides which mixture component each sample is drawn from. We then have the optimization problem

$$\text{minimize} - \sum_{\mathcal{D}} \frac{p\left(x^{(i)}\right)}{h\left(x^{(i)}\right)} \log\left(q_\theta\left(x^{(i)}, z^{(i)}\right)\right).$$

Following the standard EM procedure, we get the algorithm described in (13). Since this is a nonconvex problem, one typically runs the algorithm multiple times with random initializations of the parameters.

$$\text{E-step: For each i, set} \quad Q_i\left(z^{(i)}\right) = p\left(z^{(i)}|x^{(i)}\right),$$

$$\text{that is,} \quad w_j^{(i)} = q_{\mu,\Sigma,\phi}\left(z^{(i)} = j|x^{(i)}\right), \quad j = 1, \dots, M.$$

$$\text{M-step: Set} \quad \mu_j = \frac{\sum_{\mathcal{D}} w_j^{(i)} s^{(i)} x^{(i)}}{\sum_{\mathcal{D}} w_j^{(i)} s^{(i)}},$$

$$\Sigma_j = \frac{\sum_{\mathcal{D}} w_j^{(i)} s^{(i)} \left(x^{(i)} - \mu_j\right)\left(x^{(i)} - \mu_j\right)^T}{\sum_{\mathcal{D}} w_j^{(i)} s^{(i)}},$$

$$\phi_j = \frac{\sum_{\mathcal{D}} w_j^{(i)} s^{(i)}}{\sum_{\mathcal{D}} s^{(i)}}.$$

Test Problems

To compare the performance of this algorithm with and without the use of PL techniques, we use a couple of very simple academic problems in two and four dimensions – the Rosenbrock function in two dimensions, given by

$$G_R(x) = 100(x_2 - x_1^2)^2 + (1 - x_1)^2,$$

and the Woods function in four dimensions, given by given by

$$\begin{aligned} G_{\text{Woods}}(x) = {} & 100(x_2 - x_1)^2 + (1 - x_1)^2 \\ & +90(x_4 - x_3^2)^2 + (1 - x_3)^2 \\ & +10.1\left[(1 - x_2)^2 + (1 - x_4)^2\right] \\ & +19.8(1 - x_2)(1 - x_4). \end{aligned}$$

For the Rosenbrock, the optimum value of 0 is achieved at $x = (1, 1)$, and for the Woods problem, the optimum value of 0 is achieved at $x = (1, 1, 1, 1)$.

Application of PL Techniques

As mentioned above, there are many PL techniques beyond regularization that are designed to optimize the trade-off between bias and variance. So having cast the solution of $\arg\min_{q_\theta} \mathbb{E}(G)$ as an MCO problem, we can apply those other PL techniques instead of (or in addition to) entropic regularization. This should improve the performance of our MCO algorithm, for the exact same reason that using those techniques to trade off bias and variance improves performance in PL. We briefly mention some of those alternative techniques here.

The overall MCO algorithm is broadly described in Algorithm 1. For the Woods problem, 20 samples of x are drawn from the updated q_θ at each iteration, and for the Rosenbrock, 10 samples. For comparing various methods and plotting purposes, 1,000 samples of $G(x)$ are drawn to evaluate $\mathbb{E}_{q_\theta}[G(x)]$. Note: in an actual optimization, we will not be drawing these test

Algorithm 1 Overview of pq minimization using Gaussian mixtures

```
Draw uniform random samples on $X$
Initialize regularization parameter $\beta$
Compute $G(x)$ values for those samples
repeat
    Find a mixture distribution $q_\theta$ to minimize sampled $pq$ KL distance
    Sample from $q_\theta$
    Compute $G(x)$ for those samples
    Update $\beta$
until Termination
Sample final $q_\theta$ to get solution(s).
```

samples! All the performance results in Fig. 1 are based on 50 runs of the PC algorithm, randomly initialized each time. The sample mean performance across these runs is plotted along with 95 % confidence intervals for this sample mean (shaded regions).

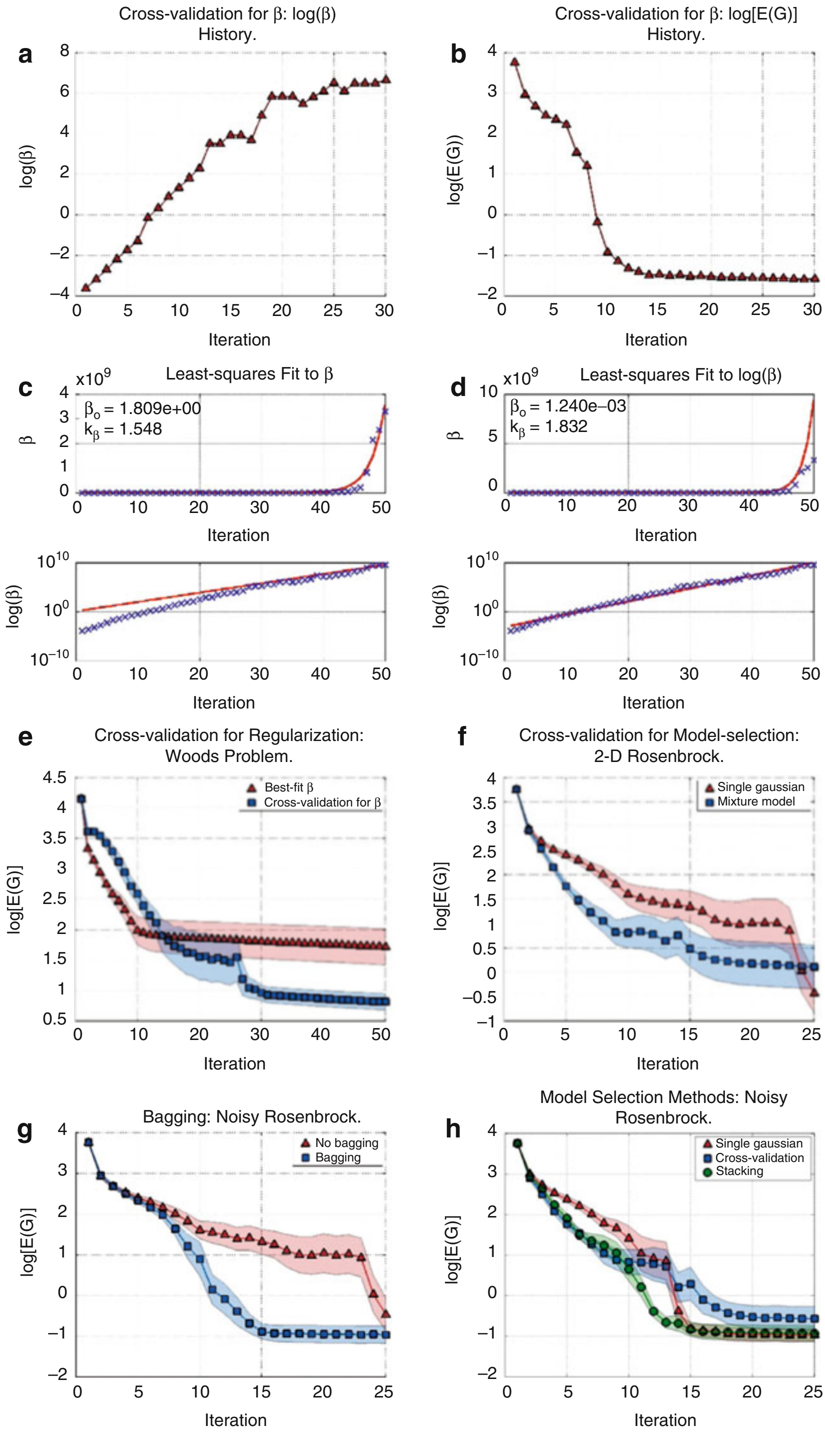
▸ *Cross-Validation for Regularization:* We note that we are using regularization to reduce variance, but that regularization introduces bias. As is done in PL, we use standard k-fold cross-validation to trade-off this bias and variance. We do this by partitioning the data into k disjoint sets. The held-out data for the ith fold is just the ith partition, and the held-in data is the union of all other partitions. First, we "train" the regularized algorithm on the held-in data $\mathcal{D}_t$ to get an optimal set of parameters $\theta^\star$ and then "test" this $\theta^\star$ by considering unregularized performance on the held-out data $\mathcal{D}_v$. In our context, "training" refers to finding optimal parameters by KL distance minimization using the held-in data, and "testing" refers to estimating $\mathbb{E}_{q_\theta}[G(x)]$ on the held-out data using the following formula (Robert and Casella 2004).

$$\widehat{g}(\theta) = \frac{\displaystyle\sum_{\mathcal{D}_v} \frac{q_\theta\left(x^{(i)}\right) G\left(x^{(i)}\right)}{h\left(x^{(i)}\right)}}{\displaystyle\sum_{\mathcal{D}_v} \frac{q_\theta\left(x^{(i)}\right)}{h\left(x^{(i)}\right)}}.$$

We do this for several values of the regularization parameter β in the interval $k_1\beta < \beta < k_2\beta$ and choose the one that yield the best held-out performance, averaged over all folds. For our experiments, $k_1 = 0.5, k_2 = 3$, and we use five equally spaced values in this interval. Having found the best regularization parameter in this range, we then use *all* the data to minimize KL distance using this optimal value of β. Note that all cross-validation is done *without* any additional evaluations of $G(x)$. Cross-validation for β in PC is similar to optimizing the annealing schedule in simulated annealing. This "auto-annealing" is seen in Fig. 1a, which shows the variation of β with iterations of the Rosenbrock problem. It can be seen that β value sometimes decreases from one iteration to the next. This can never happen in any kind of "geometric annealing schedule," $\beta \leftarrow k_\beta \beta,\ k_\beta > 1$, of the sort that is often used in most algorithms in the literature. In fact, we ran 50 trials of this algorithm on the Rosenbrock and then computed a best-fit geometric variation for β, that is, a nonlinear least squares fit to variation of β and a linear least squares fit to the variation of $\log(\beta)$. These are shown in Fig. 1c, d. As can be seen, neither is a very good fit. We then ran 50 trials of the algorithm with the fixed update rule obtained by best-fit to $\log(\beta)$ and found that the adaptive setting of β using cross-validation performed an order of magnitude better, as shown in Fig. 1e.

Cross-Validation for Model Selection: Given a set Θ (sometimes called a model class) to choose θ from, we can find an optimal $\theta \in \Theta$. But how do we choose the set Θ? In PL, this is done using cross-validation. We choose that set Θ such that $\arg\min_{\theta\in\Theta} \hat{F}(\theta)$ has the best held-out performance. As before, we use that model class Θ that yields the lowest estimate of $\mathbb{E}_{q_\theta}[G(x)]$ on the held-out data. We demonstrate the use of this PL technique for minimizing the Rosenbrock problem, which has a long curved valley that is poorly approximated by a single Gaussian. We use cross-validation to choose between a Gaussian mixture with up to four components. The improvement in performance is shown in Fig. 1d.

Bagging: In bagging (Breiman 1996a), we generate multiple data sets by resampling the given data set with replacement. These new data sets will, in general, contain replicates. We "train" the



Bias-Variance Trade-Offs: Novel Applications, Fig. 1 Various PL techniques improve MCO performance learning algorithm on each of these resampled data sets and average the results. In our case, we average the q_θ got by our KL divergence minimization on each data set. PC works even on stochastic objective functions, and on the noisy Rosenbrock, we implemented PC with bagging by resampling ten times and obtained significant performance gains, as seen in Fig. 1g.

Stacking: In bagging, we combine estimates of the same learning algorithm on different data sets generated by resampling, whereas in stacking (Breiman 1996b; Smyth and Wolpert 1999), we combine estimates of different learning algorithms on the same data set. These combined estimated are often better than any of the single estimates. In our case, we combine the q_θ obtained from our KL divergence minimization algorithm using multiple models Θ. Again, Fig. 1h shows that cross-validation for model selection performs better than a single model, and stacking performs slightly better than cross-validation.

Conclusions

The conventional goal of reducing bias plus variance has interesting applications in a variety of fields. In straightforward applications, the bias-variance trade-offs can decrease the MSE of estimators, reduce the generalization error of learning algorithms, and so on. In this article, we described a novel application of bias-variance trade-offs: we placed bias-variance trade-offs in the context of MCO and discussed the need for higher moments in the trade-off, such as a bias-variance-covariance trade-off. We also showed a way of applying just a bias-variance trade-off, as used in parametric learning, to improve the performance of MCO algorithms.

Bias-Variance-Covariance Decomposition

The bias-variance-covariance decomposition is a theoretical result underlying ▶ ensemble learning algorithms. It is an extension of the ▶ bias-variance decomposition, for linear combinations of models. The expected squared error of the ensemble $\bar{f}(x)$ from a target d is:

$$\mathcal{E}_{\mathcal{D}}\{\bar{f}(x) - d)^2\} = \overline{\text{bias}}^2 + \frac{1}{T}\overline{\text{var}} + \left(1 - \frac{1}{T}\right)\overline{\text{covar}}.$$

The error is composed of the average bias of the models, plus a term involving their average variance, and a final term involving their average *pairwise covariance*. This shows that while a single model has a two-way bias-variance tradeoff, an ensemble is controlled by a three-way tradeoff. This ensemble tradeoff is often referred to as the *accuracy-diversity* dilemma for an ensemble. See ▶ ensemble learning for more details.

Bilingual Lexicon Extraction

Bilingual lexicon extraction is the task of automatically identifying a terms in a first language and terms in a second language which are translation f one another. In this context, a term can be either a single word or an expression composed of several words the full meaning of which cannot be derived compositionally from the meaning of the individual words. Bilingual lexicon extraction is itself a form of ▶ cross-lingual text mining and is an essential preliminary step in many approaches for performing other ▶ cross-lingual text mining tasks.

Biological Learning: Synaptic Plasticity, Hebb Rule and Spike Timing Dependent Plasticity

Wulfram Gerstner
Brain Mind Institute, Lausanne EPFL, Lausanne, Switzerland

Synonyms

Correlation-based learning; Hebb rule; Hebbian learning

Definition

The brain of humans and animals consists of a large number interconnected neurons. Learning in biological neural systems is thought to take place by changes in the connections between these neurons. Since the contact points between two neurons are called synapses, the change in the connection strength is called synaptic plasticity. The mathematical description of synaptic plasticity is called a (biological) learning rule. Most of these biological learning rules can be categorized in the context of machine learning as unsupervised learning rules, and the remaining ones as reward-based or reinforcement learning. The Hebb rule is an example of an unsupervised correlation-based learning rule formulated on the level of neuronal firing rates. Spike-timing-dependent plasticity (STDP) is an unsupervised learning rule formulated on the level of spikes. Modulation of learning rates in a Hebb rule or STDP rule by a diffusive signal carrying reward-related information yields a biologically plausible form of a reinforcement learning rule.

Motivation and Background

Humans and animals can adapt to environmental conditions and learn new tasks. Learning becomes measurable by changes in the behavior: humans and animals get better at seeing and distinguishing visual objects with experience; animals can learn to go to a target location; humans can memorize a list words and recall the items 2 days later. How learning is implemented in the biological substrate is only partially known.

The brain consists billions of neurons. Each neuron has long wire-like extensions and makes contacts with thousands of other neurons. This network of neurons is not fixed but constantly changes. Connections can be formed or can disappear, and existing connections can be strengthened or weakened. Neuroscientists have shown in numerous experiments that changes can be induced by stimulating neuronal activity in an appropriate fashion. Moreover, changes in synaptic connections that have been induced in one or a few seconds can persist for hours or days, an effect called long-term potentiation (LTP) or long-term depression (LTD) of synapses.

The question arises of whether such long-lasting changes in connections are useful for learning. To answer this question, research in theoretical and computational neuroscience needs to solve two problems: First, develop a compact but realistic description of the phenomenon of synaptic plasticity observed in biology, i.e., extract learning rules from the biological data; and second, study the functional consequences of these learning rules. An important insight from experiments on LTP is that the activation of a synaptic connection alone does not lead to a long-lasting change; however, if the activation of the synapses by presynaptic signals is combined with some activation of the postsynaptic neuron, then a long-lasting change of the synapse may occur. The coactivation of presynaptic and postsynaptic neurons as a condition for learning is the key ingredient of Hebbian learning rules. Here, activation of the presynaptic neuron means that it fires one or several action potentials; activation of the postsynaptic neuron can be represented by high firing rates, a few well-timed action potentials or input from other neurons that lead to an increase in the membrane voltage.

Structure of the Learning System

The Hebb Rule

Hebbian learning rules are local, i.e., they depend only on the state of the presynaptic and postsynaptic neurons plus possibly the current value of the synaptic weight itself. Let w_{ij} denotes the weight between a presynaptic neuron j and a postsynaptic neuron i, and let us describe the activity (e.g., the firing rate) each neuron by a continuous variable ν_j and ν_i, respectively. Mathematically, we may therefore write for a local learning rule

$$\frac{\mathrm{d}}{\mathrm{d}t} w_{ij} = F(w_{ij}; \nu_i, \nu_j) \tag{1}$$

where F is an unknown function. In addition to locality, Hebbian learning requires some kind of cooperation or correlation between the activity of the presynaptic neuron and that of the postsynaptic neuron. At the moment we restrict ourselves to the requirement of *simultaneous activity* of presynaptic and postsynaptic neurons. Since F is a function of the rates ν_i and ν_j, we may expand F about $\nu_i = \nu_j = 0$. An expansion to second order of the rates yields

$$\begin{aligned}\frac{\mathrm{d}}{\mathrm{d}t} w_{ij}(t) \approx\, & c_0(w_{ij}) + c_1^{\text{pre}}(w_{ij})\nu_j + c_1^{\text{post}}(w_{ij})\nu_i \\ & + c_2^{\text{corr}}(w_{ij})\nu_i\nu_j + c_2^{\text{post}}(w_{ij})\nu_i^2 \\ & + c_2^{\text{pre}}(w_{ij})\nu_j^2 + O(\nu^3).\end{aligned} \tag{2}$$

Here, ν_i and ν_j are functions of time, i.e., $\nu_i(t)$ and $\nu_j(t)$ and so is the weight w_{ij}. The bilinear term $\nu_i(t)\nu_j(t)$ is sensitive to the instantaneous *correlations* between presynaptic and postsynaptic activities. It is this term that makes Hebbian learning a useful concept. The simplest implementation of Hebbian plasticity would be to require $c_2^{\text{corr}} > 0$ and set all other parameters in the expansion (2) to zero

$$\frac{\mathrm{d}}{\mathrm{d}t} w_{ij} = c_2^{\text{corr}}(w_{ij})\nu_i\nu_j. \tag{3}$$

Equation (3) with fixed parameter $c_2^{\text{corr}} > 0$ is the prototype of Hebbian learning. However, since the activity variables ν_i and ν_j are always positive, such a rule will lead eventually to an increase of all weights in a network. Hence, some of the other terms (e.g., c_0 or c_1^{pre}) need to have a negative coefficient to make Hebbian learning stable. In passing we note that a learning rule with $c_2^{\text{corr}} < 0$ is usually called anti-Hebbian.

Oja's rule. A particular interesting case is a model with coefficients $c_2^{\text{corr}} > 0$ and $c_2^{\text{post}} < 0$, since it guarantees the normalization of the set of weights $w_{i1}, \ldots w_{iN}$ converging onto the same postsynaptic neuron i.

BCM rule. The Bienenstock–Cooper–Munro learning rule (also called BCM rule) with

$$\frac{\mathrm{d}}{\mathrm{d}t} w_{ij} = a(w_{ij})\Phi(\nu_j - \vartheta)\nu_j \tag{4}$$

where Φ is some nonlinear function with $\Phi(0) = 0$ is a special case of (1). The parameter ϑ depends on the average firing rate.

Temporally asymmetric Hebbian learning. In the Taylor expansion (2) we focused on *instantaneous* correlations. More generally, we can use a Volterra expansion so as to also include temporal correlations with nonzero time lag. With the additional assumptions that changes are instantaneous, a Volterra expansion generates terms of the form

$$\frac{\mathrm{d}}{\mathrm{d}t} w_{ij} \propto \int_0^\infty [W_+(s) v_i(t) v_j(t-s) + W_-(s) v_j(t) v_i(t-s)] \mathrm{d}s \qquad (5)$$

with some functions W_+ and W_-. For reasons of causality, W_+ and W_- must vanish for $s < 0$. Since $W_+(s) \neq W_-(s)$, learning is asymmetric in time so that learning rules of the form (5) are called temporally asymmetric Hebbian learning. In the special case $W_+(s) = -W_-(s)$, we have antisymmetric Hebbian learning. The functions W_+ and W_- may depend on the present weight value.

STDP rule. STDP is a form of Hebbian learning with increased temporal resolution. In contrast to rate-based Hebb models, neuronal activity is described by the firing times of the neuron, i.e., the moments when the presynaptic and postsynaptic neurons emit action potentials. Let t_j^f denote the fth spike of the presynaptic neuron j and t_i^n the nth spike of the postsynaptic neuron i. The weight change in an STDP rule depends on the exact timing presynaptic and postsynaptic spikes

$$\frac{\mathrm{d}}{\mathrm{d}t} w_{ij} = \sum_n \sum_f [A(w_{ij}; t - t_j^f)\delta(t - t_i^n) + B(w_{ij}; t - t_i^f)\delta(t - t_j^f)] \qquad (6)$$

where $A(x)$ and $B(x)$ are some real-valued functions with $A(w_{ij}, x) = B(w_{ij}, x) = 0$ for $x < 0$. Thus, at the moment of a postsynaptic spike the synaptic weight is updated by an amount that depends on the time $t_i^f - t_j^f$ since a previous presynaptic spike t_j^f. Similarly, at the moment of a presynaptic spike the synaptic weight is updated by an amount that depends on the time $t_j^f - t_i^f$ since a previous postsynaptic spike t_i^f. The dependence on the present value w_{ij} can be used to keep the weight in a desired range $0 < w_{ij} < w^{\max}$. A standard choice for the functions A and B is $A(w_{ij}); t - t_j^f = A_+(w_{ij}) \exp[-(t - t_j^f)/\tau_+]$ for $t - t_j^f > 0$ and zero otherwise. Similarly, $B(w_{ij}; t - t_i^n) = B_-(w_{ij}) \exp[-(t - t_i^n)/\tau_-]$ for $t - t_i^f > 0$ and zero otherwise. Here, τ_+ and τ_- are time constants in the range of 10–50 ms. The case $A_+(x) = (w^{\max} - x)c_+$ and $B_x(x) = -c_- x$ is called soft bounds. The choice $A_+(x) = c_+ \Theta(w^{\max} - x)$ and $B_x = -c_- \Theta(x)$ is called hard bounds. Here, c_+ and c–are positive constants. The term proportional to A_+ causes potentiation (weight increase), the one proportional to A_- causes depression (weight decrease) of synapses. Note that the STDP rule (6) can be interpreted as a spike-based form of temporally asymmetric Hebbian learning.

Functional Consequences of Hebbian Learning

Sensitivity to correlations. All Hebbian learning rules are sensitive to the correlations between the activity of the presynaptic neuron j and that of the postsynaptic neuron i. If the activity of the postsynaptic neuron is given by a linear sum of all inputs rates, i.e., $v_i = \gamma \Sigma_j w_{ij} v_j$, then correlations between presynaptic and postsynaptic activities can be traced back to correlations in the input. A particular clear example of learning driven by correlations in the input is Oja's learning rule applied to a statistical ensemble of inputs with zero mean. In this case, the postsynaptic neuron becomes sensitive to the dominant principal component of the input ensemble. If the neuron model is nonlinear, Hebbian learning extracts the independent components of the statistical input ensemble. These two examples show that learning by a Hebbian learning rule makes neurons adapt to the statistics of the input. While the condition of zero-mean input is biologically not realistic (because neuronal firing rates are always positive), this condition can be relaxed so that the same result is also applicable to biologically plausible learning rules.

Receptive fields and cortical maps. Neurons in the primary visual cortex of cats and monkeys respond to visual stimuli in a localized region of the visual field. This small sensitive zone is called the receptive field of the neuron. Neighboring neurons normally have very similar receptive fields. The exact location and properties of the receptive field are not fixed, but can be influenced by sensory stimulation. Models of unsupervised Hebbian learning can explain the development of receptive fields and the adaptation of cortical maps to the statistics of the ensemble of stimuli.

Beyond the Hebb rule. Standard models of Hebbian learning are formulated on the level of neuronal firing rates, a graded variable characterizing neuronal activity. However, real neurons communicate by spikes, short electrical pulses or "action potentials" with a rather stereotyped time course. Experiments have shown that the changes of synaptic efficacy depend not only on the mean firing rate of action potentials but on the relative timing of presynaptic and postsynaptic spikes on the level milliseconds. This Spike-Timing Dependent Synaptic Plasticity (STDP) can be considered a temporally more precise form of Hebbian learning. The STDP rule indicated above supposes that pairs of spikes (one presynaptic and one postsynaptic action potential) within some time window cause a weight change. However, experimentally it was shown that at least three spikes are necessary (one presynaptic and two postsynaptic spikes). Moreover, the voltage of the postsynaptic neuron matters even in the absence of spikes.

In most models of Hebbian learning and STDP, the factors $c_0, c_1^{\text{pre}} \ldots$ are constant or depend only on the synaptic weight. However, in biological context the speed of learning is often gated by neuromodulators. Since some of these neuromodulators contain reward-related information, one can think of learning as a three-factor rule where weight changes depend on presynaptic activity, postsynaptic activity, and the presence of a reward-related factor. A prominent neuro-modulator linked to reward information is dopamine. Three factor learning rules fall in the class of reinforcement learning algorithms.

Introduction

Recent years have witnessed a tremendous increase in the use of machine learning for biomedical applications. This surge in interest has several causes. One is the successful application of machine learning technologies in other fields such as web search, speech and handwriting recognition, agent design, spatial modeling, etc. Another is the development of technologies that enable the production of large amounts of data in the time it used to take to generate a single data point (run a single experiment). A third most recent development is the advent of electronic medical/health records (EMRs/EHRs). The drastic increase in the amount of data generated has led the biologists and clinical researchers to adopt algorithms that can construct predictive models from large amounts of data. Naturally, machine learning is emerging as a tool of choice.

In this entry, we will present a few data types and tasks involving such large-scale biological data, where machine learning techniques have been applied. For each of these data types and tasks, we first present the required background, followed by the challenges involved in addressing the tasks. Then, we present the machine learning techniques that have been applied to these data sets. Finally and most importantly, we present the lessons learned in these tasks. We hope that these lessons will be helpful to researchers who aim to apply machine learning algorithms to biological applications and equip them with useful knowledge when they collaborate with biological scientists.

Some of the data types that we present in this work are:

- Gene expression microarrays
- SNPs and genetic data
- Mass spectrometry and other proteomic data
- High-throughput screening data for drug design
- Electronic medical records (EMR) and personalized medicine

Some of the key lessons learned from all these data types include the following: (1) We can often do surprisingly well with far more features than data points if there are many highly predictive features (e.g., predicting cancer from microarray data) and if we use methods that are robust to overfitting such as *voted decision stumps* (Hardin et al. 2004; Waddell et al. 2005) (ensemble learning and decision stumps), *naive Bayes* (Golub et al. 1999; Listgarten et al. 2004), or *linear SVMs* (Furey et al. 2000; Hardin et al. 2004). (2) Bayes net learning (Friedman 2000) often does not give us causality, but active learning and time-series data help if available (Pe'er et al. 2001; Ong et al. 2002; Tucker et al. 2005; Zou and Conzen 2005). (3) Multi-relational methods are useful for EMRs or molecular data as the data in these cases are very highly relational. (4) There are more important issues than just increasing the accuracy of the learned model on these data sets. Such issues include how data was created, its comprehensibility (physicians typically want to understand the model that has been learned), and its privacy (some data sets contain private information that cannot be posted on public websites and cannot even be downloaded off-site).

The rest of the entry is organized as follows: First, we present gene expression microarrays, followed by SNPs and other genetic data. We then present mass spectrometry (MS) and related proteomic data. Next, we present high-throughput screening data for drug design, followed by EMR data and personalized medicine. For each of these data types, we motivate the problem and survey the different machine learning solutions. Finally, we conclude by outlining the lessons learned from all these data types and presenting some interesting and exciting directions for future research.

Gene Expression Microarrays

This data type was presented in detail in *AI Magazine* (Molla et al. 2004), and hence we will brief it in this section. We encourage the reader to read Molla et al. (2004) for more details on this data type. Genes are contained in the DNA of an organism. The mechanism by which proteins are produced from their corresponding genes is a two-step process. The first step is the *transcription* of a gene into a messenger RNA (mRNA), and in the second step called as *translation*, a protein is built using mRNA as a blueprint.

One property that DNA and RNA have in common is that each is a chain of chemicals called as *bases*. In the case of DNA, these bases are *adenine*, *cytosine*, *guanine*, and *thymine*, commonly referred to as A, C, G, and T, respectively. RNA has the same set of four bases, except thymine; RNA has *uracil*, commonly referred as U. An important characteristic of DNA and RNA is *complementarity*, that is, each base only binds well with its complement: A with T (or U) and G with C. As a result of complementarity, a strand of either DNA or RNA has a strong affinity toward what is known as its *reverse complement*, which is a strand of either DNA or RNA that has bases exactly complementary to the original strand. Complementarity is central to the processes of replication of the DNA and transcription.

In addition, complementarity can be used to detect specific sequences of bases within strands of DNA and RNA. This is done by first synthesizing a *probe*, a piece of DNA that is the complement of a sequence that one wants to detect, and then introducing this probe to a solution containing the genetic material (DNA or RNA) to be searched. This solution of genetic material is called the *sample*. In theory, the probe will bind to the sample if and only if the probe finds its complement in the sample (in reality, this process is often imperfect). The act of binding between a sample and probe is called *hybridization*. Prior to the experiment, a biologist labels the probe using a florescent flag. After the hybridization experiment, one can easily scan to see if the probe has hybridized to its reverse complement in the sample. This allows the molecular biologist to determine the presence or absence of the sequence in the sample.

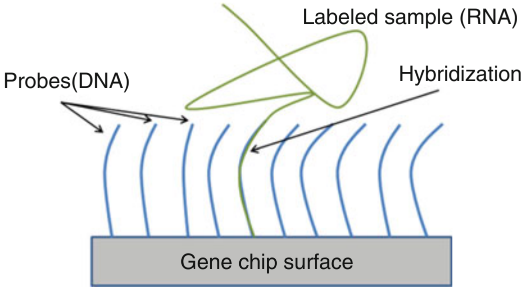
Gene Chips

DNA probe technology has been adapted for detection of tens of thousands of sequences simultaneously. This has become possible due to the device called a *microarray* or *gene chip*, the working of which is illustrated in Fig. 1. When using the chips, it is more common to label (luminescently) the samples than the probe. Thousands of copies of this labeled sample are spread across the probe, followed by washing away any copies that do not remain bound. Since the probes are attached at specific locations on the chip, if a labeled sample is detected at any position in the chip, the probe that is hybridized to its complement can be easily determined. The most common use of these gene chips is to measure the expression levels of various genes in the organism.

Probes are typically on the order of 25 bases long, whereas samples are usually about 10 times as long, with a large variation due to the process that breaks up long sequences of RNA into small samples (Molla et al. 2004).

To understand about the biology of an organism, say to understand human biology to design new drugs or lower the blood pressure or to cure diabetes, there is a necessity to understand the degree to which different genes get expressed as proteins under different conditions and different cell types. It is much easier to estimate the amount of mRNA for a gene than the protein-production rate. Microarrays provide the measurement of RNAs corresponding to the given gene rather than the amounts of protein.

In brief, experiments with the microarrays are performed as follows: As can be seen from the figure, probes are DNA strands attached to the gene chip surface. A typical probe length is



Biomedical Informatics, Fig. 1 Hybridization of sample to probe

25 bases (i.e., 25 letters from A, C, G, T to represent a gene). There may be several different subsequences of these 25 bases. Then the mRNA (which is the labeled sample) is passed over the microarrays, and the mRNA will bind to the complementary DNA corresponding to the gene better than the other DNA strings. Then the florescence levels of the different gene chips segments are measured, which in turn measures the amount of mRNA on that surface. This mRNA measurement serves as a surrogate to the expression level of the gene.

Machine Learning for Microarrays

The data from microarrays (gene chips) have been analyzed and used by machine learning researchers in two different ways:

1. Data points are genes. This is the case where the examples are genes while the features are the samples (measured expression levels of a single gene under a variety of conditions). The goal of this view is to categorize new genes based on the current set of examples.
2. Data points are samples (e.g., patients). This is the case where the examples are patients and the features are the measured expression levels of genes under one condition.

The problems have been approached in two different ways. In the unsupervised learning approach, the goal is to cluster the genes according to their expression levels or to cluster the patients (samples) based on their gene expression levels or both. Hierarchical clustering is especially widely applied. As one of many examples, see Perou et al. (1999). In the supervised learning setting, the class labels are the category of the genes or the samples. The latter is the more common supervised task, each sample being mRNA from a different patient (with the same cell type from each patient) or an organism under different conditions to learn a model that accurately predicts the class based on the features. The features could be the patient's expression values for each gene, while the class labels might be the patient's disease state. We discuss this task further in the subsequent paragraphs.

Yet another widely studied supervised learning task is to predict cancer vs. normal for a wide variety of cancer types. One of the significant lessons learned is that it is easy to predict cancer vs. normal in patients based on the gene expression by several machine learning techniques, largely regardless of the type of cancer. The main reason for this is that if cancer is present, many genes in the cancer cells "go haywire" and hence are very predictive of the cancer. The primary challenge in this prediction problem is the noise in the data (impure RNA, cross-hybridization, etc.).

Other related tasks that have been addressed include distinguishing related cancer types and distinguishing cancer from a related benign condition. An early success was a work by Golub et al. (1999), distinguishing acute myeloid leukemia and acute lymphoblastic leukemia (ALL). They used a weighted voting algorithm similar to naive Bayes and achieved a very high accuracy. This result has been repeated on this data with many other machine learning (ML) approaches. Other work examined multiple myeloma vs. benign condition. This task is challenging because the benign condition is very similar to the cancer, and hence the machine learning algorithms had a difficult time predicting accurately. We refer to Hardin et al. (2004) for more details on the experiments.

Another important lesson for machine learning researchers from this data type is that the biologists often do not want one predictive model, but a rank-ordered list of genes that a biologist can explore further with additional lab tests on certain genes. Hence, there is a need to present a small set of highly interesting genes to perform follow-up experiments on. Toward this end, statisticians have used mutual information or a t-test to rank the genes. When using a t-test, they check if the mean expression levels are different under the two conditions (cancer vs. normal), yielding a p-value. But the issue is that when working with a large number of genes (typically in the order of 30,000), there could be some genes with lower p-value by chance. This is known as the "multiple comparisons problem." One solution is to do a Bonferroni correction (multiply p-values by the number of genes), but this can be a drastic step and may eliminate all the genes. There are other methods such as false discovery rate (Storey and Tibshirani 2003) that uses the notion of q-values. We do not go into detail of this method. But the key recommendation we make is that such a method should be used along with the supervised learning method, as the biological collaborators might be interested in the ranking of genes.

One of the most important research directions for the use of microarray data lies in the prognosis and treatment. The features are the same as those of diagnosis, but the class value becomes life expectancy for a given treatment (or a positive response vs. no response to a given treatment). The goal is to use the person's genes to make these predictions. An example of this is the breast cancer prognosis study (Van't Veer et al. 2002), where the goal is to predict good prognosis (no metastasis within 5 years of initial diagnosis) vs. poor prognosis. They used an ensemble of voting algorithms and obtained very good results. Nevertheless, an important lesson learned from this experiment and others was that when using cross-validation, there is a need to tune parameters and perform feature selection *independently* on *each fold* of the cross-validation. There can be a large number of features, and it is natural to want to reduce the size of the data set before working with it. But reducing the number of features by some measure of correlation with the class, such as information gain, using the entire data set means that on each fold of cross-validation, information has leaked from the labeled test set into the training process – labels of test cases were used to eliminate many features from the training set. Hence, selecting features by looking at the entire data set can partially negate the effect of cross-validation, sometimes yielding accuracy estimates that are more than 10 % points overly optimistic. Hence the entire training process of selecting features, tuning parameters, and learning a model must be repeated for every fold in cross-validation by looking only at the training data for that fold.

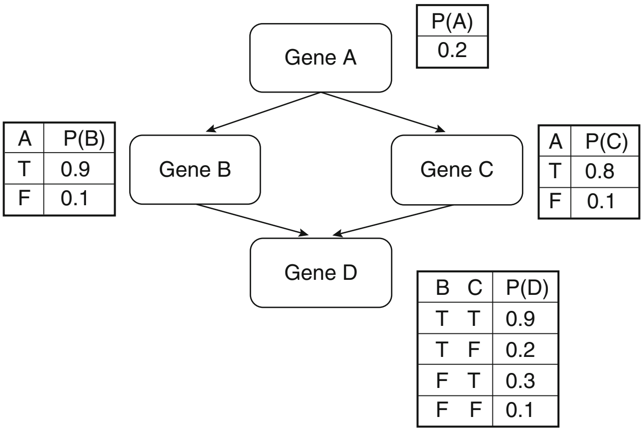
An important use of microarrays for prognosis and therapy is in the area of predictive personalized medicine (PPM). While we present the idea of PPM later in the entry, it must be mentioned that combining gene expression data with clinical trials of the patients to recommend the best treatment for the patients is a very exciting problem with promising impact in the area of PPM.

Bayesian Networks for Regulatory Pathways: Bayes nets have been one of the successful machine learning methods used for the analysis of microarray data. Recall that a Bayes net is a directed acyclic graph, such as the one shown in Fig. 2 that defines a joint distribution over the variables using a set of conditional distributions. Friedman and Halpern (1999) were the first to use Bayes nets for the microarray data type. In particular, the problem that was considered was finding regulatory pathways in genes. This problem can be posed as a supervised learning task as follows:

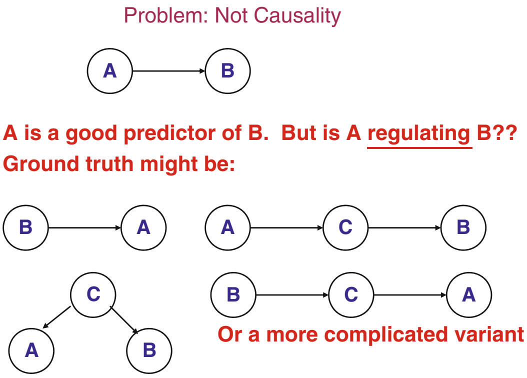
- *Given:* A set of microarray experiments for a single organism under different conditions.
- *Do:* Learn a graphical model that accurately predicts expression of some genes in terms of others.

Friedman and Halpern showed that using statistical methods, a Bayes net representing the observations (expression levels of different genes) can be learned automatically. A main advantage of Bayes nets is that they can (potentially) provide insight into the interaction networks within cells that regulate the expression of genes. But one has to exercise caution, interpreting the arcs of a learned Bayes net as representing causality. For example, in Fig. 2, one might interpret the network to mean that gene A causes gene B and gene C to be expressed, in turn influencing gene D. Note that, however, the Bayes net in this case just denotes the correlation and not the causality, that is, the direction of an arc merely represents the fact that one variable is a good predictor of the other, as illustrated in Fig. 3.

One possible method of learning causality is to use *knockout* methods (Pe'er et al. 2001), where



Biomedical Informatics, Fig. 2 A simple Bayes net. The actual learning task typically involves thousands of variables



Problem: Not Causality
A
B
A is a good predictor of B. But is A regulating B??
Ground truth might be:
B
A
A
C
B
C
A
B
B
C
A
Or a more complicated variant

Biomedical Informatics, Fig. 3 Why a learned Bayesian network may not be representing regulation of one gene by another

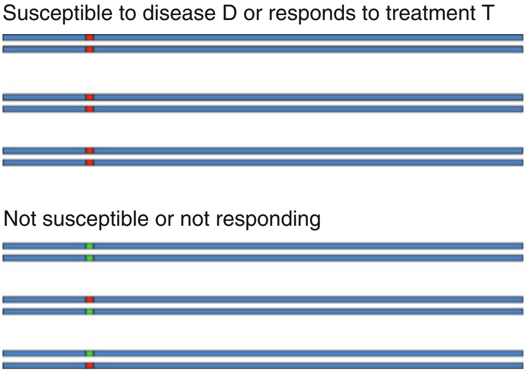
for 300 of the genes in *S. cerevisiae* (bakers' yeast), biologists have created a *knockout mutant* or a genetic mutant lacking that gene. If the parent of a gene in the Bayes net is knocked out and the child's status remains unchanged, then it is unlikely that the arc from the parent to the child captures causality. A key limitation is that the mutants are not available for many organisms. Some other approaches such as RNAi have been proposed for more efficiently doing knockouts, but a limitation is that RNAi typically reduces rather than eliminates expression of a gene.

Ong et al. (2002) used time-series data (data from the same organism at various time points) to partially address the issue of causality. They used these data to learn dynamic Bayesian networks in order to infer temporal direction for gene interactions, thereby getting a potentially better handle on causality. DBNs have been employed by other researchers for time-series gene expression data, and the approach has been extended to learn DBNs with continuous variables (Segal et al. 2005).

Single-Nucleotide Polymorphisms

Single-nucleotide polymorphisms (SNPs) are individual base positions (i.e., single-nucleotide positions) in DNA, where people (or the organism of interest) vary. Most of the variation in human DNA is due to SNP variations. (There are other variations such as copy number, insertions, and deletions that we do not consider in this entry.) There are well over three million known SNPs in humans. Technologies such as *Illumina* or *Affymetrix whole-genome* scan can measure a million SNPs in a short time. The measurement of these variations is an order of magnitude faster, easier, and cheaper than sequencing all the genes of the person.

It is believed that in the next decade, it will be possible to obtain the entire genome sequence for an individual human for under $1,000 (Mardis 2006). If we had every human's entire sequence, it could be used to predict the susceptibility of diseases for humans or the adverse reactions to drugs for a certain subset of patients. The idea is illustrated in Fig. 4. Suppose the red dots in the figure are two copies of nucleotide *A* and the green dots denote a different nucleotide, say



Susceptible to disease D or responds to treatment T
Not susceptible or not responding

Biomedical Informatics, Fig. 4 Example application of sequencing human genes. The top half is the case where patients respond to a treatment, and the bottom is the case where three patients do not respond to the treatment

C. As can be seen from the figure, people who respond to a treatment T (top half of the figure) have two copies of A (for instance, these could be the positive examples), while the people who do not respond to the treatment have at most one copy of A (negative examples and are presented in the bottom half of the figure). Now, we can imagine modeling the sequence to predict the susceptibility to a disease or responsiveness to a treatment.

SNP data can serve as a surrogate for the above problem. SNPs allow us to detect the variations among humans. An example of SNP data is presented in Fig. 5 for the prediction of *myeloma* cancer that is common with older people (with age >70) and is very rare in younger people (age <40). This data set consists of 40 people diagnosed with myeloma at young age and 40 people who weren't diagnosed till they were 70 when the disease is more common. Most SNP positions represent a pair of nucleotides and are typically restricted in the combinations of values they may assume. For example, in the figure, SNP 1 can take values from the three possible combinations $< \ CT, CC, TT \ >$ for its two positions. The goal is to use the feature values of the different SNPs to predict the class label which could be the susceptibility. That is, the goal is to determine genetic difference between people who got the disease at a young age vs. people who did not until they were old.

There is also the possibility of two patients having the same SNP pattern in the data but not the identical DNA. Patients 1 and 2 may have CT for the SNP1 and GA for SNP2, where both SNPs are on chromosome 1. But Patient 1 has C on SNP1 in the same copy of chromosome 1 as the G in SNP2, whereas Patient 2 has C on the same copy as an A. Hence, while they have the same SNP pattern of CT and GA, they do not have identical DNA. The process of converting the data from the form in the table below to the form above is called *phasing*. From a machine learning perspective, there is a choice of either working with the *unphased* data or to use an algorithm for phasing. It turns out that phasing is very difficult and is an active research area. If there are a number of unrelated patients, phasing is very hard. Hence many machine learning researchers work mainly with unphased data. Admittedly, there is a small loss of information with the unphased data that compensates for the difficulty of phasing.

Most biologists and statisticians using SNP data perform genome-wide association studies (GWAS). The goal in this work is to find individual SNPs that are significantly associated with disease, that is, such that one of the SNP values, or alleles, raises the risk of disease. This is typically measured by "relative risk" or by "odds ratio," and significance is typically measured by statistical tests such as Wald test, Score test, or LRLR (logistic regression log likelihood, where each SNP is used individually to predict disease, and log likelihood of the predictive model is compared to guessing under the null hypothesis that the SNP is not associated). One of many examples is the use of SNPs to predict susceptibility to breast cancer (Easton et al. 2007).

The advantages of SNP data compared to microarray data are the following: (1) Because SNP analysis is typically performed on DNA from saliva or peripheral blood cells, a person's SNP pattern does not change with time or disease. If the SNPs are collected from a blood sample of a person aged 40 years, the SNP patterns are probably the same as when they were born. This gives more insight to the susceptibility of the person to many diseases. Hence, we do not see the widespread changes in SNP pattern with cancer,

Person ▼ SNP▶	1	2	3	. . .	Class
Person 1	C T	A G	T T	. . .	Old
Person 2	C C	A G	C T	. . .	Young
Person 3	T T	A A	C C	. . .	Old
Person 4	C T	G G	T T	. . .	Young
. . .	. .	. . . .	.		
. . .	. .	. . . .	.		
. . .	. .	. . . .	.		

Biomedical Informatics, Fig. 5 Example of SNP data

for example, that we see in microarray data from tumor samples. (2) It is easier to collect the samples. These can be obtained from the blood samples as against obtaining, say, the biopsy of other tissue types.

The challenges of SNP data are as follows: (1) As explained earlier, the data is unphased. Algorithms exist for phasing (haplotyping), but they are error prone and do not work well with unrelated patient samples. They require the data to consist of related individuals in order to have a dense coverage. (2) Missing values are more common than in microarray data. The good news is that the amount of missing values is decreasing substantially (down from 30–40 % a few years ago to 1–2 %). (3) The sheer volume of measurements – currently, it is possible to measure a million SNPs out of over three million SNPs in the human genome. While this provides a tremendous amount of potential information, the resulting high dimensionality causes problems for machine learning. As with gene expression microarray data, we have a multiple comparisons problem, so approaches such as Bonferroni correction or q-values from false discovery rate can again be applied. But even when a significant SNP is found, it usually only increases our accuracy at predicting disease by 2 or 3 % points, because a single SNP typically either has a small effect or small penetrance (the variation is fairly rare – one value of the SNP is strongly predominant). So GWAS are missing a major opportunity to build predictive models by combining multiple SNPs with small effects – this is an exciting opportunity for machine learning.

The supervised learning task can be defined as follows:

- *Given:* A set of SNP profiles each from a different patient.

Phased: Nucleotides at each SNP position on each copy of *each chromosome* constitute the *features*, and patient's *disease susceptibility* or *drug response* constitutes the *class*.

Unphased: Unordered pair of nucleotides at each SNP position constitutes the *features*, and patient's *disease susceptibility* or *drug response* constitutes the *class*.

- *Do:* Learn a model to predict the class based on the features.

We now briefly present one example of supervised learning from SNP data. Waddell et al. (2005) found that there was evidence of a genetic component in predicting the blood cancer *multiple myeloma* as it was possible to distinguish the two cases significantly better than chance (71 % accuracy). The results from using support vector machines (SVMs) are presented in Fig. 6. Similar results were obtained using a naive Bayes model as well. Listgarten et al. (2004) also used the SNP data with the goal of predicting *lung cancer*. The accuracy of 69 % obtained by them was remark-

		Old	Young
Actual	Old	31	9
	Young	14	26

Biomedical Informatics, Fig. 6 Results on predicting multiple myeloma, young (susceptible) vs. old (less susceptible), 3,000 SNPs

ably similar to the task of predicting *multiple myeloma*. The best models for predicting lung cancer were also naive Bayes and SVMs. There is a striking similarity between the two experiments on unrelated tasks using SNPs. When only the individual SNPs were considered, the accuracy for both the experiments fell to 60 %.

The lessons learned from SNP data are the following: (1) Supervised learning algorithms such as naive Bayes and SVM that can handle a large number of features in the presence of smaller number of training examples can predict disease susceptibility at rates better than chance and better than individual SNPs. (2) Accuracies are much lower than the ones with microarray data.

This is mainly due to the fact that we are predicting the susceptibility to the diseases (or the response to a drug) as against predicting whether a person already has the disease (as with the microarray data). While we are predicting using the genetic component, there are also many environmental components that are responsible for the diseases and the response. We are not considering such components in our model, and hence the accuracies are often not very high. In spite of relatively lower accuracies, they give a different valuable insight to the human gene.

We now briefly outline a couple of exciting future directions for the use of SNP data. *Pharmacogenetics* is the problem of predicting drug response from SNP profile and has been gaining momentum over the past few years. This includes predicting drug efficacy and adverse reactions to certain drugs, given a person's SNP profile. A recent New England Journal of Medicine article showed that the analysis of SNPs can significantly improve the dosing model for the most widely used orally available blood thinner, warfarin (IWPC 2009). Another exciting direction is the combination of SNP data with other data types such as clinical data that includes the history of the patient and the lab tests and microarray data. The combination of these different data sets will not only improve the accuracy of the learned model but also provide a deeper insight to the different kinds of interactions that occur within a human, such as gene interactions with other drugs.

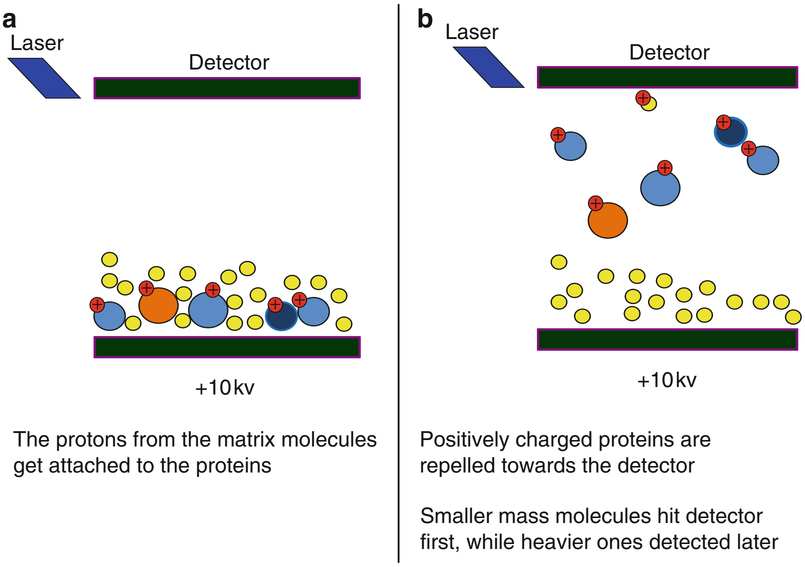
It should be mentioned that other genetic data types are becoming available and maybe useful for supervised learning as well. These data types can provide additional information about DNA sequence beyond SNPs but without the expense of full genome sequencing. They include copy-number variations and exon sequencing.

Mass Spectrometry and Proteomics

Microarrays are useful primarily because mRNA concentrations can serve as surrogates for protein concentrations and they are easier to measure. Though measuring protein concentrations directly is possible, it cannot be done in the same high-throughput manner as measuring mRNA. Recently, techniques such as *mass spectrometry* (MS or mass spec) have been successful in high-throughput measuring of proteins. Mass spec still does not give the complete coverage that microarrays provide, nor as good a quantitation.

Mass spectrometry is improving on many fronts, using many technologies. As one example, we present *time-of-flight* (*TOF*) *mass spectrometry* illustrated in Fig. 7. This measures the time required for an ionized particle starting from the sample plate (bottom of the figure) to hit the detector. The key idea is to place some proteins (indicated as larger circles) into a matrix (smaller circles are the matrix molecules). Because of mass spec limitations, the proteins typically are digested (broken into smaller peptides), for example, by the compound trypsin. When struck by a laser, the matrix molecules release protons that attach themselves to the peptides or protein fragments (shown in (a)). Note that the plate where the peptides are present

Biomedical Informatics, Fig. 7 Time-of-flight mass spectrometry



a
Laser

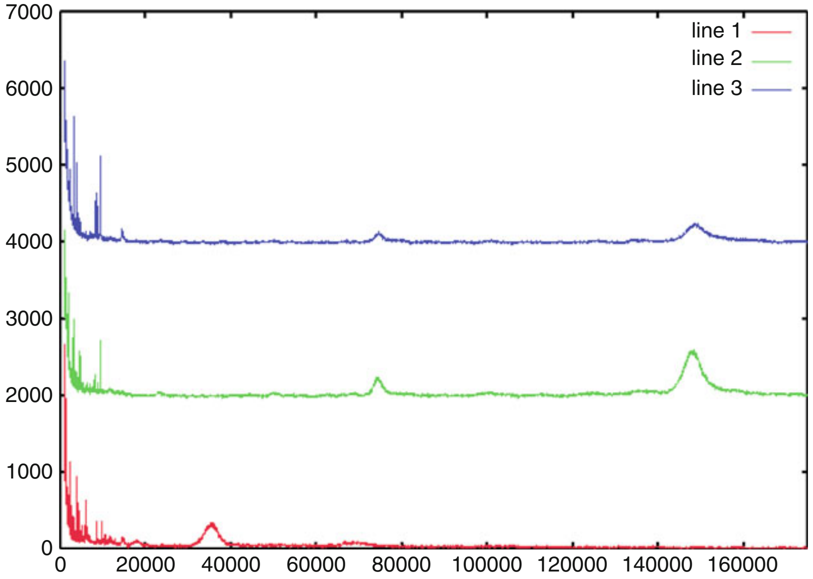
+10 kv
The protons from the matrix molecules get attached to the proteins
b
Laser
Detector
+10 kv
Positively charged proteins are repelled towards the detector
Smaller mass molecules hit detector first, while heavier ones detected later

is positively charged. This causes the peptides to migrate toward the detector.

As can be seen in (b) of the figure, the molecules with smaller mass move faster toward the detector. The idea is to detect the number of molecules that hit the detector at any given time. This makes it possible to use time as a surrogate for mass of the protein. The experiment is repeated a number of times, counting frequencies of "flight-times" Plotting time vs. the number of particles hitting the detector yields a spectrum as presented in Fig. 8. The figure shows three different fractions from the same sample. These kinds of spectra provide us an insight about the different types of proteins in a given sample. A technical detail is that sometimes molecules receive additional charge (additional protons) and hence fly faster. Therefore, the horizontal mass axis in a spectrum is actually a mass/charge ratio.

The main issues for machine learning researchers working with mass spectrometry data compared to microarray data are as follows: (1) There is a lot of noise in the data. The noise is due to extra peaks from handling of sample, from machine and environment (e.g., electrical noise). Also the mass to charge values may not exactly align across the spectra; the accuracy of the mass/charge values is the resolution of the mass spec. (2) Intensities (peak heights) are not calibrated across the spectra, making quantification difficult. This is to say that if one spectrum is compared to another, and if one of them has more intensity at a particular mass/charge, it does not necessarily mean that the levels of the peptide at that mass/charge are higher in that spectrum. (3) Another issue is that the mass spectrometry data is not as comprehensive as microarray data, in that it is not possible to measure all peptides (typically only several hundreds of them can be obtained). To get the best results, there is a need to fractionate the sample beforehand, getting different groups of proteins in different subsamples (fractions). (4) As already mentioned, the proteins themselves typically must be broken down (digested) into smaller peptides in order to get accurate readings from the mass spec. But this means processing is needed afterward not only to determine from a spectrum which peptides are present but also from that determination which proteins are present. It is worth noting that some of these challenges are being partially addressed by ongoing improvements in mass spectrometry technologies, including the use of "tandem mass spectrometry."

This data type opens up a lot of possibilities for machine learning research. Some of the learning tasks include:



Biomedical Informatics, Fig. 8 Example spectra from a competition by Lin et al.

- Learn to predict proteins from spectra, when the organism's proteome (full set of proteins) is known.
- Learn to identify isotopic distributions (combinations of multiple peaks for a given molecule arising from different isotypes of carbon, nitrogen, and oxygen).
- Learn to predict disease from either proteins, peaks, or isotopic distributions as features.
- Construct pathway models.

We will now present one case study that was successful and generated a lot of interest – *Early Detection of Ovarian Cancer* (Petricoin et al. 2002). Ovarian cancer is difficult to detect early, often leading to poor prognosis. The goal of this work was to predict ovarian cancer from blood samples. To this effect, the researchers trained and tested on mass spectra from blood serum. They used 100 training cases (50 positive) and used a held-out test set of 116 cases (50 positive). The results were extremely impressive (100 % sensitivity, 95 % specificity).

While the results were extremely impressive and while the machine learning methodology seemed very sound, it turns out that the preprocessing stage of the data may have introduced errors (Baggerly et al. 2004). Mass spectrometry is very sensitive to the external factors as well. For instance, if we run cancer samples on Monday and normal samples on Wednesday, it is possible that we could get differences from variations in the machine or nearby electrical equipment that is running on Monday but not Wednesday. Hence, one of the important lessons learned from this data type is the need for *careful randomization* of the data samples. This is to say that we should sample the positive and negative samples under identical conditions. It should not be the case that the positive examples are run through the machine on one day and the negatives on the other day. Any preprocessing of the data must be performed similarly.

While mass spectrometry is a widely used type of high-throughput proteomic data, other types of data are also important and are briefly covered next.

Protein Structures

X-ray crystallography and nuclear magnetic resonance are widely used to determine the three-dimensional structures of proteins. Predicting protein structures has been a very fertile field for machine learning research for several decades.

While the amino acid sequence of a protein is called its primary structure, it is more difficult to determine secondary structure and tertiary (3D) structure. Secondary structure maps subsequences of the primary structure in the three classes of alpha helix (helical structures akin to a telephone cord, often denoted by A), beta strand (which comes together with other strand sections to form planar structures called beta sheets, often denoted by B), and less descript regions referred to as coil, or loop regions, often denoted by C.

Predicting secondary structure and tertiary structure has been a popular topic for machine learning for many years, because training data exists, yet it is difficult and expensive to experimentally determine structures. We will not attempt to survey all the work in this area. Waltz and colleagues (Zhang et al. 1992) showed the benefit of applying neural networks to the task of secondary structure prediction, and the best secondary structure predictors (e.g., Rost and Sander 1993) have continued to be constructed by machine learning over the years. Approaches for predicting the tertiary structure have also relied heavily on machine learning and include ab initio prediction (e.g., Bonneau and Baker 2001), prediction aided by crystallography data (e.g., DiMaio et al. 2007), and homology-based prediction (by finding similar proteins). For over a decade, there has been a regular competition in the prediction of protein structures (Critical Assessment of Structure Prediction [CASP]).

Protein–Protein Interactions

Another proteomics data type is protein–protein interactions. This is illustrated in Fig. 9. The idea is to identify proteins that interact with the current protein say P. Generally, this is performed as follows: In the sample, there are some proteins of type X (shown in pink in the figure) and other types of proteins. Proteins that interact with X are bonded to X. Then antibodies (shown as Y-shaped green objects) are introduced in the sample. The idea of antibodies is to collect the proteins of type X. Once the antibodies have collected all protein X's in the sample, they can be analyzed through mass spectrometry presented earlier.

A particularly high-throughput way of measuring protein–protein interactions is through "ChIP-chip" data. The supervised learning tasks for this task include:

- Learn to predict protein–protein interactions: Protein three-dimensional structures may be critical.
- Use protein–protein interactions in construction of pathway models.
- Learn to predict protein function from interaction data.

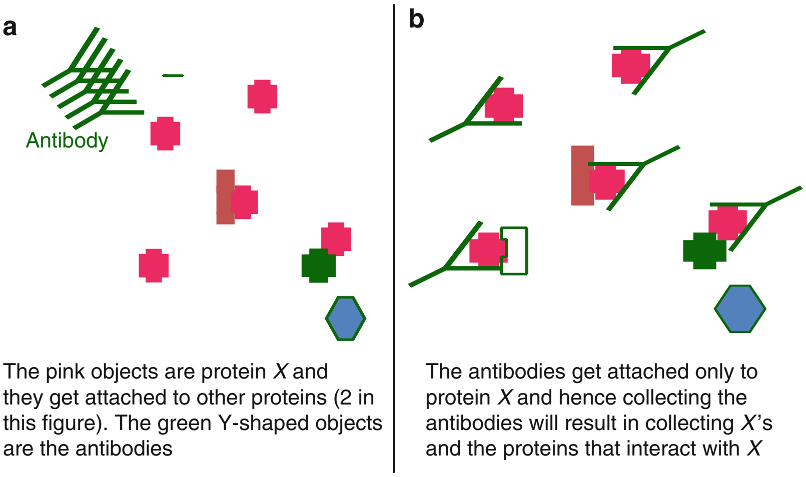
Related Data Types

- *Metabolomics* measures concentration of each low-molecular-weight molecule in sample. These typically are *metabolites*, or small molecules produced or consumed by reactions in biochemical pathways. These reactions are typically catalyzed by proteins (specifically, enzymes). This data typically uses mass spectrometry.
- *ChIP-chip* data measures protein-DNA interactions. For example, transcription factors are proteins that interact with DNA in specific locations to alter transcription of a nearby gene.
- *Lipomics* is analogous to metabolomics but measuring concentrations of lipids rather than metabolites. These potentially help induce biochemical pathway information or help in disease diagnosis or treatment choice.

High-Throughput Screening Data for Drug Design

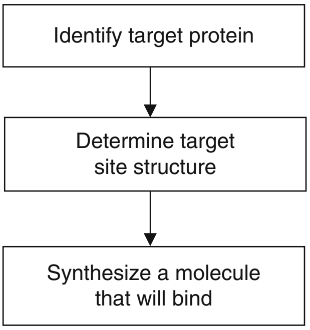
The typical steps in designing a drug are the following: (1) Identifying a target protein – for example, while developing an antibiotic, it will be useful to find a protein that belongs to the bacteria

Biomedical Informatics, Fig. 9 Schematic of antibody-based identification of protein–protein interactions



The pink objects are protein *X* and they get attached to other proteins (2 in this figure). The green Y-shaped objects are the antibodies

The antibodies get attached only to protein *X* and hence collecting the antibodies will result in collecting *X*'s and the proteins that interact with *X*



Identify target protein
Determine target site structure
Synthesize a molecule that will bind

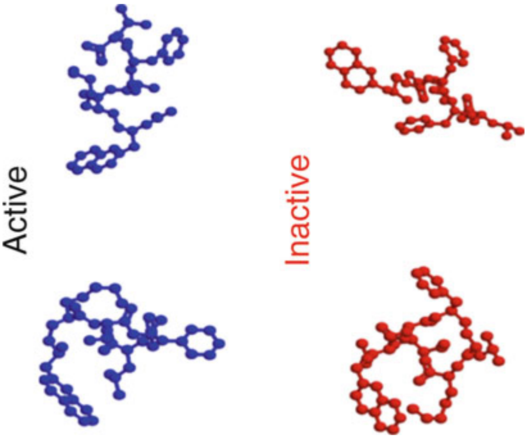
Biomedical Informatics, Fig. 10 Steps involved in drug design

that we are interested in and find a small molecule that will bind to that protein. In order to perform this, we need the knowledge of proteome/genome and the relevant biological pathways. (2) Determining the target site structure once the protein has been identified – this is typically performed using crystallography. (3) Finding a molecule that will bind to the target site. These steps are presented in Fig. 10.

The molecules that bind to the target may have a number of other problems, and hence they cannot directly be used as a drug. Some common problems are as follows: (1) They may bind too tightly or not tightly enough. (2) They may be toxic. (3) They may have unanticipated side effects in the body. (4) They may break down as soon as they get into the body or may not leave the body soon enough. (5) They may not get to the right target in the body (e.g., cross blood–brain barrier). (6) They may not diffuse from gut to bloodstream. Also, since the organisms are different, even if a molecule works in the test tube and in animal studies, it may fail in clinical trials. Also while a molecule may work for some people, it may not work for others. Conversely, while some molecules may cause harmful side effects in some people, they may not do so in others.

Often pharmaceutical companies will use robotic high-throughput screening assays to test many thousands of molecules to see if they bind to the target protein, and then computational chemists will work to determine the commonalities that allow them to bind to the target as often the structure of the target protein cannot be determined. The process of discovering the commonalities across the different molecules presents a great opportunity for machine learning research. The first study of this task using machine learning was by Dietterich, Lathrop, and Lozano-Perez and led to the formulation of multi-instance learning. Yet, another machine learning task could be to predict the reactions of the patients to the drugs.

High-Throughput Screening: When the target structure is unknown, it is a common practice to test many molecules (1,000,000) to find some that bind to the target. This is called as *high-throughput screening*. Hence, it is important to infer the shape of the target from three-



Biomedical Informatics, Fig. 11 An example of structure learning

dimensional structural similarities. The shared three-dimensional structure is called as *pharmacophore*. This is a perfect example of a machine learning task with a spatial target and is presented in Fig. 11.

Given: A set of molecules, each labeled by activity (binding affinity for a target protein) and a set of low-energy conformers for each molecule

Do: Learn a model that accurately predicts the activity (may be Boolean or real valued).

The common machine learning approaches taken toward solving this problem are:

1. Representing a molecule by thousands to millions of features and using standard techniques (KDD 2001)
2. Representing each low-energy conformer by feature vector and using multiple-instance learning (Jain et al. 1994)
3. Relational learning – using either inductive logic programming techniques (Finn et al. 1998) or graph mining

Thermolysin Inhibitors: We present some results of relational learning algorithms on thermolysin inhibitor data set (Davis 2007a). Thermolysin belongs to the family of metalloproteases and plays roles in physiological processes such as digestion and blood pressure regulation. The molecules in the data set are known inhibitors of thermolysin. Activity for these molecules is measured in $pKi = -\log Ki$, where Ki is a dissociation constant, measuring the ratio of the concentrations of bound product to unbound constituents. A higher value indicates a stronger affinity for binding. The data set that was used had the ten lowest energy conformations (as computed by the SYBYL software package [www.tripos.com]) for each of 31 thermolysin inhibitors along with their activity levels.

The key results for this data set using the relational algorithm SAYU (Davis 2007b) were:

- Ten five-point pharmacophores identified, falling into two groups (7/10 molecules):
  - Three "acceptors," one hydrophobe, and one donor
  - Four "acceptors" and one donor
- Common core of Zn ligands, Arg203, and Asn112 interactions identified
- Correct assignments of functional groups
- Correct geometry to 1 Å tolerance
- Increasing tolerance to 1.5 Å finds common six-point pharmacophore including one extra interaction

Antibacterial Peptides: This is a data set of 11 pentapeptides showing activity against *Pseudomonas aeruginosa* (Spatola et al. 1999). There are six active pharmacophores with $<64\,\mu g/ml$ of IC_{50} and five inactives. The pharmacophore that has been identified is presented in Table 1.

Dopamine Agonists: The last data set that we present here consists of dopamine agonists (Martin et al. 1993). Dopamine works as a neurotransmitter in the brain, where it plays a major role in the movement control. Dopamine agonists are molecules that function like dopamine and produce dopamine-like effects and can potentially be used to treat diseases such as Parkinson's disease. The data set had 23 dopamine agonists along with their activity levels. The pharmacophore identified using inductive logic programming is presented in Table 2.

Biomedical Informatics, Table 1 Identified pharmacophore

A molecule M is active against *Pseudomonas aeruginosa* if it has a conformation B such that:
M has a hydrophobic group C
M has a hydrogen acceptor D
The distance between C and D in conformation B is 11.7 Å
M has a positively charged atom E
The distance between C and E in conformation B is 4 Å
The distance between D and E in conformation B is 9.4 Å
M has a positively charged atom F
The distance between C and F in conformation B is 11.1 Å
The distance between D and F in conformation B is 12.6 Å
The distance between E and F in conformation B is 8.7 Å
Tolerance 1.5 Å

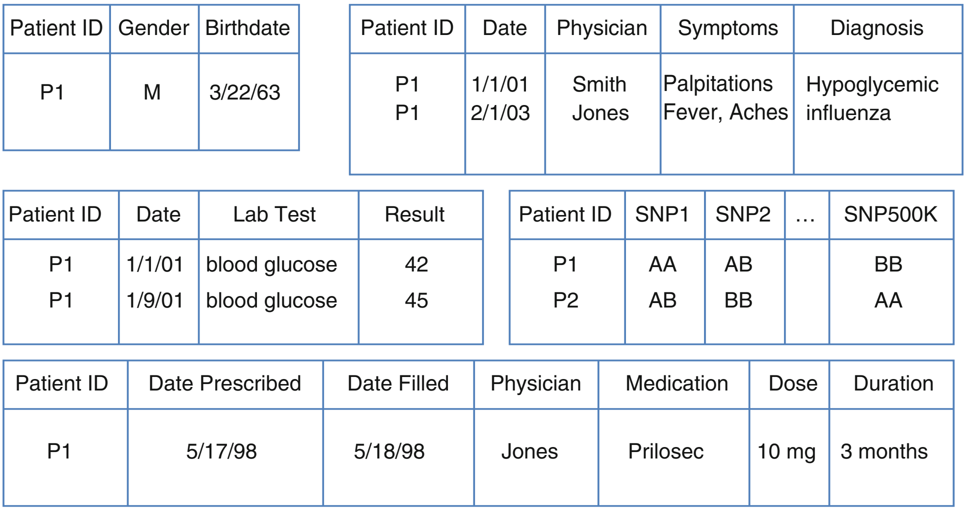
Biomedical Informatics, Table 2 Pharmacophore identified for dopamine agonists

Molecule A has the desired activity if:
• In conformation B molecule A contains a hydrogen acceptor at C • In conformation B molecule A contains a basic nitrogen group at D • The distance between C and D is 7.05966 ± 0.75 Å • In conformation B molecule A contains a hydrogen acceptor at E • The distance between C and E is 2.80871 ± 0.75 Å • The distance between D and E is 6.36846 ± 0.75 Å • In conformation B molecule A contains a hydrophobic group at F • The distance between C and F is 2.68136 ± 0.75 Å • The distance between D and F is 4.80399 ± 0.75 Å • The distance between E and F is 2.74602 ± 0.75 Å

Electronic Medical Records (EMR) and Personalized Medicine

Predictive personalized medicine (PPM) is a vision of the future, whose parts are beginning to come into place now. Under this vision, physicians can construct safer and more effective prevention and treatment plans for each patient. This is rendered possible by predicting the impact of treatments on patients – their effectiveness for different classes of patients, adverse reactions of certain drugs that are prescribed to the patients, and susceptibility of different types of patients to diseases. PPM can become a reality due to three reasons: The first is the widespread use by many clinics of *electronic medical records* (EMR, also called as *Electronic Health Records* – EHR). The second is that whole-genome scan technology makes it possible in one experiment, for well under $1,000, to measure for one patient a half million to one million SNPs or individual positions in the DNA where humans vary. The third key reason is the advancement of statistical modeling (machine learning) methods in the past decade that can handle large relational longitudinal databases with significant amount of noise. The first two reasons make it possible for the clinics to have a relational database of the form presented in Fig. 12.

Given such a database, it is conceivable to use existing machine learning algorithms for achieving the goal of PPM. These algorithms could focus on predicting which patients are at risk (positive and negative examples). Another task is predicting which patients will respond to a specific treatment – a set of patients who have undergone specific treatments in order to learn predictive models that could be extended to similar patients of the population. Similarly, it is possible to focus on certain drugs and their adverse reactions and use them to predict the adverse reactions of similar drugs that are released in the market. In this work, we focus on the machine



Patient ID	Gender	Birthdate
P1	M	3/22/63

Patient ID	Date	Physician	Symptoms	Diagnosis
P1	1/1/01	Smith	Palpitations	Hypoglycemic
P1	2/1/03	Jones	Fever, Aches	influenza

Patient ID	Date	Lab Test	Result
P1	1/1/01	blood glucose	42
P1	1/9/01	blood glucose	45

Patient ID	SNP1	SNP2	…	SNP500K
P1	AA	AB		BB
P2	AB	BB		AA

Patient ID	Date Prescribed	Date Filled	Physician	Medication	Dose	Duration
P1	5/17/98	5/18/98	Jones	Prilosec	10 mg	3 months

Biomedical Informatics, Fig. 12 Electronic health records (dramatically simplified) – most data currently do not include SNP information but are anticipated in the future

learning solutions to predict adverse drug reactions for different drugs.

There are actually at least three different tasks for machine learning in predicting adverse drug events (ADEs).

Task 1:

Given: Patient data (from claims databases and/or EMRs) and a drug D

Do: Construct a model to predict a minimum efficacious dose of drug D, because a minimum dose is less likely to induce an ADE.

An example of this task is predicting the "stable dose" of the blood thinner warfarin (Coumadin) for a patient (McCarty et al. 2005). A stable dose of Warfarin yields the desired degree of anticoagulation, whereas a higher dose can lead to bleeding ADEs; the stable dose for a patient is currently found by trial and error, modifying the dose and measuring the degree of anticoagulation. The cited study shows that a learned dosing model can predict a significantly better starting dose (significantly closer to the final "stable dose") than the 5 mg/day starting dose currently used in many clinics.

Task 2:

Given: Patient data (from claims databases and/or EMRs), a drug D, and an adverse event E

Do: Construct a model to predict which patients are likely to suffer the adverse event E if they take D.

In this second task, we assume that the association between D and E already has been hypothesized. We seek to construct models that can predict who will suffer a given event if they take the drug. Here, whether the patient will suffer adverse event E is the class variable to be predicted. This task is important for *personalized medicine*, as accurate models for this task can be used to identify patients who should not be given a particular drug. An earlier study has demonstrated the benefit of a statistical relational learning (SRL) system called SAYU (Davis 2007b) over standard machine learning approaches with a feature-vector representation of the EHR for the task of predicting which users of cox2 inhibitors would have an MI.

Task 3:

Given: Patient data (from claims databases and/or EMRs) and a drug D

Do: Determine if evidence exists that associates D with a previously unanticipated adverse event.

This third task is the most challenging because no associated event has been hypothesized. There is a need to identify the response variable to be predicted. In brief, the major approach for this task is to use machine learning "in reverse." We seek a model that can predict which patients are on drug D using the data after they start the drug (left censored) and also censoring the indications of the drug. If a model can predict (with accuracy better than chance on held-aside data) which patients are taking the drug, there must be some combination of variable settings more common among patients on the drug. Because we have left censored, in theory, this commonality should not consist of common symptoms, but common effects, presumably from the drug. The model can then be examined by the experts to see if it might indicate a possible new adverse event for the drug.

The preceding use of machine learning "in reverse" actually can be viewed as subgroup discovery (Wrobel 1997; Klösgen 2002), finding a subgroup of patients on drug D who share some subsequent clinical events. The learned model – say an if–then rule – need not correctly identify everyone on the drug but rather merely a subgroup of those on the drug, while not generating many false positives (individuals not on the drug). This task poses several different challenges that traditional ML methods will find difficult to handle.

First, the data is *multi-relational*. There are several objects such as doctors, patients, drugs, diseases, and labs that are connected through relations such as visits, prescriptions, diagnoses, etc. If traditional machine learning (ML) techniques are to be employed on this problem, they require flattening the data into a single table. All known flattening techniques such as computing a join or summary features result in either (1) changes in frequencies on which machine learning algorithms critically depend or (2) loss of information. They also typically result in loss of some correlations between the objects and explosion in database size. Second, the data is *non-i.i.d.*, as there are relationships between the objects and between different rows within a table. Third, there are *arbitrary* numbers of patient visits, diagnoses, and prescriptions for different patients. This is to say that there is no fixed pattern in the diagnoses and prescriptions of the patients. It is incorrect to assume that the patients are diagnosed a fixed number of times or to assume only the last diagnosis is relevant. To predict the adverse reactions to a drug, it is important to consider the other drugs that the patient is prescribed or has been prescribed in the past, as well as past diagnoses and laboratory results. To capture these interactions, it is critical to explicitly model time since the interactions are highly *temporal.* Some drugs taken at the same time can lead to side effects, while in some cases, drugs taken after one another cause side effects. It is important to capture such interactions to be able to make useful predictions for the physicians and the Federal Drug Authority (FDA). In this work, we focus on this hardest task and present the results on two data sets.

Cox2 Inhibitors: Recently, a study was performed to see if there were any unanticipated adverse events that occurred when subjects used cox2 inhibitors (Vioxx, Celebrex, and Bextra). Cox2 inhibitors are a nonsteroidal anti-inflammatory class of drugs that were used to reduce joint pain. Vioxx, Celebrex, and Bextra were approved for use in the late 1990s and were ranked as one of the top therapeutic drugs in the USA. Several clinical trials were conducted, and the APPROVe trial (focused on Vioxx outcomes) showed an increase of adverse events from myocardial infarction, stroke, and vascular thrombosis. The manufacturer withdrew Vioxx from the market shortly after the results were published. The other cox2 inhibitor drugs were discontinued shortly thereafter.

This study utilized the Marshfield Clinic's Personalized Medicine Research Project (McCarty et al. 2005) (PMRP) cohort consisting of approximately 19,700+ subjects. The PMRP cohort included adults aged 18 years and older, who reside in the Marshfield Epidemiology Study Area (MESA). Marshfield has one of the oldest internally developed electronic medical records (Cattails MD) in the USA, with coded diagnoses dating back to the early 1960s. Cattails MD has over 13,000 users throughout central and northern Wisconsin.

Since the data is multi-relational, an inductive logic programming (Muggleton and De Raedt 1994) system, *Aleph* (Srinivasan 2001) was used to learn the models. Aleph learns rules in the form of Prolog clauses and scores rules by positive examples covered (P) minus negative examples covered (N). Seventy-five percent of the data was used for training and rule development, while

Biomedical Informatics, Table 3 Cox2 inhibitor test data results

	Actual		
Rule	+	–	
+	438	158	596
–	269	549	818
	707	707	1,414
Accuracy	0.69801		

the remaining 25 % was used for testing. There were 14,654 subjects within the PMRP cohort that had medication records. Within this cohort, almost 20 % of the subjects indicated use of a cox2 inhibitor, and more specifically, 8.5 % indicated the use of Vioxx. Approximately, 3.5 % of this cohort had an indicated use of clopidogrel biosulfate (Plavix).

Aleph generated thousands of rules and selected a subset of the "best" rules that were based on the scoring algorithm. The authors also developed specific hypotheses to test for known adverse events to validate the approach (indicated by # A). This rule was: cox2(A):- diagnoses(A, _,'410'). It states that if finding (A), the subject would have the diagnosis coded as *410* (*myocardial infarction*). Aleph also provided summary statistics on model performance for identifying subjects on cox2 inhibitors, as indicated in Table 3. If we assume that the probability of being on the cox2 inhibitor is greater than 5 (the common threshold), then the model has a predictive probability of 69 % to predict cox2 inhibitor use.

OMOP Challenge: Observational Medical Outcomes Partnership (OMOP) designed and developed an automated procedure to construct simulated data sets to identify adverse drug events. The simulated data sets are modeled after real observational data sources but are comprised of hypothetical persons with fictional drug exposure and health outcome occurrence. The data sets are constructed such that the relationships between the fictional drugs and fictional outcomes are well characterized as *true* and *false* associations. That is, hypothetical persons are created and assigned fictional drug exposure periods and instances of health outcomes based on random sampling from probability distributions that define the relationships between the fictional drugs and outcomes. The relationships created within the simulated data sets are contrived but are representative of the types of relationships observed within real observational data sources. OMOP has made a simulated data set and the simulator itself publicly available as part of the OMOP Cup Data Mining Competition (http://omopcup.orwik.com).

Aleph was used to learn rules from a subset of the data (about 10,000 patients). Each patient had a record of drugs and diagnoses (conditions) with dates attached. A few examples of the rules learned by Aleph in this data set are:

```
on_drug(A):-condition_occurrence(B,C,A,D, E,3450,F,G,H)

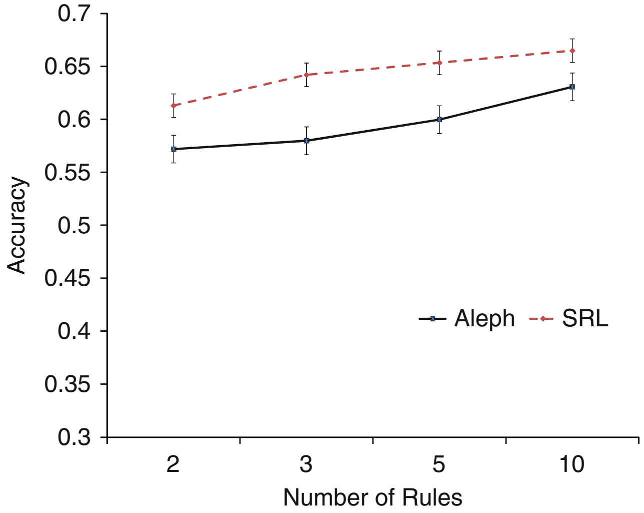
 on_drug(A):- condition_occurrence(B,C,A,D,E, 140,F,G,H)

                    condition_occurrence(I,J,A,K,L, 1487,M,N,O)
```

The first rule identifies drug *3450* as interesting, while the second rule identifies two other drugs as interesting when predicting the reaction for person A. With about 150 rules, Aleph was able to achieve a 67 % coverage. The results were compared against a statistical relational learning technique (SRL) (Getoor and Taskar 2007) that uses a probability distribution on the rules. The results are presented in Fig. 13. As expected, with a small number of rules, SRL has a better performance than Aleph, but as the number of rules increase, they converge on the same performance.

Lessons Learned: The lessons learned from the EHR data and experiments are: (1) We do not want to find patterns in the patients who get prescribed a particular drug, because we already know such patterns – they are the indications of the drug. Therefore, it is important to censor (omit) data about patients before they started the drug. Nevertheless, this left censoring is insufficient to guarantee that the learned models describe only ADEs. Some diagnoses may get repeated at a later date in the patient's record. There may be additional diagnoses, drugs, labs, or vitals that are correlated with the indication of the drug being studied. (2) Despite left censoring, a high accuracy or highly accurate discovered subgroup does not automatically mean

Biomedical Informatics, Fig. 13 Results of OMOP data



we have uncovered one or more ADEs. Instead, all rules must be vetted by a human expert to determine if they are representative of an ADE or of some other phenomenon such as that patients on arthritis medication such as cox2 inhibitors also suffer from other correlated ailments. Once these associated conditions are also censored, learning ideally should be rerun in case ADEs were masked by other rules that scored better. (3) Another lesson is that data is multi-relational, including longitudinal (temporal), and hence may be best analyzed by methods that can directly handle such data. Nevertheless, the initial approach presented earlier does not make full use of the relational nature of the data, especially of its longitudinal nature. It would be desirable to take into account time from drug exposure to events, but this is a challenging direction because different drugs can cause ADEs over different ranges of time. Some drugs may cause an ADE only within hours after they are taken, whereas others may have permanent effects that only manifest themselves as an ADE years later.

Identifying previously unanticipated ADEs, predicting who is most at risk for an ADE, and predicting safe and efficacious doses of drugs for particular patients are all important needs for society. With the recent advent of "paperless" medical record systems, the pieces are in place for machine learning to help meet these important needs.

Conclusion

In this work, we aim to survey the abundant opportunities in biomedical applications to machine learning researchers by presenting several data types to which machine learning techniques have been applied successfully or showing tremendous promise. One of the most important developments in biology and medicine over the last few years is the availability of technologies that can produce large volumes of data. This in turn has necessitated the need for processing large volumes of data in a reasonable amount of time, presenting the perfect setting for machine learning algorithms to have an impact. We outlined several data types including gene expression microarrays (measuring mRNA), mass spectrometry (measuring proteins), SNP chips (measuring genetic variation), and electronic medical/health records (EMR/EHRs).

The key lessons learned from all these data types are as follows: (1) Even if the number of features is greater than the number of data points (e.g., predicting cancer from microarray data), we can do well provided the features are highly predictive. (2) Careful randomization of data samples is necessary. (3) It is very easy to overfit the data, and hence robust techniques such as voted decision stumps, naive Bayes, or linear SVMs are in general very useful tools for such data sets. (4) Bayes nets do not give us causality, and hence knockout experiments (active learning) and DBNs with time-series data can help. (5) Multi-relational methods such as SRL and ILP are helpful for predictive personalized medicine due to the relational nature of the data. (6) Mostly, the collaborators are interested in measures other than just accuracy. Comprehensibility, privacy, and ranking are other criteria that are important to biologists.

This chapter is necessarily incomplete because so many exciting tasks and data types exist within biology and medicine. While we have touched on many of the leading such data types, other related ones also exist. For example, there are many opportunities in analyzing genomic and protein sequences (► Learning Models of Biological Sequences). Other opportunities exist within phylogenetics, for example, see work by Heckerman and colleagues on HIV (Carlson et al. 2009). New technologies such as optical mapping are constantly being developed and refined (Ananiev et al. 2008). Machine learning has great potential for developing models for computer-aided diagnosis (CAD), for example, for mammography (Burnside et al. 2009). Data types such as metabolomics and auxotrophic growth experiments raise opportunities for active learning and for automatic revision of biological network models, for example, as in the Robot Scientist projects (Jones et al. 2004; Oliver et al. 2009). Incorporation of multiple data types can further help in mapping out the regulatory entities and networks of an organism (Noto and Craven 2006). It is our hope that this article will encourage some machine learning researchers to delve deeper into these and other related opportunities.

Blog Mining

Blog mining is the application of data mining (in particular, Web mining) techniques on blogs, adapted to the content, format, and language of the medium blog. A *blog* is a (more or less) frequently updated publication on the Web, sorted in (usually reverse) chronological order of the constituent blog posts. As in other areas of the Web, mining is applied to the content of blogs, to the various types of links between blogs, and to blog-related behavior. The latter comprises blog authoring including link setting, blog reading and commenting, and querying (often in blog search engines). For more details on blogs and on mining them, see ▶ text mining for news and blogs analysis.

Boltzmann Machines

Geoffrey Hinton
University of Toronto, Toronto, ON, Canada

Definition

A Boltzmann machine is a network of symmetrically connected, neuron-like units that make stochastic decisions about whether to be on or off. Boltzmann machines have a simple learning algorithm (Hinton and Sejnowski 1983) that allows them to discover interesting features that represent complex regularities in the training data. The learning algorithm is very slow in networks with many layers of feature detectors, but it is fast in "restricted Boltzmann machines" that have a single layer of feature detectors. Many hidden layers can be learned efficiently by composing restricted Boltzmann machines, using the feature activations of one as the training data for the next.

Boltzmann machines are used to solve two quite different computational problems. For a search problem, the weights on the connections are fixed and are used to represent a cost function. The stochastic dynamics of a Boltzmann machine then allow it to sample binary state vectors that have low values of the cost function. For a learning problem, the Boltzmann machine is shown a set of binary data vectors, and it must learn to generate these vectors with high probability. To do this, it must find weights on the connections so that relative to other possible binary vectors, the data vectors have low values of the cost function. To solve a learning problem, Boltzmann machines make many small updates to their weights, and each update requires them to solve many different search problems.

Motivation and Background

The brain is very good at settling on a sensible interpretation of its sensory input within a few hundred milliseconds, and it is also very good, over a much longer timescale, at learning the code that is used to express its interpretations. It achieves both the settling and the learning using spiking neurons which, over a period of a few milliseconds, have a state of 1 or 0. These neurons have intrinsic noise caused by the quantal release of vesicles of neurotransmitter at the synapses between the neurons.

Boltzmann machines were designed to model both the settling and the learning and were based on two seminal ideas that appeared in 1982. Hopfield (1982) showed that a neural network composed of binary units would settle to a minimum of a simple, quadratic energy function provided that the units were updated asynchronously and the pairwise connections between units were symmetrically weighted. Kirkpatrick et al. (1983) showed that systems that were settling to energy minima could find deeper minima if noise was added to the update rule so that the system could occasionally increase its energy to escape from poor local minima.

Adding noise to a Hopfield net allows it to find deeper minima that represent more probable interpretations of the sensory data. More significantly, by using the right kind of noise, it is possible to make the log probability of finding the system in a particular global configuration be a linear function of its energy. This makes it possible to manipulate log probabilities by manipulating energies, and since energies are simple local functions of the connection weights, this leads to a simple, local learning rule.

Structure of Learning System

The learning procedure for updating the connection weights of a Boltzmann machine is very simple, but to understand why it works, it is first necessary to understand how a Boltzmann machine models a probability distribution over a set of binary vectors and how it samples from this distribution.

The Stochastic Dynamics of a Boltzmann Machine

When unit i is given the opportunity to update its binary state, it first computes its total input, x_i, which is the sum of its own bias, b_i, and the weights on connections coming from other active units:

$$x_i = b_i + \sum_j s_j w_{ij} \tag{1}$$

where w_{ij} is the weight on the connection between i and j and s_j is 1 if unit j is on and 0, otherwise. Unit i then turns on with a probability given by the logistic function

$$\text{prob}(s_i = 1) = \frac{1}{1 + \mathrm{e}^{-x_i}} \tag{2}$$

If the units are updated sequentially in any order that does not depend on their total inputs, the network will eventually reach a Boltzmann distribution (also called its equilibrium or stationary distribution) in which the probability of a state vector, **v**, is determined solely by the "energy" of that state vector relative to the energies of all possible binary state vectors:

$$P(\mathbf{v}) = \mathrm{e}^{-E(\mathbf{v})} / \sum_{\mathbf{u}} \mathrm{e}^{-E(\mathbf{u})} \tag{3}$$

As in Hopfield nets, the energy of state vector **v** is defined as

$$E(\mathbf{v}) = -\sum_i s_i^{\mathbf{v}} b_i - \sum_{i<j} s_i^{\mathbf{v}} s_j^{\mathbf{v}} w_{ij} \tag{4}$$

where $s_i^{\mathbf{v}}$ is the binary state assigned to unit i by state vector **v**.

If the weights on the connections are chosen so that the energies of state vectors represent the cost of those state vectors, then the stochastic dynamics of a Boltzmann machine can be viewed as a way of escaping from poor local optima while searching for low-cost solutions. The total input to unit i, x_i, represents the difference in energy depending on whether the unit is off or on, and the fact that unit i occasionally turns on even if x_i is negative means that the energy can occasionally increase during the search, thus allowing the search to jump over energy barriers.

The search can be improved by using simulated annealing. This scales down all of the weights and energies by a factor, T, which is analogous to the temperature of a physical system. By reducing T from a large initial value to a small final value, it is possible to benefit from the fast equilibration at high temperatures and still have a final equilibrium distribution that makes low-cost solutions much more probable than high-cost ones. At a temperature of 0, the update rule becomes deterministic and a Boltzmann machine turns into a Hopfield network.

Learning in Boltzmann Machines Without Hidden Units

Given a training set of state vectors (the data), the learning consists of finding weights and biases (the parameters) that make those state vectors good. More specifically, the aim is to find weights and biases that define a Boltzmann distribution in which the training vectors have high probability. By differentiating (3) and using the fact that

$$\partial E(\mathbf{v}) / \partial w_{ij} = -s_i^{\mathbf{v}} s_j^{\mathbf{v}} \tag{5}$$

it can be shown that

$$\left\langle \frac{\partial \log P(\mathbf{v})}{\partial w_{ij}} \right\rangle_{\text{data}} = \langle s_i s_j \rangle_{\text{data}} - \langle s_i s_j \rangle_{\text{model}} \tag{6}$$

where $\langle\cdot\rangle_{\text{data}}$ is an expected value in the data distribution and $\langle\cdot\rangle_{\text{model}}$ is an expected value when the Boltzmann machine samples state vectors from its equilibrium distribution at a temperature of 1. To perform gradient ascent in the log probability that the Boltzmann machine would generate the observed data when sampling from its equilibrium distribution, w_{ij} is incremented by a small learning rate times the RHS of (6). The learning rule for the bias, b_i, is the same as (6), but with s_j omitted.

If the observed data specifies a binary state for every unit in the Boltzmann machine, the learning problem is convex: there are no nonglobal optima in the parameter space. However, sampling from $\langle\cdot\rangle_{\text{model}}$ may involve overcoming energy barriers in the binary state space.

Learning with Hidden Units

Learning becomes much more interesting if the Boltzmann machine consists of some "visible" units whose states can be observed and some "hidden" units whose states are not specified by the observed data. The hidden units act as latent variables (features) that allow the Boltzmann machine to model distributions over visible state vectors that cannot be modeled by direct pairwise interactions between the visible units. A surprising property of Boltzmann machines is that, even with hidden units, the learning rule remains unchanged. This makes it possible to learn binary features that capture higher-order structure in the data. With hidden units, the expectation $\langle s_i s_j \rangle_{\text{data}}$ is the average, over all data vectors, of the expected value of $s_i s_j$ when a data vector is clamped on the visible units, and the hidden units are repeatedly updated until they reach equilibrium with the clamped data vector.

It is surprising that the learning rule is so simple because $\partial \log P(\mathbf{v})/\partial w_{ij}$ depends on all the other weights in the network. Fortunately, the locally available difference in the two correlations in (6) tells w_{ij} everything it needs to know about the other weights. This makes it unnecessary to explicitly propagate error derivatives, as in the backpropagation algorithm.

Different Types of Boltzmann Machine

The stochastic dynamics and the learning rule can accommodate more complicated energy functions (Sejnowski 1986). For example, the quadratic energy function in (4) can be replaced by an energy function that has typical term $s_i s_j s_k w_{ijk}$. The total input to unit i that is used in the update rule must then be replaced by

$$x_i = b_i + \sum_{j<k} s_j s_k w_{ijk}. \tag{7}$$

The only change in the learning rule is that $s_i s_j$ is replaced by $s_i s_j s_k$.

Boltzmann machines model the distribution of the data vectors, but there is a simple extension, the "conditional Boltzmann machine" for modeling conditional distributions (Ackley et al. 1985). The only difference between the visible and the hidden units is that when sampling $\langle s_i s_j \rangle_{\text{data}}$, the visible units are clamped and the hidden units are not. If a subset of the visible units are also clamped when sampling $\langle s_i s_j \rangle_{\text{model}}$, this subset acts as "input" units and the remaining visible units act as "output" units. The same learning rule applies, but now it maximizes the log probabilities of the observed output vectors conditional on the input vectors.

Instead of using units that have stochastic binary states, it is possible to use "mean field" units that have deterministic, real-valued states between 0 and 1, as in an analog Hopfield net. Equation (2) is used to compute an "ideal" value for a unit's state, given the current states of the other units, and the actual value is moved toward the ideal value by some fraction of the difference. If this fraction is small, all the units can be updated in parallel. The same learning rules can be used by simply replacing the stochastic, binary values by the deterministic real values (Peterson and Anderson 1987), but the learning algorithm is hard to justify and the mean field nets have problems in modeling multimodal distributions.

The binary stochastic units used in Boltzmann machines can be generalized to "softmax" units that have more than two discrete values, Gaussian units whose output is simply their total input plus Gaussian noise, binomial units, Poisson units, and any other type of unit that falls in the exponential family (Welling et al. 2005). This family is characterized by the fact that the adjustable parameters have linear effects on the log probabilities. The general form of the gradient required for learning is simply the change in the sufficient statistics caused by clamping data on the visible units.

The Speed of Learning

Learning is typically very slow in Boltzmann machines with many hidden layers because large networks can take a long time to approach their equilibrium distribution, especially when the weights are large and the equilibrium distribution is highly multimodal, as it usually is when the visible units are unclamped. Even if samples from the equilibrium distribution can be obtained, the learning signal is very noisy because it is the difference of two sampled expectations. These difficulties can be overcome by restricting the connectivity, simplifying the learning algorithm, and learning one hidden layer at a time.

Restricted Boltzmann Machines

A restricted Boltzmann machine (Smolensky 1986) consists of a layer of visible units and a layer of hidden units with no visible-visible or hidden-hidden connections. With these restrictions, the hidden units are conditionally independent given a visible vector, so unbiased samples from $\langle s_i s_j \rangle_{\text{data}}$ can be obtained in one parallel step. To sample from $\langle s_i s_j \rangle_{\text{model}}$ still requires multiple iterations that alternate between updating all the hidden units in parallel and updating all of the visible units in parallel. However, learning still works well if $\langle s_i s_j \rangle_{\text{model}}$ is replaced by $\langle s_i s_j \rangle_{\text{reconstruction}}$ which is obtained as follows:

1. Starting with a data vector on the visible units, update all of the hidden units in parallel.
2. Update all of the visible units in parallel to get a "reconstruction."
3. Update all of the hidden units again.

This efficient learning procedure approximates gradient descent in a quantity called "contrastive divergence" and works well in practice (Hinton 2002).

Learning Deep Networks by Composing Restricted Boltzmann Machines

After learning one hidden layer, the activity vectors of the hidden units, when they are being driven by the real data, can be treated as "data" for training another restricted Boltzmann machine. This can be repeated to learn as many hidden layers as desired. After learning multiple hidden layers in this way, the whole network can be viewed as a single, multilayer generative model, and each additional hidden layer improves a lower bound on the probability that the multilayer model would generate the training data (Hinton et al. 2006).

Learning one hidden layer at a time is a very effective way to learn deep neural networks with many hidden layers and millions of weights. Even though the learning is unsupervised, the highest-level features are typically much more useful for classification than the raw data vectors. These deep networks can be fine-tuned to be better at classification or dimensionality reduction using the backpropagation algorithm (Hinton and Salakhutdinov 2006). Alternatively, they can be fine-tuned to be better generative models using a version of the "wake-sleep" algorithm Hinton et al. (2006).

Relationships to Other Models

Boltzmann machines are a type of Markov random field (see ▶ Graphical Models), but most Markov random fields have simple, local interaction weights which are designed by hand rather than being learned. Boltzmann machines are also like Ising models, but Ising models typically use random or hand-designed interaction weights. The search procedure for Boltzmann machines is an early example of Gibbs sampling, a ▶ Markov chain Monte Carlo method which was invented independently (Geman and Geman 1984) and was also inspired by simulated annealing.

Boltzmann machines are a simple type of undirected graphical model. The learning algorithm for Boltzmann machines was the first learning algorithm for undirected graphical models with hidden variables (Jordan 1998). When restricted Boltzmann machines are composed to learn a deep network, the top two layers of the resulting graphical model form an undirected Boltzmann machine, but the lower layers form a directed acyclic graph with directed connections from higher layers to lower layers (Hinton et al. (2006)).

Conditional random fields (Lafferty et al. 2001) can be viewed as simplified versions of higher-order, conditional Boltzmann machines in which the hidden units have been eliminated. This makes the learning problem convex but removes the ability to learn new features.

Boosting

Boosting is a family of ▸ ensemble learning methods. The Boosting framework is an answer to a question posed on whether two complexity classes of learning problems are equivalent: *strongly learnable*, and *weakly learnable*. The Boosting framework is a proof by construction that the answer is positive, they are equivalent. The framework allows a "weak" model, only slightly better than random guessing, to be *boosted* into an arbitrarily accurate *strong* model. ▸ Adaboostis the most well known and successful of the Boosting family, though there exist many variants specialized for particular tasks, such as cost-sensitive and noise-tolerant versions. See ▸ ensemble learning for full details.

Bootstrap Sampling

Definition

Bootstrap sampling is a process for creating a distribution of datasets out of a single dataset. It is used in the ▸ ensemble learning algorithm ▸ Bagging. It can also be used in ▸ algorithm evaluation to create a distribution of training sets from which to estimate properties of an algorithm.

Bottom Clause

Synonyms

Saturation; Starting clause

Definition

The bottom clause is a notion from the field of ▶ inductive logic programming. It is used to refer to the most specific hypothesis covering a particular example when learning from entailment. When ▶ learning from entailment, a hypothesis H covers an example e relative to the background theory B if and only if $B \wedge H \models e$, that is, B together with H ▶ entails the example e. The bottom clause is now the most specific clause satisfying this relationship w.r.t the background theory B and a given example e.

For instance, given the background theory B

```
bird :- blackbird.
bird :- ostrich.
```

and the example e:

```
flies :- blackbird, normal.
```

the bottom clause is H

```
flies :- bird, blackbird, normal.
```

The bottom clause can be used to constrain the search for clauses covering the given example because all clauses covering the example relative to the background theory should be more general than the bottom clause. The bottom clause can be computed using inverse entailment.

Breakeven Point

More accurately described as *precision–recall* BEP, it is an evaluation measure originally introduced in the field of information retrieval to evaluate retrieval systems that return a list of documents ordered by their supposed relevance to the user's information need (see also ▶ Document Classification). It can also be used to evaluate any classification model f that addresses a two-class classification problem but outputs real-valued predictions $f(x)$ instead of binary ones. To use such a classifier in practice, one would select a threshold θ and predict an instance x to be positive if $f(x) > \theta$ and negative otherwise. Thus, the ▶ precision and ▶ recall of this system depend on the choice of the threshold θ. A lower threshold means higher recall, but usually also lower precision. At some point (when the number of instances predicted to be positive is the same as the actual number of positive instances), precision and recall are equal; this value of precision and recall is known as the *precision–recall BEP*. It is a useful measure of the quality of our classifier because it gives us guidance into what sort of tradeoffs are available to the user of such a classifier via the choice of threshold: if we want a precision above the BEP, we must accept that our recall will be below the BEP, and vice versa. A different meaning of the term "breakeven point" is sometimes used in ROC (▶ ROC Analysis), where the *ROC breakeven* is defined as the point where the true positive rate and the false positive rate sum to 1; smaller values of the ROC breakeven are better than larger ones. Informally, the ROC breakeven measures how close the ROC curve gets to the "ROC sweet spot" in the top left corner (where the ▶ true positive rate is 1 and the ▶ false positive rate is 0).

C

Candidate-Elimination Algorithm

Mitchell's, (1982; 1997) candidate-elimination algorithm performs a bidirectional search in the ▸ hypothesis space. It maintains a set, S, of most specific hypotheses that are consistent with the training data and a set, G, of most general hypotheses consistent with the training data. These two sets form two boundaries on the version space.

Synonyms

Cascor; CC

Definition

Cascade–correlation (often abbreviated as "Cascor" or "CC") is a supervised learning algorithm for artificial neural networks. It is related to the back-propagation algorithm ("backprop"). CC differs from backprop in that a CC network begins with no hidden units and then adds units one by one, as needed during learning.

Each new hidden unit is trained to correlate with residual error in the network built so far. When it is added to the network, the new unit is frozen, in the sense that its input weights are fixed. The hidden units form a *cascade*: each

C. Sammut, G.I. Webb (eds.), *Encyclopedia of Machine Learning and Data Mining*,
DOI 10.1007/978-1-4899-7687-1

new unit receives weighted input from all the original network inputs and from the output of every previously created hidden unit. This cascading creates a network that is as deep as the number of hidden units. Stated another way, the CC algorithm is capable of efficiently creating complex, higher-order nonlinear basis functions – the hidden units – which are then combined to form the desired outputs.

The result is an algorithm that learns complex input/output mappings very fast compared to backprop and that builds a multilayer network structure that is customized for the problem at hand.

Motivation and Background

Cascade–correlation was designed (Fahlman and Lebiere 1990) to address two well-known problems with the popular back-propagation algorithm ("backprop"). First, a backprop user has to guess what network structure – the number of hidden layers and the number of units in each layer – would be best for a given learning problem. If the network is too small or too shallow, it won't solve the problem; if it is too large or too deep, training is very slow, and the network is prone to overfitting the training data. Because there is no reliable way to choose a good structure before training begins, most backprop users have to train many different structures before finding one that is well matched to the task.

Second, even if a backprop user manages to choose a good network structure, training is generally very slow. That is particularly true in networks with many hidden units or with more than one hidden layer. One cause of slow learning in backprop is the use of a uniform learning rate parameter for updating network weights. This problem was addressed with the Quickprop algorithm (Fahlman 1988), an approximation to Newton's method that adapts the learning rate for each weight parameter depending on the first two derivatives of the local error surface. Quickprop improved learning speed, sometimes dramatically, but learning was still too slow in large or deep networks.

Another cause of slow learning in backprop is the "herd effect" (Fahlman and Lebiere 1990). If the solution to a network problem requires, say, 30 hidden units, each of these units must be trained to do a different job – that is, to compute a different nonlinear basis function. Each hidden unit starts with a different and randomly chosen set of input weights; but if the units are all trained at once, they all see the same error signal. There is no central authority telling each unit to do a separate job, so they tend to drift toward the same part of parameter space, forming a herd that moves around together. Eventually, the units may drift apart and begin to differentiate, but there is nothing to compel this, so the process is slow and unreliable. Usually, in selecting an initial topology for a backprop net, it is necessary to include many extra hidden units to increase the odds that each job will be done by some unit.

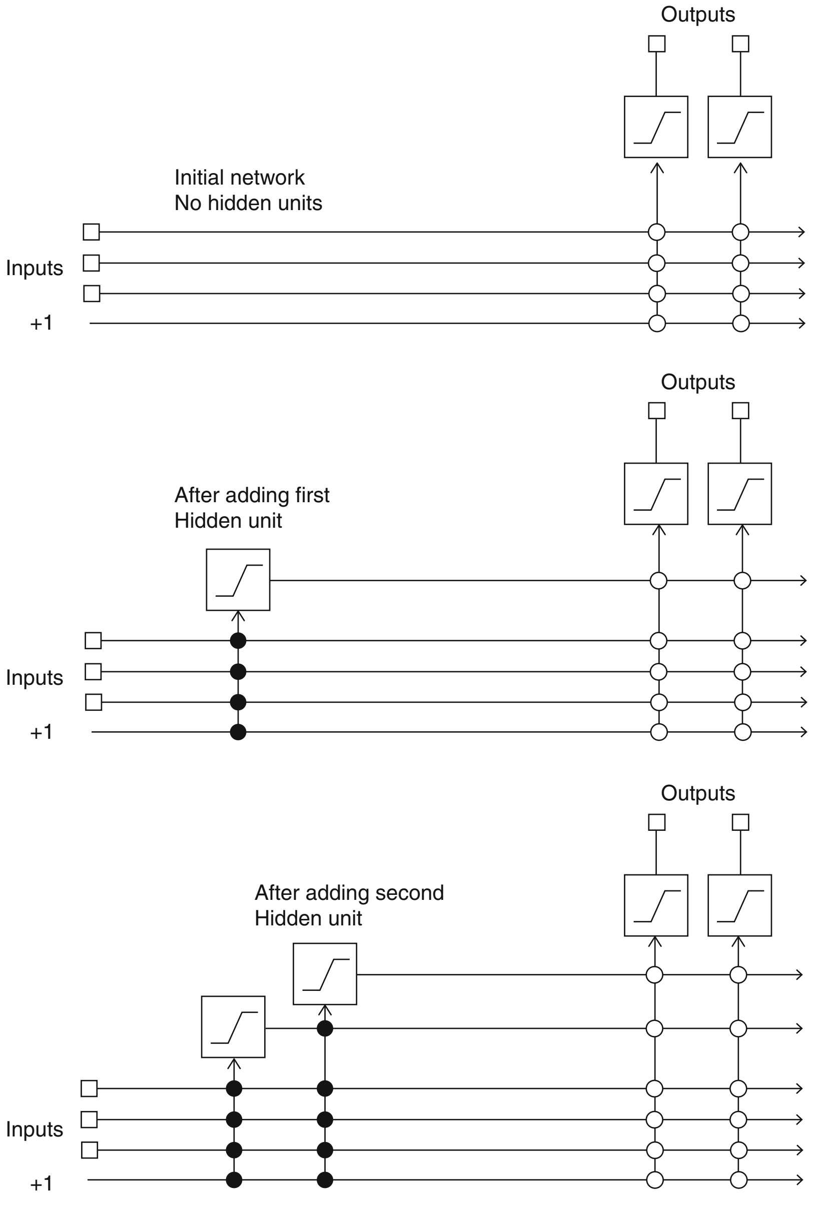
CC addresses this problem by introducing and training hidden units one by one. Each hidden unit sees a strong, clear error gradient, not confused by the simultaneous movement of other hidden units. A new hidden unit can thus move quickly and decisively to a position in parameter space where it can perform a useful function, reducing the residual error. One by one, Cascor-hidden units take up distinct jobs, instead of milling about together competing to do the same job.

Structure of Learning System

The Algorithm

The CC architecture is illustrated in Fig. 1. It begins with some inputs and one or more output units, but no hidden units. The numbers of inputs and outputs are dictated by the problem. As in backprop, the output units generally have a sigmoid activation function, but could alternatively have a linear activation function. Every input is connected to every output unit by a connection with an adjustable weight. There is also a *bias* input, permanently set to +1.

Hidden units are added to the network one by one. Each new hidden unit receives a weighted connection from each of the network's original



Cascade Correlation, Fig. 1 The Cascade–correlation (CC) architecture, as new hidden units are added. *Black circles* are frozen connection weights; *white circles* are weights trained during output training phase. The *vertical lines* sum all incoming activation

inputs and also from every existing hidden unit. Each new unit therefore adds a new single-unit layer to the network. This makes it possible to create high-order nonlinear feature detectors, customized for the problem at hand.

As noted, learning begins without hidden units. The direct input–output connections are trained as well as possible over the entire set of training examples, using Quickprop. At some point, this training approaches an asymptote. When no significant error reduction has occurred after a certain number of training cycles, this output phase is terminated and there is a shift to input phase to recruit a new hidden unit, using the unit-creation algorithm to be described. The new unit is added to the net, its input weights are frozen, and all the output weights are once again trained using Quickprop. This cycle repeats until the error is acceptably small, in the sense that all network outputs for all training patterns are within a specified threshold of their target values.

To create a new hidden unit, input phase begins with several *candidate units* that receive trainable input connections from all of the network inputs and from all existing hidden units. The outputs of these candidates are not yet connected to the network. There are a number of passes over the examples of the training set, adjusting the candidate unit's input weights after each pass. The goal of these adjustments, using Quickprop, is to maximize the correlation between each candidate's output and the residual error.

When these correlation measures show no further significant improvement, input phase stops, the best-correlating candidate's input weights are frozen, and that unit is installed in the network. The remaining candidates are discarded and the algorithm then retrains the output weights, making use of this new feature as well as all the old ones. As the new unit's output correlates well with some component of the residual error, its output weights can be quickly adjusted to reduce that component. So after adding each new hidden unit, the network's residual error should be smaller than before.

Using several candidates, each with differently initialized input weights, greatly reduces the chances of installing a bad hidden unit that gets the network stuck in a local optimum far from the global optimum value. All candidates receive the same input signals and see the same residual error for each training pattern. Because they do not interact with one another or affect the network during training, these candidates can be trained in parallel. In a pool of four to eight candidates, there are almost always several high-quality candidates with nearly equal correlation values.

Hidden units continue to be recruited until network error reaches an acceptable level, or until cross-validation signals a stop. Because only a single layer of weights is adjusted at a time, rather than back-propagating an error signal through several layers of shifting units, CC training proceeds very quickly.

Performance

CC is designed to produce a network just large enough to solve the problem and to do so much faster than backprop and related algorithms. In many reported cases that require hidden units, CC learns the desired behavior 10–100 times faster than standard backprop (Fahlman and Lebiere 1990). One striking example of this is the *two-spirals problem*, an artificial benchmark designed to be very difficult for neural networks with sigmoid units. At the time CC was developed, the best known backprop solutions for two spirals required a network with three hidden layers of five units each. CC typically solves this problem with 12 hidden units and has found solutions with as few as nine hidden units. In terms of runtime, CC training was about 50 times faster than standard backprop and 23 times faster than Quickprop used within a static network.

Variants of Cascade Correlation

Flat Cascade Correlation

In standard CC, each new hidden unit receives inputs from every existing unit, so the net becomes one level deeper every time a unit is added. This is a powerful mechanism, creating increasingly complex feature detectors as the network learns. But sometimes this added depth is not required for the problem, creating a very deep network that performs no better than a shallow one. The resulting network might have more weights than are required for the problem, raising concern about overfitting. Another concern was that the cascaded nonlinearity of CC might also compromise generalization. To address these concerns, a flat variant of Cascor adds new recruited units onto a single layer (i.e., cascaded connections are eliminated), limiting the depth of the network and eliminating all cascaded weights between hidden units.

Comparison of flat to standard CC on generalization in particular learning problems yielded inconsistent results, but a more problem–neutral, student–teacher approach found no generalization differences between flat and standard versions of CC (Dandurand et al. 2007). Here, flat and standard student CC networks learned the input–output mappings of other randomly initialized flat and standard CC teacher networks, where task complexity was systematically manipulated. Both standard and flat CC student networks learned and generalized well on problems of varying complexity. In low-complexity tasks, there were no significant performance differences between flat and standard CC student networks. For high-complexity tasks, flat CC student networks required fewer connection weights and learned with less computational cost than did standard CC student networks.

Sibling–Descendant Cascade–Correlation (SDCC)

SDCC (Baluja and Fahlman 1994) provides a more general solution to the problem of network depth. In the candidate pool, there are two kinds of candidate units: *descendant* units that receive inputs from all existing hidden units and *sibling* units that receive the same inputs as the deepest hidden units in the current net. When the time comes to choose a winning candidate, the candidate with the best correlation wins, but there is a slight preference for sibling units. So unless a descendant unit is clearly superior, a sibling unit will be recruited, making the active network larger, but not deeper. In problems where standard CC produces a network with 15 or 20 hidden units and an equal number of layers, SDCC often produces a network with only two or three hidden layers.

Recurrent Cascade–Correlation (RCC)

Standard CC produces a network that maps its *current* inputs to outputs. The network has no memory of recent inputs, so this architecture is not able to learn to recognize a sequence of inputs. In the RCC algorithm, each candidate and hidden unit takes the same inputs as in standard CC, but it also takes an additional input: the unit's own previous output, delayed by one time interval (Fahlman 1991). The weight on this time-delayed input is trained by the same algorithm as all the other inputs.

This delayed loop gives RCC networks a way of remembering past inputs and internal states, so they can learn to recognize sequences of input patterns. In effect, the architecture builds a finite-state machine tailored specifically to recognize the pattern sequences in the training set. For example, an RCC net learned to recognize characters in Morse code.

Knowledge-Based Cascade–Correlation (KBCC)

KBCC is a variant that can recruit previously-learned networks or indeed any differentiable function, in competition with single hidden units (Shultz and Rivest 2001; Shultz et al. 2007). The recruit is the candidate whose output correlates best with residual network error, just as in ordinary CC. The candidate pool usually has a number of randomly initialized sigmoid units and a number of candidate source networks, i.e., networks previously trained on other tasks. The input weights to multiple copies of the source networks are usually randomly initialized to improve optimization. Of these copies, one is typically connected with an identity matrix with off-diagonal zeros, to enable quick learning of the target task when exact knowledge is available. A hypothetical KBCC network is shown in Fig. 2.

Applications

CC

Partly because of its ability to grow its own networks and build new learning on top of existing knowledge, CC has been used to simulate many phenomena in cognitive development. These characteristics embody the constructivism that developmental psychologists often discussed but did not formulate precisely. Simulations are typically evaluated by how well they capture the various psychological phenomena that characterize a particular domain.

The balance-scale task involves presenting a child with a rigid beam balanced on a fulcrum with pegs spaced at equal intervals to the left and right of the fulcrum. A number of identical weights are placed on a peg on the left side and a peg on the right side, and the child is asked to predict which side will descend when the beam is released from its moorings. CC networks passed through the stages observed with children and captured the so-called torque difference effect, the tendency to do better on problems with large absolute torque differences than on problems with small torque differences (Shultz et al. 1994; Shultz and Takane 2007).

The conservation task presents a child with two quantities of objects that the child judges to be equal and then transforms one set in a way that either changes that relationship or conserves it. CC networks captured four important conservation regularities (Shultz 1998):

1. A shift from nonconservation to conservation beliefs
2. A sudden spurt in performance during acquisition
3. Emergence of correct conservation judgments for small quantities before larger quantities
4. Young children's choice of the longer row as having more items than the shorter row

Analysis of network solutions at various points in development revealed a gradual shift from perceptual (how the sets of items look) to cognitive (whether or not the transformation changed a quantity) solutions, similar to what had been found with children.

The seriation task requires a child to order a disordered collection of sticks of different lengths. CC networks passed through the four stages seen in children (total failure, partial sort, trial-and-error sort, and systematic sort) and captured the tendency for sets with smaller differences to be more difficult to sort (Mareschal and Shultz 1999). Analysis of network solutions revealed early success at the short end of the series that was gradually extended to the longer end, as in children.

The transitivity problem typically also employs sticks of different length. Here the child is trained on all pairs of sticks that are adjacent in length and then is asked to infer the relative length of untrained pairs. Five psychological regularities were captured when CC networks were trained to compare the relative sizes of adjacent pairs (Shultz and Vogel 2004):

1. Learning short or long adjacent pairs before adjacent pairs of medium length.
2. Faster inferences with pairs farther apart in length than with pairs close together in length, an effect that diminished with age. A constraint-satisfaction network module simulated reaction times by inputting the output of a CC network and settling over time cycles into a low-energy solution that satisfied the constraints supplied by connection weights and inputs, effectively cleaning up the output of the CC network.
3. Faster inferences with pairs containing the shortest or longest stick.
4. Faster inferences when the expression used in the question (e.g., shorter) is compatible with an end stick (e.g., the shortest stick) in the compared pair than when the question term (e.g., shorter) is incompatible with an end stick (e.g., the longest stick) in the compared pair.
5. Older children learned adjacent pairs faster and made inference comparisons faster and more accurately than did young children.

The computational bases for these effects were revealed by examining the pattern of connection weights within the CC network module. The pattern of these weights formed a cubic shape, symmetrical for the two sticks being compared, in which discrimination was better at the ends of the array than in the middle and became sharper with deeper learning.

Another task calls for integration of cues for moving objects, governed by the equation velocity = distance/time. Children were presented with information on two of those quantities and asked to infer the third. Three stages involved first using the quantity that varied positively with the quantity to be inferred, second adding or subtracting the known quantities, and finally multiplying or dividing the known quantities. Already documented stages were captured and others were correctly predicted by CC networks (Buckingham and Shultz 2000).

Semantic rules for deictic personal pronouns specify that *me* refers to the person using the pronoun and *you* refers to the person who is being addressed. Although most children acquire these pronouns without notable errors, a few reverse these pronouns, persistently calling themselves *you* and the mother *me*. Such reversals in children are produced by lack of opportunity to overhear these pronouns used by other people, where the shifting reference can be observed. CC networks covered these phenomena and generated predictions for effective therapy to correct reversal errors (Oshima-Takane et al. 1999).

Discrimination shift learning tasks repeatedly present pairs of stimuli with mutually exclusive attributes on several binary dimensions, such as color, shape, and position, and a child learns to select the correct stimulus in each pair, e.g., *square*. Feedback is given and learning continues until the child reaches a success criterion, e.g., 8/10 correct. Then reward contingencies shift, usually without warning. A *reversal* shift stays within the initially relevant dimension, e.g., from *square* to *circle*. A *nonreversal* shift is to another dimension, such as from *square* to *blue*. There are related tasks that use new stimulus values in the shift phase. These are called *intradimensional* shifts if the shift remains within the initial dimension, e.g., *square* to *triangle*, or *extradimensional* if there is a change to another dimension, e.g., from *square* to *yellow*. The *optional shift* task presents only two stimulus pairs in the shift phase, making it ambiguous whether the shift is a reversal or nonreversal shift. The pattern of subsequent choices allows determination of whether the child interprets this as a reversal or a nonreversal shift.

Age differences in the large literature on these shifts indicate that older children learn a reversal shift faster than a nonreversal shift, learn an intradimensional shift faster than an extradimensional shift, make a reversal shift in the optional task, and are initially impaired on unchanged pairs during a nonreversal shift. Younger children learn reversal and nonreversal shifts equally fast, learn an intradimensional shift faster than an extradimensional shift, make a nonreversal shift in the optional task, and are unimpaired on unchanged pairs during a nonreversal shift. These findings were simulated by CC networks (Sirois and Shultz 1998), which also generated predictions that were later confirmed.

When infants repeatedly experience stimuli from a particular class, their attention decreases, but it recovers to stimuli from a different class. This familiarize-and-test paradigm is responsible for most of the discoveries of infant psychological abilities. CC networks simulated findings on infant attention to syntactic patterns in an artificial language (Shultz and Bale 2006) and age differences in infant categorization of visual stimuli (Shultz and Cohen 2004) and generated several predictions, some of which were tested and confirmed.

SDCC

Because of SDCC's ability to create a variety of network topologies, it is beginning to be used in psychology simulations: infant learning of word-stress patterns in artificial languages (Shultz and Bale 2006), syllable boundaries (Shultz and Bale 2006), visual concepts (Shultz 2006), and false-belief tasks; learning the structure of mathematical groups (Schlimm and Shultz 2009); replication of the results of the CC simulation of conservation acquisition (Shultz 2006); and concept acquisition.

CC and SDCC networks capture developmental stages by growing in computational power and by being sensitive to statistical patterns in the training environment (Shultz 2003). The importance of growth was demonstrated by comparisons with static backprop networks, designed with the same final topology as successful CC networks, that learn only by adjusting connection weights (Shultz 2006). Coupled with the variety of successful SDCC topologies, this suggests that the constructive process is more important than precise network topologies. Capturing stages is challenging because the system has to not only succeed on the task but also make the same mistakes on the road to success that children do. CC and SDCC arguably produced the best data coverage of any models applied to the foregoing phenomena. Both static and constructive networks capture various perceptual effects by virtue of their sensitivity to quantitative variation in stimulus inputs (Shultz 2003).

Comparison of the two algorithms in psychological modeling indicates that SDCC provides the same functionality as CC but with fewer connection weights and shallower and more variable network topologies (Shultz 2006).

KBCC

KBCC also has potential for simulating psychological development, but it has so far been applied mainly to toy and engineering problems. Exploration of a variety of toy problems was important in understanding the behavior of this complex algorithm. Some toy problems involved learning about two-dimensional geometric shapes under various transformations such as translation, rotation, and size changes as well as compositions of complex shapes from simpler shapes (Shultz and Rivest 2001). Networks had to learn to distinguish points within a target shape from points outside the shape. Learning time without relevant knowledge was up to 16 times longer than with relevant knowledge on these problems. There was a strong tendency to recruit relevant knowledge whenever it was available. Direct comparison revealed that KBCC learned spatial translation problems faster than Multitask Learning networks did.

Parity problems require a network to activate an output unit only when an odd number of binary inputs are activated. When parity-4 networks were included in the candidate source pool, KBCC learned parity-8 problems (with eight binary inputs) faster and with fewer recruits than did CC networks. Parity-4 networks were recruited by these KBCC target networks whenever available.

KBCC also learned complex chessboard shapes from knowledge of simpler chessboards. As with parity, networks used simpler previous knowledge to compose a solution to a more complex problem and learning was speeded accordingly.

In a more realistic vein, KBCC networks recruiting knowledge of vowels from one sort of speaker (e.g., adult females) learned to recognize vowels spoken by other sets of speakers (e.g., children and adult males) faster than did knowledge-free networks.

KBCC learned an efficient algorithm for detecting prime numbers by recruiting previously learned knowledge of divisibility (Shultz et al. 2007). This well-known detection algorithm tests the primality of an integer n by checking if n is divisible by any integers between 2 and the integer part of $\sqrt{n}$. Starting with small primes is efficient because the smaller the prime divisor, the more composites are detected in a fixed range of integers. The candidate pool contained networks that had learned whether an integer could be divided by each of a range of integers, e.g., a divide- by-2 network, a divide-by-3 network, etc., up to a divisor of 20. KBCC target networks trained on 306 randomly selected integers from 21 to 360 recruited only source networks involving prime divisors below the square root of 360, in order from small to large divisors. KBCC avoided recruiting single hidden units, source networks with composite divisors, any divisors greater than the square root of 360 even if prime, and divisor networks with randomized connection weights. KBCC never recruited a divide-by-2 source network because it instead learned to check the last binary digit of n to determine if n was odd or even, an effective shortcut to dividing by 2. Such KBCC networks learned the training patterns in about one third the time required by knowledge-free networks, with fewer recruits on fewer network layers, and they generalized almost perfectly to novel test integers. In contrast, even after mastering the training patterns, CC networks generalized less well than automatic guessing that the integer was composite, which was true for 81 % of integers in this range. As predicted by the simulation, adults testing primality also used mainly prime divisors below $\sqrt{n}$ and ordered divisors from small to large.

This work underscores the possibility of neural network approaches to compositionality because KBCC effectively composed a solution to prime number detection by recruiting and organizing previously learned parts of the problem, in the form of divisibility networks.

Future Directions

One new trend is to inject symbolic rules or functions into KBCC source networks. This is similar to KBANN, but more flexible because a KBCC target network decides whether and how to recruit these functions. This provides one method of integrating symbolic and neural computation and allows for simulation of the effects of direct instruction.

Abstract

Case-based reasoning (CBR) solves problems by retrieving similar, previously solved problems and reusing their solutions. The case base contains a set of cases, and each case holds knowledge about a problem or situation, together with its corresponding solution or action. The case base acts as a memory, remembering is achieved using similarity-based retrieval, and the retrieved solutions are reused. Newly solved problems may be retained in the case base and so the memory is able to grow as problem-solving occurs.

CBR reuses remembered experiences, where the experience need not record *how* the solution was reached, simply that the solution was used for the problem. The reliance on stored experiences means that CBR is particularly relevant in domains which are ill defined, not well understood, or where no underlying theory is available. CBR systems are a useful way to capture corporate memory of human expertise.

The fundamental assumption of CBR is that *similar problems have similar solutions*: a patient with similar symptoms will have the same diagnosis, the price of a house with similar accommodation and location will be similar, the design for a kitchen with a similar shape and size can be reused, and a journey plan is similar to an earlier trip. A related assumption is that the world is a regular place, and what holds true today will probably be true tomorrow. A further assumption relevant to memory is that situations repeat, because if they do not, there is no point remembering them!

Synonyms

Experience-based reasoning; Lessons-learned systems; Memory-based learning

Theory/Solution

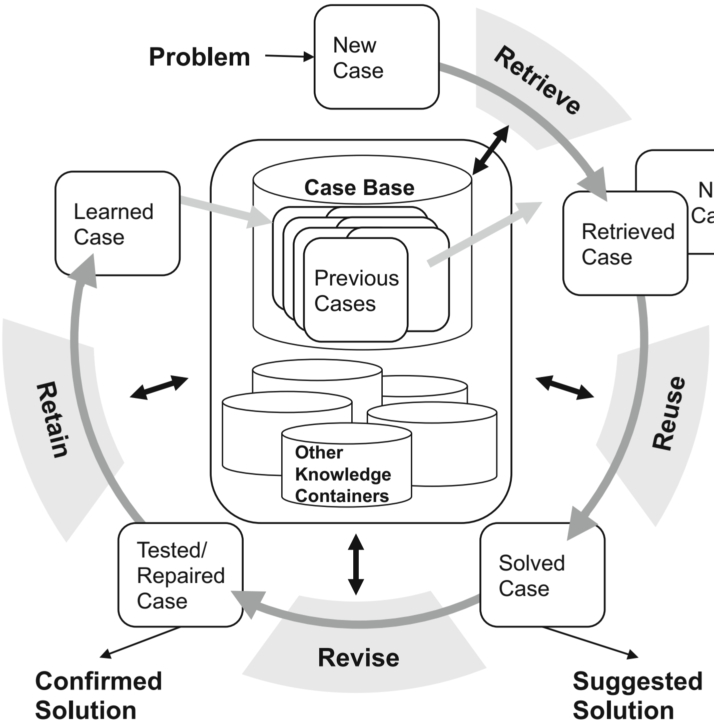
Case-based reasoning (CBR) is inspired by memory-based human problem-solving in which instances of earlier problem-solving are remembered and applied to solve new problems. For example, in case law, the decisions in trials are based on legal precedents from previous trials. In this way, specific experiences are memorized, and remembered and reused when appropriate. This contrasts with rule-based or theory-based problem-solving in which knowledge of *how* to solve a problem is applied. A doctor diagnosing a patient's symptoms may apply knowledge about how diseases manifest themselves, or she may remember a previous patient who demonstrated similar symptoms and thus apply a case-based approach.

CBR is an example of ▶ lazy learning because there is no learned model to apply to solve new problems. Instead, the generalization needed to solve unseen problems happens when a new problem is presented and the similarity-based retrieval identifies relevant previous experiences.

Figure 1 shows the CBR problem-solving cycle proposed by Aamodt and Plaza (1994). A case base of Previous Cases is the primary knowledge source in a CBR system, with additional knowledge being used to identify similar cases in the Retrieve stage, and to Reuse and Revise the retrieved case. A CBR system learns as it solves new problems when a Learned Case is created from the New Case and its Confirmed Solution, and Retained as a new case in the case base.

Aamodt and Plaza's four-stage CBR cycle for problem-solving and learning is commonly referred to as the "Four REs" or "R^4" cycle to recognize the following stages in Fig. 1:

- Retrieve: The cases that are most similar to the New Case defined by the description of the new problem are identified and retrieved from the case base. The Retrieve stage uses



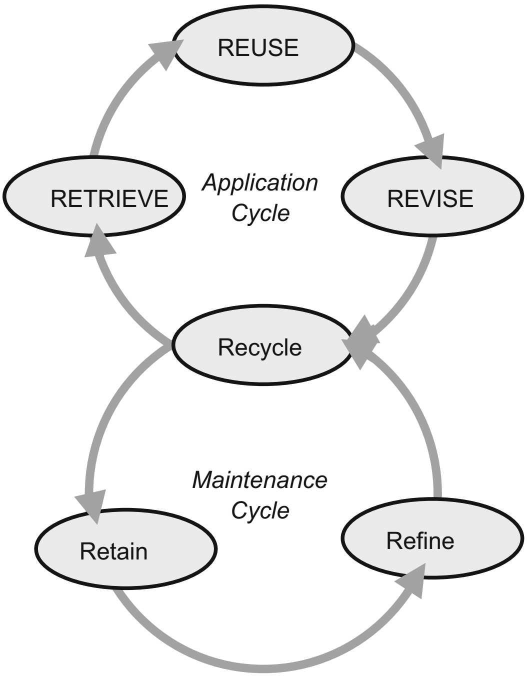
Case-Based Reasoning, Fig. 1 CBR cycle (Adapted from Aamodt and Plaza 1994) the similarity knowledge container in addition to the case base.

- Reuse: The solutions in the Retrieved (most similar) Cases are reused to build a Suggested Solution to create the Solved Case from the New Case. The Reuse stage may use the adaptation knowledge container to refine the retrieved solutions.
- Revise: The Suggested Solution in the Solved Case is evaluated for correctness and is repaired if necessary to provide the Confirmed Solution in the Tested/Repaired Case. The Revise stage may be achieved manually or may use adaptation knowledge, but it should be noted that a revision to a Suggested Solution is likely to be a less demanding task than solving the problem from scratch.
- Retain: The Repaired Case may be retained in the case base as a newly Learned Case if it is likely to be useful for future problem-solving. Thus the primary knowledge source for CBR may be added to during problem-solving and is an evolving, self-adaptive collection of problem-solving experiences.

This "Four REs" cycle simply Retained the Tested/Repaired Case as a new Learned Case. More recently, the Retain stage has been replaced with a Recycle-Retain-Refine loop of a "Six REs" cycle proposed by Gokër and Roth-Berghofer (1999) and shown in Fig. 2. Learned Cases are Recycled as potential new cases, the Retain step validates their correctness, before the Refine stage decides if the case should be integrated and how this should be done. The new case may be added, used to replace redundant cases, or merged with existing cases, and other case base maintenance may be required to maintain the integrity of the CBR system. The maintenance cycle is often executed separately from the problem-solving Application Cycle.

Knowledge Containers

Case knowledge is the primary source of knowledge in a CBR system. However, case knowledge is only one of four knowledge containers identified by Richter (2009):



Case-Based Reasoning, Fig. 2 Six REs CBR cycle (Adapted from Gokër and Roth-Berghofer 1999)

- Vocabulary: The representation language used to describe the cases captures the concepts involved in the problem-solving.
- Similarity knowledge: The similarity measure defines how the distances between cases are computed so that the nearest neighbors are identified for retrieval.
- Adaptation knowledge: Reusing solutions from retrieved cases may require some adaptation to enable them to fit the new problem.
- Case base: The stored cases capture the previous problem-solving experiences.

The content of each knowledge container is not fixed, and knowledge in one container can compensate for lack of knowledge in another. It is easy to see that a more sophisticated knowledge representation could be less demanding on the content of the case base. Similarly, vocabulary can make similarity assessment during retrieval easier, or a more complete case base could reduce the demands on adaptation during reuse. Further knowledge containers are proposed by others (e.g., maintenance by Gokër and Roth-Berghofer 1999) .

Cases may be represented as simple feature vectors containing nominal or numeric values. A case capturing a whisky-tasting experience might contain features such as sweetness, peatiness, color, nose and palate, and the ▶ classification as the distillery where it was made.

Sweet-ness	Peati-ness	Color	Nose	Palate	Distillery
6	5	amber	full	medium dry	Dalmore

More structured representations can use frame-based or object-oriented cases. The choice of representation depends on the complexity of the experiences being remembered and is influenced by how similarity should be determined. Hierarchical case representations allow cases to be remembered at different levels of abstraction, and retrieval and reuse may occur at these different levels.

For ▶ classification tasks, the case base can be considered to contain exemplars of problem-solving. This notion of exemplar confirms a CBR case base as a source of knowledge; it contains only those experiences that are believed to be useful for problem-solving. A similar view is taken for non-classification domains where the case base contains useful prototypes: for example, designs that can be used for redesign, plans for replanning, etc.

One of the advantages of CBR is that a case base is composed of independent cases that each captures some local problem-solving knowledge that has been experienced. Therefore, the "knowledge acquisition bottleneck" of many rule-based and model-based systems is reduced for CBR. However, the other knowledge containers provide additional knowledge acquisition demands that may lessen the advantage of CBR for some domains.

Retrieval

CBR retrieval compares the problem part of the new case with each of the cases in the case base to establish the distance between the new case and the stored cases. The cases closest to the new case are retrieved for reuse. Retrieval is a major focus of López de Mántaras et al.'s (2005) review of research contributions related to the CBR cycle.

Similarity- and distance-based neighborhoods are commonly used interchangeably when discussing CBR retrieval. Similarity and distance are inverses: the similarity is highest when the distance is close to 0, and the similarity is 0 when the distance is large. Several functions may be applied to define a suitable relationship between a distance d and a similarity s, including the following simple versions:

Inverse: $s = \dfrac{1}{d+1}$

Linear: $s = 1 - d$ for normalized d $(0 \leq d \leq 1)$

It is common to establish the distance between each pair of feature values and then to use a distance metric, often Euclidean or ▶ Manhattan distance (see also ▶ Similarity Measures), to calculate the distance between the feature vectors for the New and Retrieved Cases. The distance between two numeric feature values v and w for a feature F is normally taken to be the distance between the normalized values:

$$d(v, w) = \frac{\mid v - w \mid}{F_{\max} - F_{\min}}$$

where $F_{\max}/F_{\min}$ are the maximum/minimum values of the feature F.

For nominal values v and w, the simplest approach is to apply a binary distance function:

$$d(v, w) = \begin{cases} 0 \text{ if } v = w \\ 1 \text{ otherwise} \end{cases}$$

For ordered nominal values, a more fine-grained distance may be appropriate. The distance between the ith value v_i and the jth value v_j in the ordered values $v_1, v_2, \ldots, v_n$ may use the separation in the ordering to define the distance:

$$d(v_i, v_j) = \frac{\mid i - j \mid}{n - 1}.$$

Extending this to arbitrary nominal values, a distance matrix D may define the distance between each pair of nominal values by assigning the distance $d(v_i, v_j)$ to d_{ij}. Alternatively there may be background knowledge in the form of an ontology or concept hierarchy where their depth D in the structure compared to the depth of their least common ancestor (lca) can provide a measure of separation:

$$d(v_i, v_j) = \frac{D(v_i) + D(v_j)}{2D(\text{lca})}$$

Returning to the whisky-tasting example, suppose sweetness and peatiness score values 0–10, color takes ordered values {pale, straw, gold, honey, amber}, palate uses binary distance, and nose is defined by the following distance matrix:

Nose Distance Matrix

Distances	peat	fresh	soft	full
peat	0	0.3	1	0.5
fresh	0.3	0	0.5	0.7
soft	1	0.5	0	0.3
full	0.5	0.7	0.3	0

Dalmore whisky above can be compared with Laphroaig and The Macallan as follows:

Sweetness	Peatiness	Color	Nose	Palate	Distillery
2	10	amber	peat	medium dry	Laphroaig
7	4	gold	full	big body	The Macallan

The Manh distances are:

$$\begin{aligned} d(\text{Dalmore, Laphroaig}) &= 0.4 + 0.5 + 0 + 0.5 \\ &\quad + 0 = 1.4; \\ d(\text{Dalmore, The Macallan}) &= 0.1{+}0.1{+}0.5{+}0 \\ &\quad + 1 = 1.7. \end{aligned}$$

Taking all the whisky features with equal importance, Dalmore is more similar to Laphroaig than to The Macallan.

In situations where the relative importance of features should be taken into account, a weighted version of the distance function should be used; for example, the weighted Manhattan distance between two normalized vectors $\mathbf{x} = (x_1, x_2, \ldots x_n)$ and $\mathbf{y} = (y_1, y_2, \ldots y_n)$ with weight w_i for the ith feature is

$$d(\mathbf{x}, \mathbf{y}) = \frac{\sum_{i=1}^{n} w_i \mid x_i - y_i \mid}{\sum_{i=1}^{n} w_i}$$

In the example above, if Peatiness has weight 4 and the other features have weight 1, then the weighted Manhattan distances are:

$$\begin{aligned} d(\text{Dalmore, Laphroaig}) &= (0.4 + 4 \times 0.5 + 0 \\ &\quad +0.5{+}0)/8{=}0.36; \\ d(\text{Dalmore, The Macallan}) &= (0.1{+}4{\times}0.1{+}0.5 \\ &\quad +0 + 1)/8{=}0.25. \end{aligned}$$

Therefore, emphasizing the distinctive Peatiness feature, Dalmore is more similar to The Macallan than to Laphroaig.

The similarity knowledge container contains knowledge to calculate similarities. For simple feature vectors, a weighted sum of distances is often sufficient, and the weights are similarity knowledge. However, even our whisky-tasting domain had additional similarity knowledge containing the distance matrix for the nose feature. Structured cases require methods to calculate the similarity of two cases from the similarities of components. CBR may use very knowledge-intensive methods to decide similarity for the retrieval stage. Ease of reuse or revision may even be incorporated as part of the assessment of similarity. Similarity knowledge may also define how ▶ missing values are handled: the feature may be ignored, the similarity may be maximally pessimistic, or a default or average value may be used to calculate the distance.

A CBR case base may be indexed to avoid similarity matching being applied to all the cases in the case base. One approach uses kd trees to partition the case base according to hyperplanes. ▶ Decision Tree algorithms may be used to build the kd tree by using the cases as training data, partitioning the cases according to the chosen decision nodes and storing the cases in the appropriate leaf nodes. Retrieval first traverses the decision tree to select the cases in a leaf node, and similarity matching is applied to only this partition. Case Retrieval Nets are designed to speed up retrieval by applying spreading activation to select relevant cases. In Case Retrieval Nets, the feature value nodes are linked via similarity to each other and to cases. Indexes can speed up retrieval but they also preselect cases according to some criteria that may differ from similarity.

Reuse and Revision

Reuse may be as simple as copying the solution from the Retrieved Case. If k nearest neighbors are retrieved, then a vote of the classes predicted in the retrieved cases may be used for ▶ classification, or the average of retrieved values for ▶ regression. A weighted vote or weighted average of the retrieved solutions can take account of the nearness of the retrieved cases in the calculation. For more complex solutions, such as designs or plans, the amalgamation of the solutions from the Retrieved Cases may be more knowledge intensive.

If the New Case and the Retrieved Case are different in a significant way, then it may be that the solution from the Retrieved Case should be adapted before being proposed as a Suggested Solution. Adaptation is designed to recognize significant differences between the New and Retrieved Cases and to take account of these by adapting the solution in the Retrieved Case.

In classification domains, it is likely that all classes are represented in the case base. However, different problem features may alter the classification and so adaptation may correct for a lack of cases. In constructive problem-solving like design and planning, however, it is unlikely that all solutions (designs, plans, etc.) will be represented in the case base. Therefore, a retrieved case suggests an initial design or plan, and adaptation alters it to reflect novel feature values.

There are three main types of adaptation that may be used, as part of the reuse step to refine the solution in the Retrieved Case to match better the new problem, or as part of the revise stage to repair the Suggested Solution in the Solved Case:

- Substitution: Replace parts of the retrieved solution. In Hammond's (1990) CHEF system to plan Szechuan recipes, the substitution of ingredients enables the requirements of the new menu to be achieved. For example, the beef and broccoli in a retrieved recipe are substituted with chicken and snowpeas.
- Transformation: Add, change, or remove parts of the retrieved solution. CHEF adds a skinning step to the retrieved recipe that is needed for chicken but not for beef.
- Generative Adaptation: Replay the method used to derive the retrieved solution. Thus the retrieved solution is not adapted but a new solution is generated from reusing the retrieved method for the new circumstances. This approach is similar to reasoning by analogy.

CHEF also had a clear REVISE stage where the Suggested Solution recipe was tested in simulation and any faults were identified, explained, and repaired using repair templates for different types of explained failures. In one recipe a strawberry soufflé was too liquid, and one repair is to drain the strawberry pulp, and this transformation adaptation is one REVISE operation that could be applied.

The adaptation knowledge container is an important source of knowledge for some CBR systems, particularly for design and planning, where refining an initial design or plan is expected. Acquiring adaptation knowledge can be onerous, and learning adaptation knowledge from the cases in the case base or from background knowledge of the domain has been effective (Craw et al. 2006; Jalali and Leake 2013).

Retention and Maintenance

The retention of new cases during problem-solving is an important advantage of CBR systems. However, it is not always advantageous to retain all new cases. The ▶ Utility Problem – *that the computational benefit from additional knowledge must not outweigh the cost of applying* *it* – in CBR refers to cases and the added cost of retrieval. The case base must be kept "lean and mean," and so new cases are not retained automatically, and cases that are no longer useful are removed. New cases should be retained if they add to the competence of the CBR system by providing problem-solving capability in an area of the problem space that is currently sparse. Conversely, existing cases should be reviewed for the role they play, and forgetting cases is an important maintenance task. Existing cases may contain outdated experiences and so should be removed, or they may be superseded by new cases.

Case base maintenance manages the contents of the case base to achieve high competence. Competence depends on the domain and may involve:

- quality of solution;
- user confidence in solution; or
- efficiency of solution prediction (e.g., speed-up learning).

As a result, the RETAIN step in Aamodt and Plaza's (1994) "four REs" problem-solving cycle is normally replaced by some form of case base maintenance cycle, such as the ReCycle-Retain-Refine loop in Gokër and Roth-Berghofer's (1999) "six REs" cycle.

Case base maintenance systems commonly assume that the case base contains a representative sample of the problem-solving experiences. They exploit this by using a leave-one-out approach where repeatedly for each case in the case base, the one extracted case is used as a new case to be solved, and the remaining cases become the case base. This enables the problem-solving competence of the cases in the case base to be estimated using the extracted cases as representative new cases to be solved. Various researchers build a competence model for the case base by identifying groups of cases with similar problem-solving ability and use this model to underpin maintenance algorithms that prioritize cases for deletion and to identify areas where new cases might be added.

There are several trade-offs to be managed by case base maintenance algorithms: larger case bases contain more experiences but take longer for retrieval; smaller case bases are likely to lack some key problem-solving ability; cases whose solution is markedly different from their nearest neighbors may be noisy or may be an important outlier. The competence of a case depends on other knowledge containers, and so case base maintenance should not proceed in isolation.

CBR Applications and Tools

Two notable successful deployed applications of CBR are Verdande's Drilledge that monitors oil-well drilling operations to reduce non-productive time (Gundersen et al. 2013), and General Electric's FormTool for plastic color matching (Cheetham 2005). Many more applications are described in the *Fielded Applications of CBR* article in Knowledge Engineering Review 20(3) CBR Special Issue (2005) and Montani and Jain's *Successful Case-Based Reasoning Applications* texts (Springer, 2010 & 2014):

- *Classification* – Medical diagnosis systems include SHRINK for psychiatry, CASEY for cardiac disease, and ICONS for antibiotic therapy for intensive care. Other diagnostic systems include failure prediction of rails for Dutch railways, Boeing's CASSIOPÉE for trouble-shooting aircraft engines, and the HOMER Help-Desk (Gokër and Roth-Berghofer 1999).
- *Design* – Architectural design was a popular early domain: ARCHIE and CADsyn. Other design applications include CADET and KRITIK for engineering design, pharmaceutical tablet formulation, Déjà Vu for plant control software, and Lockheed's CLAVIER for designing layouts for autoclave ovens.
- *Planning* – PRODIGY is a general purpose planner that uses analogical reasoning to adapt retrieved plans. Other planning applications include PARIS for manufacturing planning, mission planning for US navy, and route planning for DaimlerChrysler cars. A recent focus is planning in simulated complex environments as found in Real-Time Strategy Games (Jaidee et al. 2013; Ontañón and Ram

2011; Wender and Watson 2014). CBR has other Game AI applications including robot soccer and poker.

- *Textual CBR* – Legal decision support systems were an important early application domain for textual CBR, including HYPO, GREBE, and SMILE. Question answering was another fruitful text-based domain: FAQ-Finder and FA11Q. More recently, textual CBR is used for industrial decision support based on textual reports; e.g., incident management and Health & Safety.
- *Conversational CBR* – Conversational systems extract the problem specification from the user through an interactive case-based dialogue. Examples include help-desk support, CBR Strategist for fault diagnosis, and Wasabi and ShowMe product recommender systems.
- *Recommender Systems* – There has been a large growth in the use of CBR for recommendation of products, travel planning, and online music. Current topics include preference recommenders for individuals and groups (Quijano-Sánchez et al. 2012) and sentiment/opinion mining from social media to improve personalization (Dong et al. 2014).
- *Workflows* – A recent interest in process-oriented CBR has used the CAKE Collaborative Agile Knowledge Engine to create office workflows (Minor et al. 2014). Other applications include science workflows, medical pathways, modeling interaction traces, and recipes. These applications use structured cases and demand knowledge-rich adaptation for reuse. An annual Computer Cooking Competition at recent ICCBR conferences has encouraged the development of various case-based recipe systems including Taaable, JADAWeb, CookIIS, ChefFroglingo, GoetheShaker (cocktails), and EARL (sandwiches).

There are two main open-source CBR tools: myCBR and Colibri. Both provide state-of-the-art CBR functionality, and Colibri also incorporates a range of facilities for textual CBR. The myCBR tool originated from the INRECA methodology, and its website www.mycbr-project.net offers downloads, documentation, tutorials, and publications. Similar Colibri information is available at gaia.fdi.ucm.es/research/colibri, with the jColibri framework also available from www.sourceforge.net. Empolis is one of the pioneers in CBR with CBR Works being one of the first commercial CBR tools. It is now part of Empolis' Information Access System, and is available at www.empolis.com.

Future Directions

The drivers for ubiquitous computing – wireless communication and small devices – also affect future developments in CBR. The local, independent knowledge of case bases makes mobile devices ideal to collect experiences and to deliver experience-based knowledge for reuse.

Textual CBR systems are becoming increasingly important for extracting and representing knowledge captured in textual documents. This is particularly influenced by the availability of electronic documents in the Web and social media as sources of data for the extraction of representation knowledge. They also provide background knowledge from which to learn knowledge for similarity and adaptation containers.

Categorical Data Clustering

Periklis Andritsos[1] and Panayiotis Tsaparas[2]
[1]Faculty of Information, University of Toronto, Toronto, ON, Canada
[2]Department of Computer Science & Engineering, University of Ioannina, Ioannina, Greece

Abstract

In this chapter, we provide an overview of the categorical data clustering problem. We first present different techniques for the general cluster analysis problem, and then study how these techniques specialize to the case of non-numerical (categorical) data. We also present measures and techniques developed specifically for this domain.

Synonyms

Clustering of nonnumerical data; Grouping

Definition

Data clustering is informally defined as the problem of partitioning a set of objects into groups, such that objects in the same group are similar, while objects in different groups are dissimilar. Categorical data clustering refers to the case where the data objects are defined over *categorical* attributes. A categorical attribute is an attribute whose domain is a set of discrete values that are not inherently comparable. That is, there is no single ordering or inherent distance function for the categorical values, and there is no mapping from categorical to numerical values that is semantically sensible.

Motivation and Background

Clustering is a problem of great practical importance that has been the focus of substantial research in several domains for decades. As the volume of collected data grows, the need to mine and understand the data becomes imperative. Clustering plays an instrumental role in this process. As a result in the recent years, there has been a surge of research activity in devising new clustering algorithms that can handle large amounts of data and produce results of high quality.

In data clustering we want to partition objects into groups such that similar objects are grouped together, while dissimilar objects are grouped separately. This definition assumes that there is some well-defined notion of similarity, or distance, between data objects, and a way to decide if a group of objects is a homogeneous cluster. Most of the clustering algorithms in the literature focus on data sets where objects are defined over numerical attributes. In such cases, the similarity (or dissimilarity) of objects can be defined using well-studied measures that are derived from geometric analogies. These definitions rely on the semantics of the data values themselves (e.g., the values $100,000 and $110,000 are more similar than $100,000 and $1). The existence of a distance measure enables us to define a quality measure for a clustering (e.g., the mean square distance between each point and the representative of its cluster). Clustering then becomes the problem of grouping together points such that the quality measure is optimized.

Categorical Data Clustering, Table 1 An instance of a movie database

	Director	Actor	Genre
$\mathbf{t}_1$ (Godfather II)	Scorsese	De Niro	Crime
$\mathbf{t}_2$ (Good fellas)	Coppola	De Niro	Crime
$\mathbf{t}_3$ (Vertigo)	Hitchcock	Stewart	Thriller
$\mathbf{t}_4$ (N by NW)	Hitchcock	Grant	Thriller
$\mathbf{t}_5$ (Bishop's wife)	Koster	Grant	Comedy
$\mathbf{t}_6$ (Harvey)	Koster	Stewart	Comedy

However, there are many data sets where the data objects are defined over attributes, which are neither numerical nor inherently comparable in any way. We term such data sets *categorical*, since they represent values of certain categories. As a concrete example, consider the toy data set in Table 1 that stores information about movies. For the purpose of exposition, a movie is characterized by the attributes "director," "actor/actress," and "genre." In this setting, it is not immediately obvious what the distance, or similarity, is between the values "Coppola" and "Scorsese" or the tuples "Vertigo" and "Harvey."

There are plenty of examples of categorical data: product data, where products are defined over attributes such as brand, model, or color; census data, where information about individuals includes attributes such as marital status, address, and occupation; ecological data where plants and animals can be described with attributes such as shape of petals or type of habitat. There is a plethora of such data sets, and there is always a need for clustering and analyzing them.

The lack of an inherent distance or similarity measure between categorical data objects makes clustering of categorical data a challenging problem. The challenge lies in defining a quality measure for categorical data clustering that captures the human intuition of what it means for categorical data objects to be similar. In the following, we will present an overview of the different efforts at addressing this problem and the resulting clustering algorithms.

Structure of the Learning System

Generic Data Clustering System

We first describe the outline for a generic data clustering system, not necessarily of categorical data. We will then focus on techniques specific to categorical data clustering.

Data clustering is not a one-step process. In one of the seminal texts on cluster analysis, Jain and Dubes (1988) divided the clustering process into seven different stages starting from the data collection and ending with the result interpretation. In this article we are interested in problems relating to the representation of the data, which affects the notion of similarity between the categorical tuples and the clustering strategy, which determines the final algorithm. These lie in the heart of the data clustering problem, and there has been considerable research effort in these areas within the data mining and machine learning communities. More specifically we will consider the following two subproblems: (a) the formal formulation of the clustering problem and (b) the clustering algorithm.

Formal formulation of the clustering problem: In order to devise algorithms for clustering, we need to mathematically formulate the intuition behind the informal definition of the clustering problem where "similar objects are grouped together and dissimilar objects are grouped separately." The problem formulation typically requires at least one of the following:

- A measure of similarity or distance between two data objects.
- A measure of similarity or distance between a data object and a cluster of objects. This is often defined by defining a representative for a cluster as a (new) data object and comparing the data object with the representative.
- A measure of the quality of a cluster of data objects.

The result of the formulation step is to define a clustering optimization criterion that guides the grouping of the objects into clusters.

When the data is defined over numerical attributes, these measures are defined using geometric analogies. For example, in one possible formulation, we can view each object as a point in the Euclidean space, and define the distance between two points as the Euclidean distance, and the representative of a cluster as the mean Euclidean vector. The quality of a cluster can be defined with respect to the "variance" of the cluster, that is, the sum of squares of the distances between each object and the mean of the cluster. The optimization problem then becomes to minimize the variance over all clusters.

The clustering algorithm: Once we have a mathematical formulation of the clustering problem, we need an algorithm that will find the optimal clustering in an efficient manner. In most cases finding the optimal solution is an NP-hard problem, so there are a variety of efficient heuristics or approximation algorithms. There is an extensive literature on this subject that approaches the problem from different angles and a wide variety of different clustering techniques and algorithms. We now selectively describe some broad classes of clustering algorithms and problems. A thorough categorization of clustering techniques can be found in Han and Kamber (2001), where different clustering problems, paradigms, and techniques are discussed.

Hierarchical clustering algorithms: This is a popular clustering technique since it is easy to implement, and it lends itself well to visualization and interpretation. Hierarchical algorithms create a hierarchical decomposition of the objects. They are either *agglomerative* (*bottom-up*) or *divisive* (*top-down*). *Agglomerative* algorithms start with each object being a separate cluster itself and successively merge groups according to some criterion. *Divisive* algorithms follow the opposite strategy. They start with one cluster consisting of all objects and successively split clusters into smaller ones, until each object falls in one cluster, or the desired given condition is met. The hierarchical *dendrogram* produced is often in itself the output of the algorithm, since it can be used for visualizing the data. Most of the times, both approaches suffer from the fact that once a merge or a split is committed, it cannot be undone or refined.

Partitional clustering algorithms: Partitional clustering algorithms define a clustering optimization criterion and then seek the partition that optimizes this criterion. Exhaustive search over all partitions is infeasible since even for few data objects, the number of possible partitions is prohibitively large. Partitional clustering algorithms often start with an initial, usually random, partition and proceed with its refinement by locally improving the optimization criterion. The majority of them could be considered as greedy-like algorithms. They suffer from the fact that they can easily get stuck to local optima.

Spectral clustering algorithms: Spectral algorithms use the data set to be clustered to construct a two-dimensional matrix of data objects and attributes. The entries in the matrix may be the raw values or some transformation of these values. The principal eigenvectors of the matrix are then used to reveal the clustering structure in the data. There is a rich literature on different types of spectral algorithms.

Graph clustering: Graph clustering defines a range of clustering problems, where the distinctive characteristic is that the input data is represented as a graph. The nodes of the graph are the data objects, and the (possibly weighted) edges capture the similarity or distance between the data objects. The data may come naturally in the form of a graph (e.g., a social network), or the graph may be derived in some way from the data (e.g., link two products if they appear together in a transaction). Some of the techniques we describe above are directly applicable to graph data.

Categorical Data Clustering System

In the clustering paradigm we outlined, a step of fundamental importance is to formally formulate the clustering problem, by defining a clustering optimization criterion. As we detail above, for this step we need a measure of distance or similarity between the data objects or a measure of cluster quality for a group of data objects. For categorical data there exists no inherent ordering or distance measure, and no natural geometric analogies we can explore, causing the clustering paradigm to break down. Research efforts on categorical data clustering have focused on addressing this problem by imposing distance measures on the categorical data and defining clustering quality criteria. We now outline some of these approaches.

Overlap-based similarity measures: A simple and intuitive method for comparing two categorical data objects is to view them as sets of attribute values and count the overlap between the categorical values of the objects. The higher the overlap, the more similar the two objects are. This intuition leads to the use of well-known measures such as the (*generalized*) *Hamming distance* (Jain and Dubes 1988), which measures the number of common values between two tuples, or the *Jaccard* similarity measure, which is defined as the intersection over the union of the values in the two tuples. In the example of Table 1, tuples $\mathbf{t}_1$ and $\mathbf{t}_2$ have Hamming distance 1 and Jaccard coefficient $1/2$.

Two algorithms that make use of overlap-based measures are *k-modes* (Huang 1998) and *ROCK (RObust Clustering using linKs)* (Guha et al. 1999). The k-modes algorithm is a partitional algorithm inspired by the *k-means* algorithm, a well-known clustering algorithm for numerical data. The representative of a categorical data cluster is defined to be a data object where each attribute takes the *mode* value: the mode of an attribute is the most frequent attribute value in the cluster. The ROCK algorithm makes use of the Jaccard coefficient to define *links* between data objects. The data is then represented in the form of a graph, and the problem becomes essentially a graph clustering problem. Given two clusters of categorical data, ROCK measures the similarity of two clusters by comparing their *aggregate interconnectivity* against a user-specified model, thus avoiding the problem of defining a cluster representative.

Context-based similarity measures: One way to define relationships between categorical values is by comparing the *context* in which they appear. For two categorical attribute values, we define the context as the values of other attributes with which they co-occur in the data set. The more similar these two contexts are, the more similar the attribute values are. For example, in Table 1, Scorsese and Coppola are close since they appear in exactly the same context, while Scorsese and Hitchcock are far since their contexts are completely disjoint. Defining a distance between value contexts can be done using overlap similarity measures (Das and Mannila 2000) or by using information-theoretic measures, i.e., comparing the distributions defined by the two contexts (Andritsos et al. 2004). Once we have the relationships between the values, we can use standard clustering techniques for solving the clustering problem.

There are various algorithms that make use of the idea that similar values should appear in similar contexts in order to cluster categorical data. The *CACTUS (clustering categorical data using summaries)* algorithm (Ganti et al. 1999) creates groups of attribute values based on the similarity of their context. It then uses a hierarchical greedy algorithm for grouping tuples and attributes. In a slightly different fashion, *STIRR (sieving through iterated relational reinforcement)* (Ganti et al. 1998) uses the idea that similar tuples should contain co-occurring values, and similar values should appear in tuples with high overlap. This idea is implemented via a dynamical system, inspired by information retrieval techniques. When the dynamical system is linear, the algorithm is similar to spectral clustering algorithms. *CLICKS* (Zaki et al. 2005) is an algorithm that is similar to STIRR. Rather than a measure of similarity/distance, it uses a graph-theoretic approach to find k disjoint sets of vertices in a graph constructed for a particular data set. One special characteristic of this algorithm is that it discovers clusters in a subset of the underlying set of attributes.

Information-theoretic clustering criteria: The information content in a data set can be quantified through the well-studied notions of *entropy* and *mutual information* (Cover and Thomas 1991). Entropy measures the uncertainty in predicting the values of the data when drawn from a distribution. If we view each tuple, or cluster of tuples, as a distribution over the categorical values, then we can define the *conditional entropy* of the attribute values given a set of tuples, as the uncertainty of predicting the values in this set of tuples. If we have a single tuple, then the entropy is zero, since we can accurately predict the values. For tuple $\mathbf{t}_1$ we know the director, the actor, and the genre with full certainty. As we group tuples together, the uncertainty (and entropy) increases. Grouping together tuples $\mathbf{t}_1$ and $\mathbf{t}_2$ creates uncertainty about the director attribute, while grouping $\mathbf{t}_1$ and $\mathbf{t}_3$ creates uncertainty about all attributes. Hence the latter grouping has higher entropy than the former. Information-theoretic criteria for clustering aim at generating clusters with low entropy, since this would imply that the clusters are homogeneous, and there is little *information loss*. This formulation allows for defining the distance between sets of tuples, using entropy-based divergences, such as the *Jensen-Shannon* divergence (Cover and Thomas 1991). Jensen-Shannon divergence captures the information contained in the data set, in a similar way that mean-squared distance captures geometric notions inherent in numerical data.

Two algorithms that make use of this idea are *COOLCAT* (Barbarà et al. 2002) and *LIMBO (scalable information bottleneck)* (Andritsos et al. 2004). COOLCAT is a partitional algorithm that performs a local search for finding the partition with k clusters with the lowest entropy. LIMBO works by constructing a summary of the data set that preserves as much information about the data as possible and then produce a hierarchical clustering of the summary. It is a scalable algorithm that can be used in both static and streaming environments.

A related approach is adopted by the COBWEB algorithm (Fisher 1987; Gluck and Corter 1985), a divisive hierarchical algorithm that optimizes the *category utility* measure, which measures how well particular values can be predicted given the clustering as opposed to having them in the original data set unclustered.

Categorical clustering as clustering aggregation: A different approach to the categorical data clustering problem is to view it as a *clustering aggregation problem*. Given a collection of clusterings of the data objects, the clustering aggregation problem looks for the single clustering that agrees as much as possible from the input clusterings. The problem of clustering aggregation has been shown to be equivalent to categorical data clustering (Gionis et al. 2007), where each categorical attribute defines a clustering of the data objects, grouping all the objects with the same value together. For example, in Table 1, the attribute "genre" defines three clusters: the crime cluster, the thriller cluster, and the comedy cluster. Similarly, the attribute "actor" defines three clusters, and the attribute "director" defines four clusters.

Various definitions have been considered in the literature for the notion of agreement between the output clustering and the input clusterings. One definition looks at all pairs of objects and defines a *disagreement* between two clusterings if one clustering places the two objects in the same cluster, while the other places them in different clusters; an *agreement* is defined otherwise. The clustering criterion is then to minimize the number of disagreements (or maximize the number of agreements). Other definitions are also possible, which make use of information-theoretic measures or mappings between the clusters of the two clusterings. There is a variety of algorithms for finding the best aggregate cluster, many of which have also been studied theoretically.

Causality

Ricardo Silva
Centre for Computational Statistics and Machine Learning, University College London, London, UK

Abstract

Causality is an essential concept in our understanding of the world as, in order to predict how a system behaves under an intervention, it is necessary to have causal knowledge of the impact of interventions. This knowledge should be expressed in a language built on top of probabilistic models, since the axioms of probability do not provide a way of expressing how external interventions affect a system. Learning this knowledge from data also poses additional challenges compared to the standard machine learning problem, as much data comes from passive observations that do not follow the same regime under which our predictions will take place.

Definition

The main task in causal inference is the prediction of the outcome of an intervention. For example, a treatment assigned by a doctor that will change the patient's heart condition is an intervention. Predicting the change in patient condition is a causal inference task. In general, an intervention is an action taken by an external agent that changes the original values, or the probability distributions, of some of the variables in the system. Besides predicting outcomes of actions, causal inference is also concerned with explanation: identifying which were the causes of a particular event that happened in the past.

Motivation and Background

Many problems in machine learning are prediction problems. Given a feature vector $\mathbf{X}$, the task is to provide an estimate of some output vector $\mathbf{Y}$ or its conditional probability distribution $P(\mathbf{Y}|\mathbf{X})$. This typically assumes that the distribution of $\mathbf{Y}$ given $\mathbf{X}$ during learning is the same distribution at prediction time. There are many scenarios where this is not the case.

Epidemiology and several medical sciences provide counterexamples. Consider two seemingly straightforward learning problems. In the first example, one is given epidemiological data where smokers are clearly more inclined than nonsmokers to develop lung cancer. Can I use this data to learn that smoking causes cancer? In the second example, consider a group of patients suffering from a type of artery disease. In this group, those that receive a bypass surgery are likely to survive longer than those that receive a particular set of drugs with no surgery.

There is no fundamental problem on using such datasets to predict the probability of a smoker developing lung cancer or the life expectancy of someone who went through surgery. Yet, the data does not necessarily tell you if smoking is a cause of lung cancer or that nationwide the government should promote surgery as the treatment of choice for that particular heart disease. What is going on?

There are reasons to be initially suspicious of such claims. This is well known in statistics as the expression "association is not causation" (Wasserman 2004, p. 253). The data generating mechanism for our outcome **Y** ("developing lung cancer," "getting cured from artery disease") given the relevant inputs **X** ("smoking habit," "having a surgery") might change under an *intervention* for reasons such as follows.

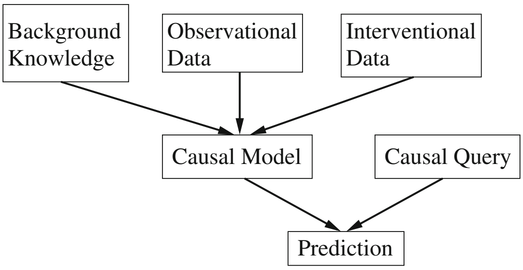
In the smoking example, the reality might be that there are several *hidden common causes* that are responsible for the observed association. A genetic factor includes, for instance, the possibility that there is a class of genotypes on which people are more likely to pick up smoking *and* develop lung cancer, without any direct causal connection between these two variables. In the artery disease example, surgery might not be the best choice to be made by a doctor. It might have been the case that so far patients in better shape were more daring in choosing, by themselves, the surgery treatment. This *selection bias* will favor surgery over drug treatment, since from the outset the patients that are most likely to improve take that treatment.

When treatment is enforced by an *external agent* (the doctor), such selection bias disappears, and the resulting $P(\mathbf{Y}|\mathbf{X})$ will not be the same. One way of learning this relationship is through *randomized trials* (Rosenbaum 2002). The simplest case consists on flipping a coin for each patient on the training set. Each face of the coin corresponds to a possible treatment, and assignment is done accordingly. Since assignment does not depend on any hidden common cause or selection bias, this provides a basis for learning causal effects. Machine learning and statistical techniques can be applied directly in this case (e.g., logistic regression). Data analysis performed with a randomized trial is sometimes called an *interventional study*.

The smoking case is more complicated: a direct intervention is not possible, since it is not acceptable to force someone to smoke or not to smoke. The inquiry asks only for a *hypothetical intervention*, i.e., if someone is forced to smoke, will his or her chances of developing lung cancer increase? Such an intervention will not take place, but this still has obvious implications in public policy. This is the heart of the matter in issues such as deciding on raising tobacco taxes or forbidding smoking in public places. However, data that measures this interventional data generation mechanism will never be available for ethical reasons. The question has to be addressed through an *observational study*, i.e., a study for causal predictions without interventional data.

Observational studies arise not only under the impossibility of performing interventions but also in the case where performing interventions is too expensive or time consuming. In this case, observational studies, or a combination of observational and interventional studies, can provide extra information to guide an experimental analysis (Hyttinen et al. 2013; Sachs et al. 2005; Cooper and Yoo 1999; Eaton and Murphy 2007). The use of observational data, or the combination of several interventional datasets, is where the greatest contributions of machine learning to causal inference rest.

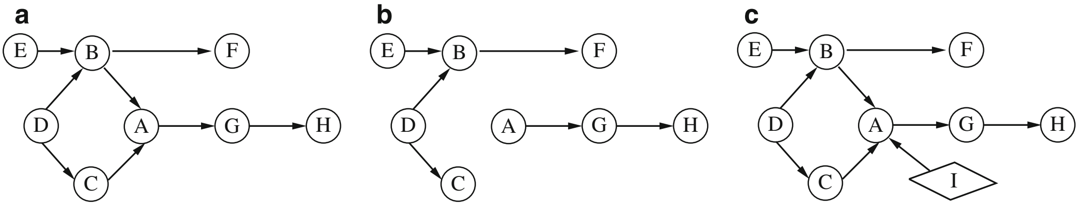
Structure of the Learning System



Structure of Causal Inference

In order to use observational data, a causal inference system needs a way of linking the state of the world under an intervention to the *natural* state of the world. The natural state is defined as the one to which no external intervention is applied. In the most general formulation, this link between the natural state and the manipulated world is defined for interventions in any subset of variables in the system.

A common language for expressing the relationship between the different states of the world is a *causal graph*, as explained in more detail in the next section. A causal model is composed of the graph and a probability distribution that



Causality, Fig. 1 (**a**) A causal DAG. (**b**) Structure of the causal graph under some intervention that sets the value of A to a constant. (**c**) Structure of the causal graph under some intervention that changes the distribution of A

factorizes according to the graph, as in a standard graphical model. The only difference between a standard graphical model and a causal graphical model is that in the latter, extra assumptions are made. The graphical model can be seen as a way of encoding such assumptions.

The combination of assumptions and observational and interventional data generates such a graphical causal model. In the related problem of reinforcement learning, the agent has to maximize a specific utility function and typically has full control on which interventions (actions) can be performed. Here we will focus on the unsupervised problem of learning a causal model for a fixed input of observational and interventional data.

Because only some (or no) interventional data might be available, the learning system might not be able to answer some causal queries. That is, the system will not provide an answer for some prediction tasks.

Languages and Assumptions for Causal Inference

Directed acyclic graphs (DAGs) are a popular language in machine learning to encode qualitative statements about causal relationships. A DAG is composed of a set of vertices and a set of directed edges. The notions of parents, children, ancestors, and descendants are the usual ones found in graphical modeling literature.

In terms of causal statements, a directed edge $A \rightarrow B$ states that A is a *direct* cause of B: that is, different interventions on A will result on different distributions for B, even if we intervene on all other variables. The assumption that A is a cause of B is not used in non-causal graphical models.

A causal DAG G satisfies the *causal Markov condition* if and only if a vertex is independent of all of its non-descendants given its direct causes (parents). In Fig. 1a, A is independent of D, E, and F given its parents, B and C. It may or may not be independent of G given B and C.

The causal Markov condition implies several other conditional independence statements. For instance, in Fig. 1a, we have that H is independent of F given A. Yet, this is not a statement about the parents of any vertex. Pearl's d-separation criterion (Pearl 2000) is a sound and complete way of reading off independencies, out of a DAG, which are entailed by the causal Markov condition. We assume that the joint probability distribution over the vertex variables is *Markov* with respect to the graph, that is, any independence statement that is encoded by the graph should imply the corresponding independence in the distribution.

Representing Interventions

The local modularity given by the causal Markov condition leads to a natural notion of intervention. Random variable V, represented by a particular vertex in the graph, is following a *local mechanism*: its direct causes determine the distribution of V before its direct effects are generated. The role of an intervention is to *override* the natural local mechanism. An external agent substitutes the natural $P(V|Parents(V))$ by a new distribution $P_{Man}(V|Parents(V))$ while keeping the rest of the model unchanged ("Man" here stands for a particular manipulation). The notion of intervening by changing a single local mechanism is sometimes known as an *ideal intervention*. Other general types of interventions can be defined (Eaton and Murphy 2007), but the most common frameworks for calculating causal effects rely on this notion.

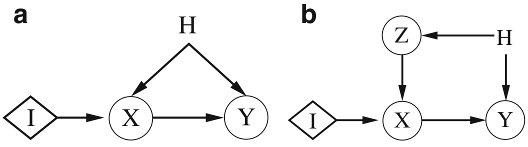
A common type of intervention is the point mass intervention, which happens when V is set to some constant v. This can be represented graphically by "wiping out" all edges into V. Figure 1b represents the resulting graph in (a) under a point manipulation of A. Notice that A is now d-separated from its direct causes under this regime. It is also probabilistically independent, since A is now constant. This allows for a graphical machinery that can read off independencies out of a *manipulated* graph (i.e., the one with removed edges). It is the idea of representing the natural state of the world with a single causal graph, and allowing for modifications in this graph according to the intervention of choice, that links the different regimes obtained under different interventions.

For the general case where a particular variable V is set to a new distribution, a *manipulation node* is added as an extra parent of V: this represents that an external agent is acting over that particular variable (Spirtes et al. 2000; Pearl 2000; Dawid 2003), as illustrated in Fig. 1c. $P(V|Parents(V))$ under intervention I is some new distribution $P_{Man}(V|Parents(V), I)$.

Calculating Distributions Under Interventions

The notion of independence is a key aspect of probabilistic graphical models, where it allows for efficient computation of marginal probabilities. In causal graphical models, it also fulfills another important role: independencies indicate that the effect of some interventions can be estimated using observational data.

We will illustrate this concept with a simple example. One of the key difficulties in calculating a causal effect is *unmeasured confounding*, i.e., hidden common causes. Consider Fig. 2a, where X is a direct cause of Y and H is a hidden common cause of both. I is an intervention vertex. Without extra assumptions, there is no way of estimating the effect of X on Y using a training set that is sampled from the observed marginal $P(X, Y)$. This is more easily seen in the case where the model is multivariate Gaussian with zero mean. In this case, each variable is a linear combination of its parents with standard Gaussian additive noise



Causality, Fig. 2 (**a**) X and Y have a hidden common cause H. (**b**) Y is dependent on the intervention node I given X, but conditioning on Z and marginalizing it out will allow us to eliminate the "backdoor" path that links X and Y through the hidden common cause H

$$\begin{aligned} X &= aH + \epsilon_X \\ Y &= bX + cH + \epsilon_Y \end{aligned}$$

where H is also a standard normal random variable. The manipulated distribution $P_{Man}(Y|X, I)$, where I is a point intervention setting $X = x$, is a Gaussian distribution with mean $b \cdot x$. Value x is given by construction, but one needs to learn the unknown value b.

One can verify that the covariance of X and Y in the natural state is given by $a + bc$. Observational data, i.e., data sampled from $P(X, Y)$, can be used to estimate the covariance of X and Y in the natural state, but from that it is not possible to infer the value of b: there are too many degrees of freedom.

However, there *are* several cases where the probability of $\mathbf{Y}$ given some intervention on $\mathbf{X}$ can be estimated with observational data and a given causal graph. Consider the graph in Fig. 2b. The problem again is to learn the distribution of Y given X under regime I, i.e., $P(Y|X, I)$. It can be read off from the graph that I and Y are not independent given X, which means $P(Y|X, I) \neq P(Y|X)$. How can someone then estimate $P(Y|X, I)$ if no data for this process has been collected? The answer lies on *reducing the "causal query" to a "probabilistic query"* where the dependence on I disappears (and, hence, the necessity of having data measured under the I intervention). This is done by relying on the assumptions encoded by the graph:

$$\begin{aligned} P(Y|X,I) &= \textstyle\sum_z P(Y|X,I,z)P(Z=z|X,I) && (Z \text{ is discrete in this example}) \\ &= \textstyle\sum_z P(Y|X,z)P(Z=z|X,I) && (Y \text{ and } I \text{ are independent given } Z) \\ &\propto \textstyle\sum_z P(Y|X,z)P(X|z,I)P(Z=z|I) && (\text{By Bayes' rule}) \\ &= \textstyle\sum_z P(Y|X,z)P(X|z,I)P(Z=z) && (Z \text{ and } I \text{ are marginally independent}) \end{aligned} \tag{1}$$

In the last line, we have $P(Y|X,Z)$ and $P(Z)$, which can be estimated with observational data, since no intervention variable I appears in the expression. $P(X|Z,I)$ is set by the external agent: its value is known by construction. This means that the causal distribution $P(Y|X,I)$ can be learned even in this case where X and Y share a hidden common cause H.

There are several notations for denoting an interventional distribution such as $P(Y|X,I)$. One of the earliest was due to Spirtes et al. (2000), which used the notation $P(Y|set\ X = x)$ to represent the distribution under an intervention I that fixed the value of X to some constant x. Pearl (2000) defines the operator *do* with an analogous purpose:

$$P(Y|do(X=x)) \tag{2}$$

Pearl's *do*-calculus is essentially a set of operations for reducing a probability distribution that is a function of some intervention to a probability distribution that does not refer to any intervention. All reductions are conditioned on the independencies encoded in a given causal graph. This is in the same spirit of the example presented above.

The advantage of such notations is that, for point interventions, they lead to simple yet effective transformations (or to a report that no transformation is possible). Spirtes et al. (2000) and Pearl (2000) provide a detailed account of such prediction tools. By making a clear distinction between $P(Y|X)$ (X under the natural state) and $P(Y|do(X))$ (X under some intervention), much of the confusion that conflates causal and noncausal predictions disappears.

It is important to stress that methods such as the *do*-calculus are nonparametric, in the sense that they rely on conditional independence constraints only. More informative reductions are possible if one is willing to provide extra information, such as assuming linearity of causal effects. For such cases, other parametric constraints can be exploited (Spirtes et al. 2000; Pearl 2000).

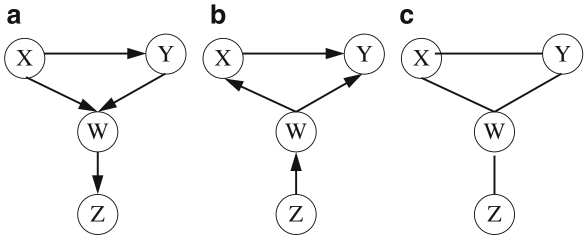
Learning Causal Structure

In all of the previous sections, we assumed that a causal graph was available. Since background knowledge is often limited, learning such graph structures becomes an important task. However, this cannot be accomplished without extra assumptions. To see why, consider again the example in Fig. 2a: if $a + bc = 0$, it follows that the X and Y are independent in the natural state. However, Y is *not* causally independent of X (if $b \neq 0$): $P(Y|do(X{=}x_1))$ and $P(Y|do(X{=}x_2))$ will be two different Gaussians with means $b \cdot x_1$ and $b \cdot x_2$, respectively.

This example demonstrates that an independence constraint that is testable by observational data does not warrant causal independence, at least based on the causal Markov condition only. However, an independence constraint that arises from particular identities such as $a + bc = 0$ is not *stable*, in the sense that it does not follow from the qualitative causal relations entailed by the Markov condition: a change in any of the parameter values will destroy such a constraint.

The artificiality of unstable independencies motivates an extra assumption: the *faithfulness* condition (Spirtes et al. 2000), also known as the *stability* condition (Pearl 2000). We say that a distribution P is faithful to a causal graph G if P is Markov with respect to G *and* if each conditional independence in P corresponds to some d-separation in G. That is, on top of the causal Markov condition, we assume that all independencies in P are entailed by the causal graph G.

The faithfulness condition allows us to reconstruct classes of causal graphs from observational data. In the simplest case, observing that X and Y are independent entails that there is no causal connection between X and Y. Conse-



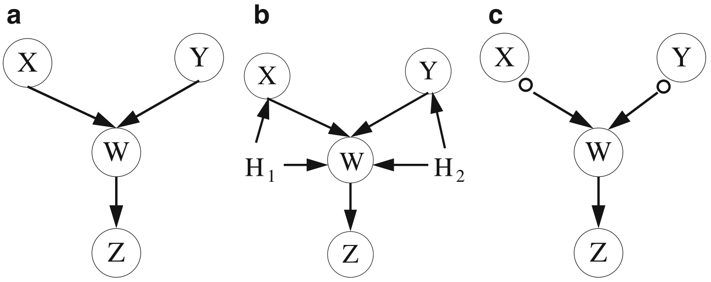
Causality, Fig. 3 (**a**) A particular causal graph which entails a few independence constraints, such as X and Z being independent given W. (**b**) A different causal graph that entails exactly the same independence constraints as in (**a**). (**c**) A representation for all graphs that entail the same conditional independencies as (**a**) and (**b**)

quently, $P(Y|do(X)) = P(Y|X) = P(Y)$. No interventional data was necessary to arrive at this conclusion, given the faithfulness condition.

In general, the solution is undetermined: more than one causal graph will be compatible with a set of observable independence constraints. Consider a simple example, where data is generated by a causal model with a causal graph given as in Fig. 3a. This graph entails some independencies, for instance, that X and Z are independent given W or that X and Y are not independent given any subset of $\{W, Z\}$. However, several other graphs entail the same conditional independences. The graph in Fig. 3b is one example. The learning task is then discovering an *equivalence class* of graphs, not necessarily a particular graph. This is in contrast with the problem of learning the structure of non-causal graphical models: the fact that there are other structures compatible with the data is not important in this case, since we will not use such graphical models to predict the effect of some hypothetical intervention. An equivalence class might not be enough information to reduce a desired causal query to a probabilistic query, but it might require much less prior knowledge than specifying a full causal graph.

Assume for now that no hidden common causes exist in this domain. In particular, the graphical object in Fig. 3c is a representation of the equivalence class of graphs that are compatible with the independencies encoded in Fig. 3a (Pearl 2000; Spirtes et al. 2000). All members of the equivalence class will have the same *skeleton* of this representation, i.e., the same adjacencies. An undirected edge indicates that there are two members in the equivalence class where directionality of this particular edge goes in opposite directions. Some different directions are illustrated in Fig. 3b. One can verify from the properties of d-separation that, if an expert or an experiment indicates that $X - W$ should be directed as $X \rightarrow W$, then the edge $W - Z$ is *compelled* to be directed as $W \rightarrow Z$: the direction $W \leftarrow Z$ is incompatible with the simultaneous findings that X and Z are independent given W and that X causes W .

More can be discovered if more independence constraints exist. In Fig. 4a, X is not a cause of Y. If we assume no hidden common causes exist in this domain, then no other causal graph is compatible with the independence constraints of Fig. 4a: the equivalence class is this graph only. However, the assumption of no hidden common causes is strong and undesirable. For instance, the graph in Fig. 4b, where H_1 and H_2 are hidden, is in the same equivalence class of (a). Yet, the graph in (a) indicates that $P(W|do(X)) = P(W|X)$, which can be arbitrarily different from the real $P(W|do(X))$ if Fig. 4b is the real graph. Some equivalence class representations, such as the Partial Ancestral Graph representation (Spirtes et al. 2000), are robust to hidden common causes: in Fig. 4c, an edge that has a circle as endpoint indicates that is not known if there is a causal path into both, e.g., X and W (which would be the case for a hidden common cause of X and W). The arrow into W does indicate that W cannot be a cause of X. A fully directed edge such as $W \rightarrow Z$ indicates total information: W is a cause of Z,



Causality, Fig. 4 (**a**) A particular causal graph with no other member on its equivalence class (assuming there are no hidden common causes). (**b**) Graph under the presence of two hidden common causes H_1 and H_2. (**c**) A representation for all graphs that entail the same conditional independencies as (**a**), without assuming the nonexistence of hidden common causes

Z is not a cause of W, and W and Z have no hidden common causes.

Given equivalence class representations and background knowledge, different types of algorithms explore independence constraints to learn an equivalence class. It is typically assumed that the true graph is acyclic. The basic structure is to evaluate how well a set of conditional independence hypotheses is supported by the data. Depending on which constraints are judged to hold in the population, we keep, delete, or orient edges accordingly. Some algorithms, such as the PC algorithm (Spirtes et al. 2000), test a single independence hypothesis at a time and assemble the individual outcomes in the end into an equivalence class representation. Other algorithms such as the GES algorithm (Meek 1997; Chickering 2002) start from a prior distribution for graphs and parameters and proceed to compare the marginal likelihood of members of different equivalence classes (which can be seen as a Bayesian joint test of independence hypotheses). In the end, this reduces to a search for the maximum a posteriori equivalence class estimator. Both PC and GES have consistency properties: in the limit of infinite data, they return the right equivalence class under the faithfulness assumption. However, both PC and GES, and most causal discovery algorithms, assume that there are no hidden common causes in the domain. The Fast Causal Inference (FCI) algorithm of Spirtes et al. (2000) is able to generate equivalence class representations as in Fig. 4c. As in the PC algorithm, this is done by testing a single independence hypothesis at a time and therefore is a high-variance estimator given small samples. A GES-like algorithm with the consistency properties of FCI is not currently known. An algorithm that allows for cyclic networks is discussed by Richardson (1996).

Semiparametric Models

Our examples relied on conditional independence constraints. In this case, the equivalence class is known as the *Markov equivalence class*. Markov equivalence classes are “nonparametric,” in the sense that they do not refer to any particular probability family. In practice, this advantage is limited by our ability to test independence hypotheses within flexible probability families. Another shortcoming of Markov equivalence classes is that they might be poorly informative if few independence constraints exist in the population. This will happen, for instance, if a single hidden variable is a common cause of all observed variables. If one is willing to incorporate further assumptions, such as linearity of causal relationships, semiparametric constraints can be used to define other types of equivalence classes that are more discriminative than the Markov equivalence class. Silva et al. (2006) describe how some rank constraints in the covariance matrix of the observed variables can be used to learn the structure of linear models, even if no independence constraints are observable. Shimizu et al. (2006) provide a solution to find the causal ordering of a linear DAG model without latent variables, by exploiting information beyond the second moments of a distribution in the non-Gaussian case. Entner et al. (2012) introduce an approach to estimate causal effects in non-Gaussian linear systems under some assumptions of directionality but allowing for unmeasured confounding. Peters et al. (2014) develop a general method for learning directionality in nonlinear models with additive noise.

Confidence Intervals

Several causal learning algorithms such as the PC and FCI algorithms (Spirtes et al. 2000) are consistent, in the sense that they can recover the correct equivalence class given the faithfulness assumption and an infinite amount of data. Although point estimates of causal effects are important, it is also important to provide confidence intervals. From a frequentist perspective, it has been shown that this is not possible given the faithfulness assumption only (Robins et al. 2003). An intuitive explanation is as follows: consider the model such as the one in Fig. 2a. For any given sample size, there is at least one model such that the associations due to the paths $X \leftarrow H \rightarrow Y$ and $X \rightarrow Y$ nearly cancel each other (faithfulness is still preserved), making the covariance of X and Y statistically indistinguishable from zero. In order to achieve uniform consistency, causal inference algorithms need assumptions stronger than faithfulness. Zhang and Spirtes (2003) provide some directions.

Other Languages and Tasks in Causal Learning

A closely related language for representing causal models is the *potential outcomes* framework popularized by Donald Rubin (Rubin 2005). In this case, random variables for a same variable Y are defined for each possible state of the intervened variable X. Notice that, by definition, only one of the possible Y outcomes can be observed for any specific data point. This framework is popular in the statistics literature as a type of missing data model. The relation between potential outcomes and several other representations of causality is discussed by Richardson and Robins (2013).

A case where potential outcomes become particularly motivated is in *causal explanation*. In this setup, the model is asked for the probability that a particular event in time was the cause of a particular outcome. This is often cast as a *counterfactual question*: had A been false, would B still have happened? Questions in history and law are of this type: the legal responsibility of an airplane manufacturer in an accident depends on technical malfunction being an *actual cause* of the accident. Ultimately, such issues of causal explanation, actual causation and other counterfactual answers, are untestable. Although machine learning can be a useful tool to derive the consequences of assumptions combined with data about other events of the same type, in general the answers will not be robust to changes in the assumptions, and the proper assumptions ultimately cannot be selected with the available data. Some advances in generating explanations with causal models are described by Halpern and Pearl (2005).

Category; Collection; Kind; Set; Sort; Type

Definition

A class is a collection of things that might reasonably be grouped together. Classes that we commonly encounter have simple names so, as humans, we can easily refer to them. The class of dogs, for example, allows me to say "my dog ate my newspaper" without having to describe a particular dog, or indeed, a particular newspaper. In machine learning, the name of the class is called the class label. Exactly what it means to belong to a class, or category, is a complex philosophical question but often we think of a class in terms of the common properties of its members. We think particularly of those properties which seperate them from other things which are in many ways similar, e.g., cats mieow and dogs bow-wow. We would be unlikely to form a class from a random collection of things, as they would share no common properties. Knowing something belonged to such a collection would be of no particular benefit. Although many every day classes will have simple names, we may construct them however we like, e.g., "The things I like to eat for breakfast on a Saturday morning." As there is no simple name for such a collection, in machine learning we would typically refer to it as the positive class, and all occurences of it are positive examples; the negative class would be everything else.

Motivation and Background

The idea of a class is important in learning. If we discover something belongs to a class, we suddenly know quite a lot about it even if we have not encountered that particular example before. In machine learning, our use of the term accords closely with the mathematical definition of a class, as a collection of sets unambiguously defined by a property that all its members share. It also accords with the idea of equivalence classes, which group similar things. Sets have an intension, the description of what it means to be a member, and an extension, things that belong to the set, useful properties of a class in machine learning. Class is also a term used extensively in knowledge bases to denote an important relationship between groups, of sub-class and super class. Learning is often viewed as a way of solving the knowledge acquisition bottleneck (Buchanan et al. 1983) in knowledge bases and the use of the term class in machine learning highlights this connection.

Class Binarization

Johannes Fürnkranz
Knowledge Engineering Group, TU Darmstadt, Darmstadt, Deutschland
Department of Information Technology, University of Leoben, Leoben, Austria

Abstract

Many learning algorithms are only designed to separate two classes from each other. For example, ▶ concept-learning algorithms assume positive examples and negative examples (counterexamples) for the concept to learn, and many statistical learning techniques, such as neural networks or ▶ support vector machines, can only find a single separating decision surface. One way to apply these algorithms to multi-class problem is to transform the original multi-class problem into multiple binary problems.

Synonyms

Error-correcting output codes (ECOC); One-against-all training; One-against-one training; Pairwise classification

Methods

The best-known techniques are:

One against all: one concept-learning problem is defined for each class, i.e., each class is in turn used as the positive class, and all other classes form the negative class.

Pairwise (One against one): one concept is learned for each pair of classes (Fürnkranz 2002). This may be viewed as a special case of ▶ preference learning.

Error-correcting output codes: ECOC allow arbitrary subsets of the classes to form the positive and negative classes of the binary problems. In the original formulation (Dietterich and Bakiri 1995), all classes have to be used for each problem, a later generalization (Allwein et al. 2000) allows arbitrary combinations. Clearly, one against all and one against one are special cases of ECOC.

The predictions of the binary classifiers must then be combined into an overall prediction. Commonly used techniques include voting and finding the nearest neighbor in the ECOC decoding matrix (Allwein et al. 2000).

Class Imbalance Problem

Charles X. Ling and Victor S. Sheng
The University of Western Ontario, London, ON, Canada

Definition

Data are said to suffer the *Class Imbalance Problem* when the class distributions are highly imbalanced. In this context, many ▶ classification learning algorithms have low predictive accuracy for the infrequent class. ▶ Cost-sensitive learning is a common approach to solve this problem.

Motivation and Background

Class imbalanced datasets occur in many real-world applications where the class distributions of data are highly imbalanced. For the two-class case, without loss of generality, one assumes that the minority or rare class is the positive class, and the majority class is the negative class. Often the minority class is very infrequent, such as 1 % of the dataset. If one applies most traditional (cost-insensitive) classifiers on the dataset, they are likely to predict everything as negative (the majority class). This was often regarded as a problem in learning from highly imbalanced datasets.

However, Provost (2000) describes two fundamental assumptions that are often made by traditional cost-insensitive classifiers. The first is that the goal of the classifiers is to maximize the accuracy (or minimize the error rate); the second is that the class distribution of the training and test datasets is the same. Under these two assumptions, predicting everything as negative for a highly imbalanced dataset *is often the right thing to do*. Drummond and Holte (2005) show that it is usually very difficult to outperform this simple classifier in this situation.

Thus, the imbalanced class problem becomes meaningful only if one or both of the two assumptions above are not true; that is, if the cost of different types of error (false positive and false negative in the binary classification) is not the same, or if the class distribution in the test data is different from that of the training data. The first case can be dealt with effectively using methods in cost-sensitive meta-learning (see ▶ Cost-sensitive learning).

In the case when the misclassification cost is not equal, it is usually more expensive to misclassify a minority (positive) example into the majority (negative) class, than a majority example into the minority class (otherwise it is more plausible to predict everything as negative). That is, *FNcost* > *FPcost*. Thus, given the values of *FNcost* and *FPcost*, a variety of cost-sensitive meta-learning methods can be, and have been, used to solve the class imbalance problem (Japkowicz and Stephen 2002; Ling and Li 1998). If the values of *FNcost* and *FPcost* are not unknown explicitly, *FNcost* and *FPcost* can be assigned to be proportional to the number of positive and negative training cases (Japkowicz and Stephen 2002).

In case the class distributions of training and test datasets are different (e.g., if the training data is highly imbalanced but the test data is more balanced), an obvious approach is to sample the training data such that its class distribution is the same as the test data. This can be achieved by oversampling (creating multiple copies of examples of) the minority class and/or undersampling (selecting a subset of) the majority class (Provost 2000).

Note that sometimes the number of examples of the minority class is too small for classifiers to learn adequately. This is the problem of insufficient (small) training data and different from that of imbalanced datasets.

Definition

In common usage, the word classification means to put things into categories, group them together in some useful way. If we are screening for a disease, we would group people into those with the disease and those without. We, as humans, usually do this because things in a group, called a ▶ class in machine learning, share common characteristics. If we know the class of something, we know a lot about it. In machine learning, the term classification is most commonly associated with a particular type of learning where examples of one or more ▶ classes, labeled with the name of the class, are given to the learning algorithm. The algorithm produces a classifier which maps the properties of these examples, normally expressed as ▶ attribute-value pairs, to the class labels. A new example whose class is unknown is classified when it is given a class label by the classifier based on its properties. In machine learning, we use the word classification because we call the grouping of things a class. We should note, however, that other fields use different terms. In philosophy and statistics, the term categorization is more commonly used. In many areas, in fact, classification often refers to what is called clustering in machines learning.

Motivation and Background

Classification is a common, and important, human activity. Knowing something's class allows us to predict many of its properties and so act appropriately. Telling other people its class allows them to do the same, making for efficient communication. This emphasizes two commonly held views of the objectives of learning. First, it is a means of ▶ generalization, to predict accurately the values for previously unseen examples. Second, it is a means of compression, to make transmission or communication more efficient. Classification is certainly not a new idea and has been studied for some considerable time. From the days of the early Greek philosophers such as Socrates, we had the idea of categorization. There are essential properties of things that make them what they are. It embodies the idea that there are natural kinds, ways of grouping things, that are inherent in the world. A major goal of learning, therefore, is recognizing natural kinds, establishing the necessary and sufficient conditions for belonging to a category. This "classical" view of categorization, most often attributed to Aristotle, is now strongly disputed. The main competitor is prototype theory; things are categorized by their similarity to a prototypical example (Lakoff 1987), either real or imagined. There is also much debate in psychology (Ashby and Maddox 2005), where many argue that there is no single method of categorization used by humans.

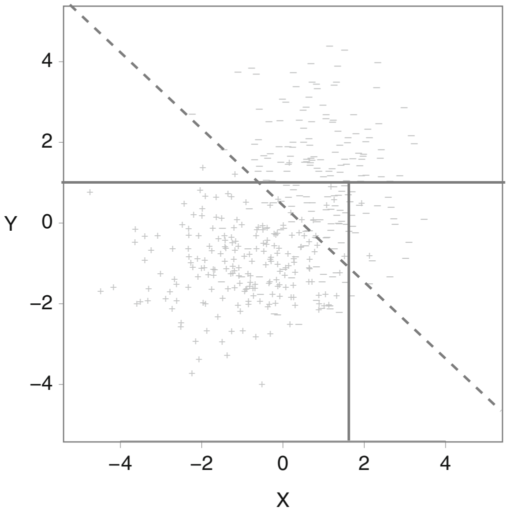
As much of the inspiration for machine learning originated in how humans learn, it is unsurprising that our algorithms reflect these distinctions. ▶ Nearest neighbor algorithms would seem to have much in common with prototype theory. These have been part of pattern recognition for some time (Cover and Hart 1967) and have become popular in machine learning, more recently, as ▶ instance-based learners (Aha et al. 1991). In machine learning, we measure the distance to one or more members of a concept rather a specially constructed prototype. So, this type of learning is perhaps more a case of the exemplar learning found in the psychological literature, where multiple examples represent a category. The closest we have to prototype learning occurs in clustering, a type of ▶ unsupervised learning, rather than classification. For example, in ▶ k-means clustering group membership is determined by closeness to a central value.

In the early days of machine learning, our algorithms (Mitchell 1977; Winston 1975) had much in common with the classical theory of categorization in philosophy and psychology. It was assumed that the data were consistent, there were no examples with the same attribute values but belonging to different classes. It was quickly realized that, even if the properties where necessary and sufficient to capture the class, there was often noise in the attribute and perhaps the class values. So, complete consistency was seldom attainable in practice. New ▶ classification algorithms were designed, which could tolerate some noise, such as ▶ decision trees (Breiman et al. 1984; Quinlan 1986, 1993) and rule-based learners (see ▶ Rule Learning) (Clark and Niblett 1989; Holte 1993; Michalski 1983).

Structure of the Learning System

Whether one uses instance-based learning, rule-based learning, decision trees, or indeed any other classification algorithm, the end result is the division of the input space into regions belonging to a single class. The input space is defined by the Cartesian product of the attributes, all possible combinations of possible values.

As a simple example, Fig. 1 shows two classes + and −, each a random sample of a normal distribution. The attributes are X and Y of real type. The values for each attribute range from $\pm\infty$. The figure shows a couple of alternative ways that the space may be divided into regions. The bold dark lines, construct regions using lines that are parallel to the axes. New examples that have Y less than 1 and X less than 1.5 with be classified as +, all others classified as −. Decision trees and rules form this type of boundary. A ▶ linear discriminant function, such as the bold dashed line, would divide the space into half-spaces, with new examples below the line being classified as + and those above as −. Instance-based learning will also divide the space into re-



Classification, Fig. 1 Dividing the input space gions but the boundary is implicit. Classification occurs by choosing the class of the majority of the nearest neighbors to a new example. To make the boundary explicit, we could mark the regions where an example would be classified as + and those classified as −. We would end up with regions bounded by polygons.

What differs among the algorithms is the shape of the regions, and how and when they are chosen. Sometimes the regions are implicit as in lazy learners (see ▸ Lazy Learning) (Aha 1997), where the boundaries are not decided until a new example is being classified. Sometimes the regions are determined by decision theory as in generative classifiers (see ▸ Generative Learning) (Rubinstein and Hastie 1997), which model the full joint distribution of the classes. For all classifiers though, the input space is effectively partitioned into regions representing a single class.

Applications

One of the reasons that classification is an important part of machine learning is that it has proved to be a very useful technique for solving practical problems. Classification has been used to help scientists in the exploration, and comprehension, of their particular domains of interest. It has also been used to help solve significant industrial problems. Over the years a number of authors have stressed the importance of applications to machine learning and listed many successful examples (Brachman et al. 1996; Langley and Simon 1995; Michie 1982). There have also been workshops on applications (Kodratoff 1994; Aha and Riddle 1995; Engels et al. 1997) at major machine learning conferences and a special issue of Machine Learning (Kohavi and Provost 1998), one of the main journals in the field. There are now conferences that are highly focused on applications. Collocated with major artificial intelligence conferences is the Innovative Applications of Artificial Intelligence conference. Since 1989, this conference has highlighted practical applications of machine learning, including classification (Schorr and Rappaport 1989). In addition, there are now at least two major knowledge discovery and data mining conferences (Fayyad and Uthurusamy 1995; Komorowski and Zytkow 1997) with a strong focus on applications.

Future Directions

In machine learning, there are already a large number of different classification algorithms, yet new ones still appear. It seems unlikely that there is an end in sight. The “no free lunch theory” (Wolpert and Macready 1997) indicates that there will never be a single best algorithm, better than all others in terms of predictive power. However, apart from their predictive performance, each classifier has its own attractive properties which are important to different groups of people. So, new algorithms are still of value. Further, even if we are solely concerned about performance, it may be useful to have many different algorithms, all with their own biases (see ▸ Inductive Bias). They may be combined together to form an ensemble classifier (Caruana et al. 2004), which outperforms single classifiers of one type (see ▸ Ensemble Learning).

Limitations

Classification has been critical part of machine research for some time. There is a concern that the emphasis on classification, and more generally on ▸ supervised learning, is too strong. Certainly much of human learning does not use, or require, labels supplied by an expert. Arguably, unsupervised learning should play a more central role in machine learning research. Although classification does require a label, it does necessarily need an expert to provide labeled examples. Many successful applications rely on finding some, easily identifiable, property which stands in for the class.

Classification Algorithms

There is a very large number of classification algorithms, including ▸ decision trees, ▸ instance-based learners, ▸ support vector machines, ▸ rule-based learners, ▸ neural networks, ▸ Bayesian networks. There also ways of combining them into ensemble classifiers such as ▸ boosting, ▸ bagging, ▸ stacking, and forests of trees.

To delve deeper into classifiers and their role in machine learning, a number of books are recommended covering machine learning (Bishop 2007; Mitchell 1997; Witten and Frank 2005) and artificial intelligence (Russell and Norvig 2003) in general. Seminal papers on classifiers can be found in collections of papers on machine learning (Dietterich and Shavlik 1990; Kodratoff and Michalski 1990; Michalski et al. 1983, 1986).

Classification Rule

Johannes Fürnkranz

University of Leoben, Leoben, Austria

Abstract

A classification rule is an `IF-THEN` rule. The condition of the rule (the *rule body* or *antecedent*) typically consists of a conjunction of Boolean terms, each one constituting a constraint that needs to be satisfied by an example. If all constraints are satisfied, the rule is said to *fire*, and the example is said to be *covered* by the rule. The *rule head* (also called the *consequent* or *conclusion*) consists of a single ▶ class value, which is predicted in case the rule fires. This is in contrast to ▶ association rules, which allow multiple features in the head.

Method

Typical terms consist of tests for the presence of a particular ▶ attribute value or, in the case of numerical attributes, of an inequality that requires that the observed value is above or below a threshold. More expressive constraints include *set-valued attributes* (several values of the same attribute can be observed in the training examples), *internal disjunctions* (only one of several values of the same attribute needs to present), *hierarchical attributes* (certain values of the attributes subsume other values), etc.

Conjunctive combinations of features may be viewed as statements in ▶ propositional logic (▶ propositional rules). If relations between features can be considered (i.e., if propositions can be formulated in ▶ first-order logic), we speak of ▶ first-order rules.

Classifier Calibration

Peter A. Flach
Department of Computer Science, University of Bristol, Bristol, UK

Abstract

Classifier calibration is concerned with the scale on which a classifier's scores are expressed. While a classifier ultimately maps instances to discrete classes, it is often beneficial to decompose this mapping into a *scoring classifier* which outputs one or more real-valued numbers and a *decision rule* which converts these numbers into predicted classes. For example, a linear classifier might output a positive or negative score whose magnitude is proportional to the distance between the instance and the *decision boundary*, in which case the decision rule would be a simple threshold on that score. The advantage of calibrating these scores to a known, domain-independent scale is that the decision rule then also takes a domain-independent form and does not have to be learned. The best-known example of this occurs when the classifier's scores approximate, in a precise sense, the ▸ posterior probability over the classes; the main advantage of this is that the optimal decision rule is to predict the class that minimizes expected cost averaged over all possible true classes. The main methods to obtain calibrated scores are *logistic calibration*, which is a parametric method that assumes that the distances on either side of the decision boundary are normally distributed and a nonparametric alternative that is variously known as *isotonic regression*, the *pool adjacent violators* (PAV) method or the *ROC convex hull* (ROCCH) method.

Synonyms

Isotonic calibration; Logistic calibration; Probability calibration; Sigmoid calibration

Motivation and Background

A predictive model can be said to be well calibrated if its predictions match observed distributions in the data. In particular, a probabilistic classifier is well calibrated if, among the instances receiving a predicted probability vector p, the class distribution is approximately distributed as p. Hence, the classifier approximates, in some sense, the class posterior, although the approximation can be crude: for example, a constant classifier predicting the overall class distribution for every instance is perfectly calibrated in this sense.

Calibration is closely related to optimal decision making and cost-sensitive classification, where we wish to determine the predicted class that minimizes expected misclassification cost averaged over all possible true classes. The better our estimates of the class posterior are, the closer we get to the (irreducible) Bayes risk. A sufficiently calibrated classifier can be simply thresholded at a threshold directly derived from the misclassification costs. Similar thresholds can be used to optimally adapt to a change in class prior or to a combination of both.

Some training algorithms naturally yield well-calibrated classifiers, including ▸ logistic regression and ▸ decision trees (with Laplace smoothing but without pruning; Provost and Domingos 2003; Ferri et al. 2003). Others do not take sufficient account of distributional factors (e.g., ▸ support vector machines) or make unrealistic assumptions (e.g., ▸ naive Bayes) and need to be calibrated in post-processing. Well-established calibration methods include logistic calibration (parametric) and the ROC convex hull method, also known as pair-adjacent violators and isotonic regression (nonparametric).

In order to evaluate the quality of probability estimates, we can use the Brier score, which measures mean squared deviation from the "ideal" probabilities 1 and 0. The Brier score can be decomposed into refinement loss and calibration loss, where the former assesses the likelihood of instances from different classes receiving the same probability estimate, and the latter measures the mean squared deviation from the empirical probabilities. Both quantities can be further decomposed: e.g., the refinement loss has model-dependent and model-independent components (grouping loss and irreducible loss), and the calibration loss has a component that can be reduced to zero by a simple affine transformation of the scores (Kull and Flach 2015). These losses and decompositions can be visualized by means of various cost curves.

One topic of current interest is that the above view of classifier calibration is closely tied to a particular family of losses (error rate and cost-sensitive variants). Class posteriors are the right thing to model for this family, but not for others. For example, it is known that thresholds on the class posterior that are optimal for F1-score are lower than optimal thresholds for accuracy, but there is no one-to-one mapping between the two. The cost-sensitive perspective offers an alternative view of calibration: a classifier is well calibrated if it outputs, for every instance, the cost parameter for which that instance is on (or close to) the decision boundary. This naturally leads to the idea of classifiers outputting several scores, each calibrated for a different cost model (e.g., accuracy and F1-score).

Solutions

We start by demonstrating that better approximation of posterior probabilities allows the classifier to make better predictions in a decision-theoretic sense (see also ▸ Cost-Sensitive Classification). Denote the cost of predicting class j for an instance of true class i as $C(\hat{Y} = j|Y = i)$. Since we don't know the true class of an unlabelled instance, we need to base our prediction on an assessment of the expected cost over all possible true classes. The (true) expected cost of predicting class j for instance x is

$$\begin{aligned} C(\hat{Y} = j|X = x) \\ = \sum_i P(Y = i|X = x)C(\hat{Y} = j|Y = i) \end{aligned} \tag{1}$$

where $P(Y = i|X = x)$ is the probability of instance x having true class i. The optimal decision is then to predict the class which minimizes expected cost:

$$\begin{aligned} \hat{Y}^* &= \arg\min_j C(\hat{Y} = j|X = x) \\ &= \arg\min_j \sum_i P(Y{=}i|X{=}x)C(\hat{Y}{=}j|Y{=}i) \end{aligned}$$

In the special case that all misclassifications have equal cost, we can assume without loss of generality that $C(\hat{Y} = j|Y = i) = 1$ for $i \neq j$ and $C(\hat{Y} = j|Y = i) = 0$ for $i = j$, which gives

$$\begin{aligned} C(\hat{Y} = j|X = x) &= \sum_{i \neq j} P(Y = i|X = x) \\ &= 1 - P(Y = j|X = x) \\ \hat{Y}^* &= \arg\min_j [1 - P(Y = j|X = x)] \\ &= \arg\max_j P(Y = j|X = x) \end{aligned}$$

The main point is that *knowing the true class posterior allows the classifier to make optimal decisions*, either in a cost-sensitive or cost-indifferent setting. It therefore makes sense for a classifier to (approximately) learn the true class posterior. (Notice that this crucially depends on the cost model expressed by Eq. (1), which assumes that our aim is to optimize a cost-based version of accuracy. A different cost model will require a different notion of calibrated score, as will be briefly considered later for the case of the F_β score.) For the remainder of this entry, we will concentrate on binary classification, returning to the challenges of multiclass calibration at the end.

Optimal Decision Thresholds

In binary classification we have the following expected costs for positive and negative predictions:

$$\begin{aligned} C(\hat{Y} = +|X = x) &= P(+|x)C(+|+) \\ &\quad + (1 - P(+|x))C(+|-) \\ C(\hat{Y} = -|X = x) &= P(+|x)C(-|+) \\ &\quad + (1 - P(+|x))C(-|-) \end{aligned}$$

where $P(+|x)$ is shorthand for $P(Y{=}+|X{=}x)$ and $C(j|i)$ for $C(\hat{Y} = j|Y = i)$. On the optimal decision boundary, these two expected costs are equal, which gives

$$P(+|x)C(+|+) + (1 - P(+|x))C(+|-) \\ = P(+|x)C(-|+) + (1 - P(+|x))C(-|-)$$

and so

$$P(+|x) \\ = \frac{C(+|-) - C(-|-)}{C(+|-) - C(-|-) + C(-|+) - C(+|+)} \triangleq c \tag{2}$$

This demonstrates that, from a decision-theoretic perspective, the cost matrix has one degree of freedom. Without loss of generality, we can therefore assume that costs are expressed on an arbitrary (but linear) scale and that correct classifications have zero cost: under this interpretation, c quantifies the proportion of loss attributed to the negatives if equal numbers of positives and negatives are misclassified. This *relative cost* then gives the optimal threshold on the positive posterior. For example, if a false positive incurs four units of cost and a false negative one unit, then $c = 4/5$, and hence we would increase the decision threshold from the default, cost-indifferent threshold of $1/2$, in order to make fewer positive predictions which are much more costly when wrong.

How is the class posterior affected when the class prior changes, but the class-conditional likelihoods $P(X|Y)$ stay the same? Suppose the proportion of positives changes from π to π', and let p denote the posterior probability under prior π, then Elkan (2001) derives the following expression for the posterior probability under prior π' (assuming the class-conditional likelihoods remain unchanged):

$$p' = \pi' \frac{p - p\pi}{\pi - p\pi + \pi' p - \pi\pi'}$$

Noting that the denominator can be rewritten to $(1 - \pi)\pi' p + \pi(1 - \pi')(1 - p)$ and switching to odds, we obtain an expression that can be rewritten as a product of odds:

$$\frac{p'}{1 - p'} = \frac{\pi'}{1 - \pi'} \frac{1 - \pi}{\pi} \frac{p}{1 - p}$$

This is best interpreted right to left. The rightmost term is the posterior odds under the original prior π; multiplying this with the reciprocal of the original prior odds gives the likelihood ratio, and multiplying this again with the new prior odds gives the desired posterior odds under the new prior π'. For example, if at training time we have balanced classes ($\pi = 1/2$), while at deployment time we have 20 % positives ($\pi' = 1/5$), then p' is adjusted downward accordingly. Conversely, the (cost-indifferent) deployment decision threshold $p' = 1/2$ corresponds to $p = 4/5$, highlighting the duality with the cost-sensitive example above.

More generally, for $p' = 1/2$ we have that

$$p = \frac{(1 - \pi')\pi}{(1 - \pi')\pi + \pi'(1 - \pi)} \triangleq d \tag{3}$$

is the decision threshold on the original posterior that takes account of the changed class distribution. Hence, d parameterizes the distribution change from π to π' in the same way as c parameterizes the change from cost-indifference to cost-sensitivity. Clearly, this opens up the way to combining changes in both class and cost distribution in a straightforward way.

Evaluation Metrics for Calibration

A multiclass scoring classifier outputs, for every test instance x, a probability vector $(p_1(x), \ldots, p_k(x))$, where k is the number of classes and $\sum_{i=1}^{k} p_i(x) = 1$. Suppose the true class is represented by a bit vector $(b_1(x), \ldots, b_k(x))$ such that the bit corresponding to the true class is set to 1 and the remaining are 0, then the *Brier score* over a test set T is defined as

$$BS = \frac{1}{|T|} \sum_{x \in T} \frac{1}{2} \sum_{i=1}^{k} (p_i(x) - b_i(x))^2$$

The factor 1/2 ensures that the squared error per example is normalized between 0 and 1: the worst possible situation is that a wrong class is predicted with certainty, in which case two "bits" are wrong (Brier did not include this factor $1/2$ in his original account; Brier 1950). For binary classification this expression can be simplified to $BS = 1/|T| \sum_{x \in T}(p(x) - b(x))^2$, where $p(x)$ is the predicted probability of a designated class (the true class, say) and $b(x)$ is 1 if the designated class is the actual one and 0 otherwise.

Suppose we want to assign the same probability vector $(p_1, \ldots, p_k)$ to all labeled instances in a given set S – for example, all training instances that get filtered into the same leaf of a decision tree. Which assignment results in the lowest Brier score? As it turns out, this is exactly the empirical class distribution in the set, which will be denoted $(\dot{p}_1, \ldots, \dot{p}_k)$. This follows from the fact that the Brier score over S can be decomposed as

$$BS(S) = \frac{1}{2}\sum_{i=1}^{k}(p_i - \dot{p}_i)^2 + \frac{1}{2}\sum_{i=1}^{k}\dot{p}_i(1 - \dot{p}_i)$$

The first term in this decomposition is known as the *calibration loss*, and the second term is called the *refinement loss*. As both terms in this decomposition are nonnegative and refinement loss is independent of p_i, the overall expression is minimized by minimizing calibration loss, which gives $p_i = \dot{p}_i$ for all i.

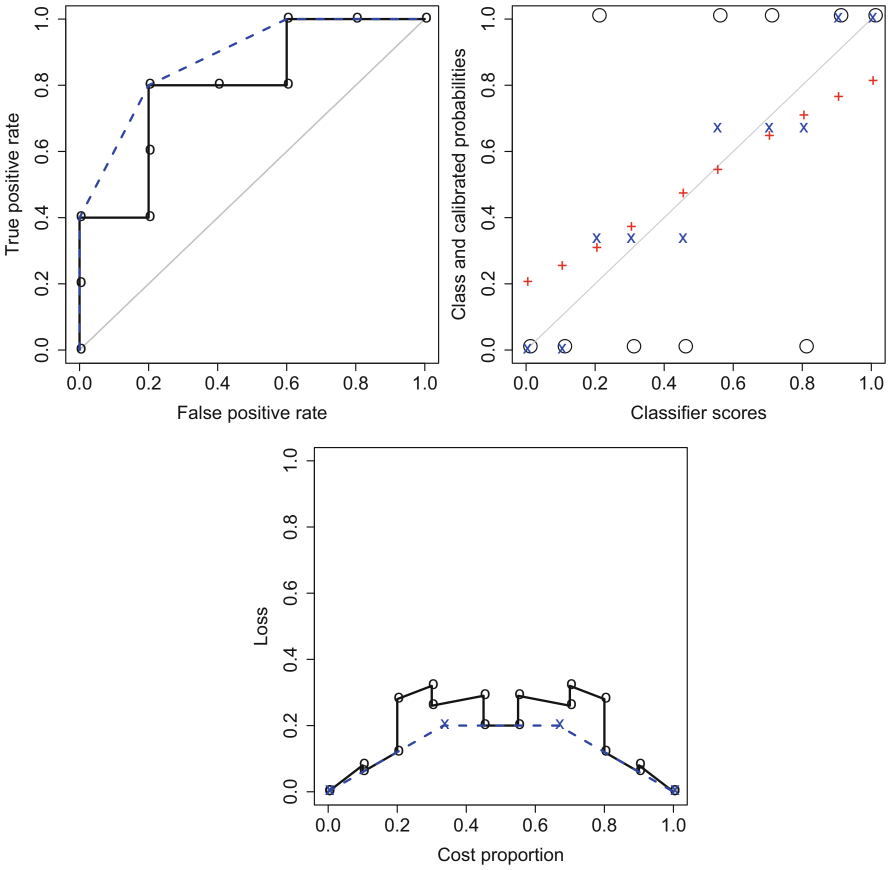
By taking a weighted average over all leaves of a decision tree, the decomposition can be applied to the Brier score over the entire data set. However, for a linear classifier which potentially assigns unique probabilities to every test instance, we need some way to group instances with similar probabilities together so that we can calculate the empirical probabilities. There are several ways of achieving this grouping, but the decomposition will in general be approximate (unless we have access to the true distributions, for which Hernández-Orallo et al. (2012) give the exact decomposition). Nevertheless, the important point to note is that Brier score is a combined measure of how well calibrated a classifier is and how well separated the scores for positives and negatives are.

The fact that Brier score is minimized if the predicted probabilities match the empirical probabilities identifies it as a so-called proper scoring rule (Gneiting and Raftery 2007). Many other proper scoring rules exist, including logarithmic loss which penalizes a probability vector with the negative logarithm of the probability assigned to the true class. These other scoring rules are amenable to similar decompositions: e.g., logarithmic loss uses Kullback-Leibler divergence between predicted and empirical probabilities to quantify calibration loss and Shannon entropy to quantify refinement loss of the empirical probabilities. Kull and Flach (2015) give an overview and also provides an underlying four-way decomposition which includes a model-independent irreducible component as well as a component that can be reduced to zero by a simple affine transformation of the scores.

Calibration Methods

In order to understand what it means for a classifier to be calibrated, it is instructive to consider its ROC curve (see ▶ ROC Analysis). A ROC curve plots true positive rate against false positive rate when the decision threshold is varied, and its slope is proportional to the empirical probability among instances receiving the same (or similar) scores from the classifier. Consider a small example in which a classifier assigns scores (1.00, 0.90, 0.80, 0.70, 0.55, 0.45, 0.30, 0.20, 0.10, 0.0) to 10 test instances with true classes $(1, 1, 0, 1, 1, 0, 0, 1, 0, 0)$, which is visualized in Fig. 1. The first thing we note is that the ROC curve on the top left has "dents" or concavities where the slope – and therefore the empirical probability – increases but the scores decrease (e.g., scores $(0.80, 0.70, 0.55)$ with empirical probabilities $(0, 1, 1)$). We can "repair" these concavities by tying the scores $(2/3, 2/3, 2/3)$, thereby forming the ROC convex hull (dashed line in the top left figure) and a piecewise constant calibration map (crosses in the middle figure).

The idea of using the ROC convex hull as a calibration method is related to isotonic regression, which differs from standard least-



Classifier Calibration, Fig. 1 (*top left*) Example ROC curve (*black*, *solid line*) and convex hull (*blue*, *dashed line*) on a small data set with 10 instances. (*top right*) Uncalibrated scores against true classes (*black circles*), calibrated scores obtained with isotonic regression (*blue crosses*), and logistic calibration (*red plusses*); the effect of calibration is larger for points further away from the diagonal. (*bottom*) Cost curves obtained when thresholding at cost proportion *c* for the original, uncalibrated scores (*black*, *solid line*) and isotonically calibrated scores (*blue*, *dashed line*); the difference between the two curves represents the decrease in Brier score achievable by calibration

squares regression in that the fitted line be piecewise constant. The standard algorithm to perform isotonic regression is the *pool adjacent violators* (PAV) method, which was introduced to the machine learning community by Zadrozny and Elkan (2001). The method, which we will call isotonic calibration in this entry, was demonstrated to be equivalent to the ROC convex hull algorithm by Fawcett and Niculescu-Mizil (2007). The key idea is that the slope of a ROC curve segment represents an empirical likelihood ratio *LR* and hence

$$p = \frac{LR}{LR + a} \tag{4}$$

with $a = (1 - \pi)/\pi$ is the corresponding empirical posterior probability (where π is the proportion of positives). See ▶ ROC Analysis for further details.

Alternatively, we can obtain *LR* from a parametric model. For example, suppose that the scores are obtained from a linear model $s(\mathbf{x}) = \mathbf{w} \cdot \mathbf{x} - t$ and assume for simplicity that the weight vector $\mathbf{w}$ is unit length, then $s(\mathbf{x})$ gives the signed distance of $\mathbf{x}$ from the decision boundary in the direction given by $\mathbf{w}$. The parametric assumption is that these distances are normally distributed within each class with the same variance σ^2, from which we can derive

$$
\begin{aligned}
LR(\mathbf{x}) &= \exp(\gamma(\mathbf{w}\cdot\mathbf{x} - t')) \\
&= \exp(\gamma(s(\mathbf{x}) - (t' - t))) \\
\gamma &= \mathbf{w}\cdot(\mu^+ - \mu^-)/\sigma^2 \\
t' &= \mathbf{w}\cdot(\mu^+ + \mu^-)/2
\end{aligned}
$$

where μ^+ and μ^- are the class means. Plugging this back into Eq. (4) and assuming $a = 1$ for simplicity gives

$$
\begin{aligned}
p(\mathbf{x}) &= \frac{1}{1 + \exp(-\gamma(\mathbf{w}\cdot\mathbf{x} - t'))} \\
&= \frac{1}{1 + \exp(-\gamma(s(\mathbf{x}) - (t' - t)))}
\end{aligned}
$$

Interpreted as a mapping from s to p, this defines a logistic curve with midpoint $s = t' - t$ and slope γ at this midpoint. The location parameter $t' - t$ shifts the decision boundary such that it cuts the line connecting the two class means halfway; the shape parameter γ quantifies how well separated the two classes are. This method was popularized by John Platt as a way to get probabilities out of ▸ support vector machines (Platt 2000) and is often referred to as *Platt scaling*; we call it logistic calibration in this entry.

Figure 1 shows the results of both logistic and isotonic calibration on the running example. The isotonically calibrated classifier both has higher AUC than the uncalibrated one (0.88 rather than 0.80) – since tying the scores as suggested by the ROC convex hull leads to a better ranking – and also lower Brier score (0.1333 rather than 0.1885). The latter is visualized in the cost curves on the bottom, which plot the cost-sensitive loss for different values of the cost proportion c (Drummond and Holte 2006). Treating the uncalibrated scores as if they were calibrated and hence using c for the decision threshold as derived in Eq. (2) yields the upper, solid cost curve, the area under which is equal to the uncalibrated Brier score (Hernández-Orallo et al. 2011). Using the isotonically calibrated scores yields the lower, dashed cost curve upon which we cannot improve without changing the model.

Also shown in the top right plot are the logistically calibrated scores; as this is a monotonic transformation, it doesn't affect the ranking or the ROC curve. The model assumptions of logistic calibration (normally distributed scores per class) are not really satisfied on this small example, and hence the logistically calibrated scores only lead to a small decrease in Brier score (0.1871) with a cost curve similar to the uncalibrated one (not shown).

If we decompose the Brier score into calibration loss and refinement loss, we see that for the uncalibrated scores refinement loss is zero as no instances from different classes receive the same score, so the Brier score equals calibration loss. Conversely, we see that for the isotonically calibrated scores, the calibration loss is zero, and hence the Brier score equals the refinement loss (on the labeled data on which calibration was carried out). Hence, isotonic calibration increases the refinement loss in order to achieve a larger decrease in calibration loss. In contrast, logistic calibration only affects calibration loss.

Practically speaking, calibration methods require a separate calibration set to avoid overfitting. For experimental studies on classifier calibration methods, see Niculescu-Mizil and Caruana (2005) and Bella et al. (2013).

Future Directions

Multiclass and Multilabel Calibration

Calibration of a multiclass classifier is not a solved problem, but there are several possible strategies. As logistic calibration essentially involves fitting a univariate logistic regression model to the scores output by the classifier, a natural way to extend this to more than two classes is to use multinomial logistic regression. This is again a parametric model which assumes that scores are normally distributed within each class.

A simple method that is recommended by Zadrozny and Elkan (2002) is to perform a logistic or isotonic calibration for each class separately, treating all other classes as the negative class (one-versus-rest). Since the resulting probabilities don't necessarily add up to one, they can be renormalized by dividing them by their sum.

Alternatively, one might consider to calibrate each class against each other class (one-versus-one). This results in more probabilities than there are classes, and hence methods to produce a multinomial probability vector are more involved. Hastie and Tibshirani (1998) proposed a solution called coupling, and Zadrozny (2001) generalized it to other code matrices (see ▶ Error Correcting Output Codes). Kong and Dietterich (1997) proposed an alternative method, also based on ECOC.

Multilabel classifiers differ from multiclass classifiers in that several labels may apply simultaneously. In the presence of sparse labels, calibration is particularly important, but it needs to be considered in the context of how multilabel classification performance will be evaluated. For example, one popular evaluation metric is Hamming loss which calculates the proportion of labels that are mispredicted – this effectively puts all labels in the same bag, and hence there is no point in separately calibrating the scores for each label. Other evaluation metrics are calculated label-wise or even instance-wise. Further research is needed to identify the right calibration methods for these cases.

Calibrating for Different Losses

Throughout this entry we have made an implicit assumption that our goal is to maximize accuracy: the proportion of correctly classified instances (true positives and true negatives). This justifies the additive cost model of Eq. (1) which led to the model-independent thresholds summarized in Eqs. (2) and (3). However, there is a range of recent results demonstrating that this threshold is suboptimal for other performance metrics. For example, Zhao et al. (2013) proved that if our goal is to maximize the F-score (the harmonic mean of precision and recall), then the optimal threshold θ^* on the true posterior is half the F-score obtained at that threshold – it follows that the optimal threshold for F-score is less than or equal to the optimal threshold for accuracy, with equality obtained only for perfect classifiers. Koyejo et al. (2014) extends the analysis to a family of performance metrics including accuracy and the F_β-score (a weighted harmonic mean of precision and recall, with $\beta = 1$ yielding the F-score). Specifically, if F^*_β denotes the optimal F_β-score achievable by a model, then $\theta^* = F^*_\beta/(1+\beta^2)$.

Instead of investigating how to adapt the decision rule on the class posterior to account for a different performance metric – which is necessarily classifier dependent – Flach and Kull (2015) suggest for the classifier to output a different score specifically adapted for the F_β metric. Let p be the calibrated posterior probability for a given instance; let B be the value of β for which the instance is on the F_β decision boundary (i.e., the F_β-score would be the same regardless of whether the instance is predicted to be positive or negative); and let F^*_B be the optimal F_β-score achievable by the model for that value of $\beta = B$; then the model outputs the score $p/F^*_B = 1/(1+B^2)$. All quantities involved can be precomputed from the ROC convex hull. This naturally leads to the idea of a classifier outputting *multiple* calibrated scores: calibrated estimates of the posterior probability for optimizing accuracy, adjustments of the posterior as just described for optimizing F-scores, and possibly others. The latter can still be seen as calibrated scores if we adopt a broader view of calibration: *a well-calibrated classifier calculates the cost parameters under which the expected cost for the instance under consideration is the same regardless of the predicted class.*

Synonyms

Genetics-based machine learning; Learning classifier systems

Definition

Classifier systems are rule-based systems that combine ▶ temporal difference learning or ▶ supervised learning with a genetic algorithm to solve classification and ▶ reinforcement learning problems. Classifier systems come in two flavors: Michigan classifier systems, which are designed for online learning, but can also tackle offline problems; and Pittsburgh classifier systems, which can only be applied to offline learning.

In Michigan classifier systems (Holland 1976), learning is viewed as an online adaptation process to an unknown environment that represents the problem and provides feedback in terms of a numerical reward. Michigan classifier systems maintain a single candidate solution consisting of a set of rules, or a population of classifiers. Michigan systems apply (1) temporal difference learning to distribute the incoming reward to the classifiers that are accountable for it; and (2) a genetic algorithm to select, recombine, and mutate individual classifiers so as to improve their contribution to the current solution.

In contrast, in Pittsburgh classifier systems (Smith 1980), learning is viewed as an offline optimization process in which a genetic algorithm alone is applied to search for the best solution to a given problem. In addition, Pittsburgh classifier systems maintain not one, but a set of candidate solutions. While in the Michigan classifier system each individual classifier represents a part of the overall solution, in the Pittsburgh system each individual is a complete candidate solution (itself consisting of a set of classifiers). The fitness of each Pittsburgh individual is computed offline by testing it on a representative sample of problem instances. The individuals compete among themselves through selection, while crossover and mutation recombine solutions to search for better solutions.

Motivation and Background

Machine learning is usually viewed as a search process in which a solution space is explored until an appropriate solution to the target problem is found (Mitchell 1982) (see ▸ Supervised Learning). Machine learning methods are characterized by the way they represent solutions (e.g., using ▸ decision trees, rules), by the way they evaluate solutions (e.g., classification accuracy, information gain) and by the way they explore the solution space (e.g., using a ▸ general-to-specific strategy or a specific-to-general strategy).

Classifier systems are methods of *genetics-based* machine learning introduced by Holland, the father of ▸ genetic algorithms. They made their first appearance in Holland (1976) where the first diagram of a classifier system, labeled "cognitive system," was shown. Subsequently, they were described in detail in the paper "Cognitive Systems based on Adaptive Algorithms" (Holland and Reitman 1978). Classifier systems are characterized by a rule-based representation of solutions and a genetics-based exploration of the solution space. While other ▸ rule learning methods, such as CN2 (Clark and Niblett 1989) and FOIL (Quinlan and Cameron-Jones 1995), generate one rule at a time following a sequential covering strategy (see ▸ Covering Algorithm), classifier systems work on one or more solutions at once, and they explore the solution space by applying the principles of natural selection and genetics.

In classifier systems (Holland 1976; Holland and Reitman 1978; Wilson 1995), machine learning is modeled as an online adaptation process to an unknown *environment*, which provides feedback in terms of a numerical reward. A classifier system perceives the environment through its detectors and, based on its sensations, it selects an action to be performed in the environment through its effectors. Depending on the efficacy of its actions, the environment may eventually reward the system. A classifier system learns by trying to maximize the amount of reward it receives from the environment. To pursue such a goal, it maintains a set (a *population*) of condition-action-prediction rules, called *classifiers*, which represents the current solution. Each classifier's condition identifies some part of the problem domain; the classifier's action represents a decision on the subproblem identified by its condition; and the classifier's prediction, or strength, estimates the value of the action in terms of future rewards on that subproblem. Two separate components, credit assignment and rule discovery, act on the population with different goals. ▸ Credit assignment, implemented either by methods of temporal difference or supervised learning, exploits the incoming reward to estimate the action values in each subproblem so as to identify the best classifiers in the population. At the same time, rule discovery, usually implemented by a genetic algorithm, selects, recombines, and mutates the classifiers in the population to improve the current solution.

Classifier systems were initially conceived as modeling tools. Given a real system with unknown underlying dynamics, for instance a financial market, a classifier system would be used to generate a behavior that matched the real system. The evolved rules would provide a plausible, human readable model of the unknown system – a way to look inside the box. Subsequently, with the developments in the area of machine learning and the rise of reinforcement learning, classifier systems have been more and more often studied and presented as alternatives to other machine learning methods. Wilson's XCS (1995), the most successful classifier system to date, has proven to be both a valid alternative to other reinforcement learning approaches and an effective approach to classification and data mining (Bull 2004; Bull and Kovacs 2005; Lanzi et al. 2000).

Kenneth de Jong and his students (de Jong 1988; Smith 1980, 1983) took a different perspective on genetics-based machine learning and modeled learning as an *optimization* process rather than an *adaptation* process as done in Holland (1976). In this case, the solution space is explored by applying a genetic algorithm to a population of individuals each representing a *complete* candidate solution – that is, a set of rules (or a production system, de Jong 1988; Smith 1980. At each cycle, a critic is applied to each individual (to each set of rules) to obtain a performance measure that is then used by the genetic algorithm to guide the exploration of the solution space. The individuals in the population compete among themselves through selection, while crossover and mutation recombine solutions to search for better ones.

The approaches of Holland (Holland 1976; Holland and Reitman 1978) and de Jong (de Jong 1988; Smith 1980, 1983) have been extended and improved in several ways (see Lanzi et al. (2000) for a review). The models of classifier systems that are inspired by the work of Holland (1976) at the University of Michigan are usually called Michigan classifier systems; the ones that are inspired by Smith (1980, 1983) and de Jong (1988) at the University of Pittsburgh are usually termed Pittsburgh classifier systems – or briefly, Pitt classifier systems.

Pittsburgh classifier systems separate the evaluation of candidate solutions, performed by an external critic, from the genetic search. As they evaluate candidate solutions as a whole, Pittsburgh classifier systems can easily identify and emphasize sequentially cooperating classifiers, which is particularly helpful in problems involving partial observability. In contrast, in Michigan classifier systems the credit assignment is focused, due to identification of the actual classifiers that produce the reward, so learning is *much* faster but sequentially cooperating classifiers are more difficult to spot. As Pittsburgh classifier systems apply the genetic algorithm to a set of solutions, they only work offline, whereas Michigan classifier systems work online, although they can also tackle offline problems. Finally, the design of Pittsburgh classifier systems involves decisions as to how an entire solution should be represented and how solutions should be recombined – a task which can be daunting. In contrast, the design of Michigan classifier systems involves simpler decisions about how a rule should be represented and how two rules should be recombined. Accordingly, while the representation of solutions and its related issues play a key role in Pittsburgh models, Michigan models easily work with several types of representations (Lanzi 2001; Lanzi and Perrucci 1999; Mellor 2005).

Structure of the Learning System

Michigan and Pittsburgh classifier systems were both inspired by the work of Holland on the broadcast language (Holland 1975). However, their structures reflect two different ways to model machine learning: as an adaptation process in the case of Michigan classifier systems; and as an optimization problem, in the case of Pittsburgh classifier systems. Thus, the two models, originating from the same idea (Holland's broadcast language), have radically different structures.

Michigan Classifier Systems

Holland's classifier systems define a general paradigm for genetics-based machine learning. The description in Holland and Reitman (1978) provides a list of principles for online learning through adaptation. Over the years, such principles have guided researchers who developed several models of Michigan classifier systems (Butz 2002; Wilson 1994, 1995, 2002) and applied them to a large variety of domains

(Bull 2004; Lanzi and Riolo 2003; Lanzi et al. 2000). These models extended and improved Holland's original ideas, but kept all the ingredients of the original recipe: a population of classifiers, which represents the current system knowledge; a performance component, which is responsible for the short-term behavior of the system; a credit assignment (or reinforcement) component, which distributes the incoming reward among the classifiers; and a rule discovery component, which applies a genetic algorithm to the classifiers to improve the current knowledge.

Knowledge Representation

In Michigan classifier systems, knowledge is represented by a population of classifiers. Each classifier is usually defined by four main parameters: the *condition*, which identifies some part of the problem domain; the *action*, which represents a decision on the subproblem identified by its condition; the *prediction* or strength, which estimates the amount of reward that the system will receive if its action is performed; and finally, the *fitness*, which estimates how good the classifier is in terms of problem solution.

The knowledge representation of Michigan classifier systems is extremely flexible. Each one of the four classifier components can be tailored to fit the need of a particular application, without modifying the main structure of the system. In problems involving binary inputs, classifier conditions can be simply represented using strings defined over the alphabet {0, 1, #}, as done in Holland and Reitman (1978), Goldberg (1989), and Wilson (1995). In problems involving real inputs, conditions can be represented as disjunctions of intervals, similar to the ones produced by other rule learning methods (Clark and Niblett 1989). Conditions can also be represented as general-purpose symbolic expressions (Lanzi 2001; Lanzi and Perrucci 1999) or first-order logic expressions (Mellor 2005). Classifier actions are typically encoded by a set of symbols (either binary strings or simple labels), but continuous real-valued actions are also available (Wilson 2007). Classifier prediction (or strength) is usually encoded by a parameter (Goldberg 1989; Holland and Reitman 1978; Wilson 1995). However, classifier prediction can also be computed using a parameterized function (Wilson 2002), which results in solutions represented as an ensemble of local approximators – similar to the ones produced in generalized reinforcement learning (Sutton and Barto 1998).

Performance Component

A simplified structure of Michigan classifier systems is shown in Fig. 1. We refer the reader to Goldberg (1989) and Holland and Reitman (1978) for a detailed description of the original model and to Butz (2002) and Wilson (1994, 1995, 2001) for descriptions of recent classifier system models.

A classifier system learns through trial and error interactions with an unknown environment. The system and the environment interact continually. At each time step, the classifier system perceives the environment through its detectors; it builds a *match set* containing all the classifiers in the population whose condition matches the current sensory input. The match set typically contains classifiers that advocate contrasting actions; accordingly, the classifier system evaluates each action in the match set, and selects an action to be performed balancing exploration and exploitation. The selected action is sent to the effectors to be executed in the environment; depending on the effect that the action has in the environment, the system receives a scalar reward.

Credit Assignment

The *credit assignmentcomponent* (also called reinforcement component, Wilson 1995) distributes the incoming reward to the classifiers that are accountable for it. In Holland and Reitman (1978), credit assignment is implemented by Holland's bucket brigade algorithm (Holland 1986), which was partially inspired by the credit allocation mechanism used by Samuel in his pioneering work on learning checkers-playing programs (Samuel 1959).

Classifier Systems, Fig. 1 Simplified structure of a Michigan classifier system. The system perceives the environment through its detectors and (1) it builds the match set containing the classifiers in the population that match the current sensory inputs; then (2) all the actions in the match set are evaluated, and (3) an action is selected to be performed in the environment through the effectors

In the early years, classifier systems and the bucket brigade algorithm were confined to the evolutionary computation community. The rise of reinforcement learning increased the connection between classifier systems and temporal difference learning (Sutton 1988; Sutton and Barto 1998): in particular, Sutton (1988) showed that the bucket brigade algorithm is a kind of temporal difference learning, and similar connections were also made in Watkins (1989) and Dorigo and Bersini (1994). Later, the connection between classifier systems and reinforcement learning became tighter with the introduction of Wilson's XCS (1995), in which credit assignment is implemented by a modification of Watkins Q-learning (Watkins 1989). As a consequence, in recent years, classifier systems are often presented as methods of reinforcement learning with genetics-based generalization (Bull and Kovacs 2005).

Rule Discovery Component

The *rule discovery component* is usually implemented by a genetic algorithm that selects classifiers in the population with probability proportional to their fitness; it copies the selected classifiers and applies genetic operators (usually crossover and mutation) to the offspring classifiers; the new classifiers are inserted in the population, while other classifiers are deleted to keep the population size constant.

Classifiers selection plays a central role in rule discovery. Classifier selection depends on the definition of classifier fitness and on the subset of classifiers considered during the selection process. In Holland and Reitman (1978), classifier fitness coincides with classifier prediction, while selection is applied to all the classifiers in the population. This approach results in a pressure toward classifiers predicting high returns, but typically tends to produce overly general solutions. To avoid such solutions, Wilson (1995) introduced the XCS classifier system in which accuracy-based fitness is coupled with a niched genetic algorithm. This approach results in a pressure toward accurate maximally general classifiers, and has made XCS the most successful classifier system to date.

Pittsburgh Classifier Systems

The idea underlying the development of Pittsburgh classifier systems was to show that interesting behaviors could be evolved using a simpler model than the one proposed by Holland with Michigan classifier systems (Holland 1976; Holland and Reitman 1978).

In Pittsburgh classifier systems, each individual is a set of rules that encodes an entire candidate solution; each rule has a fixed length, but each rule set (each individual) usually contains a variable number of rules. The genetic operators, crossover and mutation, are tailored to the rule-based, variable-length representation. The individuals in the population compete among themselves, following the selection-recombination-mutation cycle that is typical of genetic algorithms (Goldberg 1989; Holland 1975). While in Michigan classifier systems individuals in the population (the single rules) cooperate, in Pittsburgh classifier systems there is no cooperation among individuals (the rule sets), so that the genetic algorithm operation is simpler for Pittsburgh models. However, as Pittsburgh classifier systems explore a much larger search space, they usually require more computational resources than Michigan classifier systems.

The pseudo-code of a Pittsburgh classifier system is shown in Fig. 2. At first, the individuals in the population are randomly initialized (line 2). At time t, the individuals are evaluated by an external critic, which returns a performance measure that the genetic algorithm exploits to compute the fitness of individuals (lines 3 and 10). Following this, selection (line 6), recombination, and mutation (line 7) are applied to the individuals in the population – as done in a typical genetic algorithm. The process stops when a termination criterion is met (line 4), usually when an appropriate solution is found.

The design of Pittsburgh classifier systems follows the typical steps of genetic algorithm design, which means deciding how a rule set should be represented, what genetic operators should be applied, and how the fitness of a set of rules should be calculated. In addition, Pittsburgh classifier systems need to address the *bloat* phenomenon (Tackett 1994) that arises with any variable-sized representation, like the rule sets evolved by Pittsburgh classifier systems. Bloat can be defined as the growth of individuals without an actual fitness improvement. In Pittsburgh classifier systems, bloat increases the size of candidate solutions by adding useless rules to individuals, and it is typically limited by introducing a parsimony pressure that discourages large rule sets (Bassett and de Jong 2000). Alternatively, Pittsburgh classifier systems can be combined with multi-objective optimization, so as to separate the maximization of the rule set performance and the minimization of the rule set size.

Examples of Pittsburgh classifier systems include SAMUEL (Grefenstette et al. 1990), the Genetic Algorithm Batch-Incremental Concept Learner (GABIL) (de Jong and Spears 1991), GIL Janikow (1993), GALE (Llorá 2002), and GAssist (Bacardit 2004).

Applications

Classifier systems have been applied to a large variety of domains, including computational

Classifier Systems, Fig. 2 Pseudo-code of a Pittsburgh classifier system

economics (e.g., Arthur et al. 1996), autonomous robotics (e.g., Dorigo and Colombetti 1998), classification (e.g., Barry et al. 2004), fighter aircraft maneuvering (Bull 2004; Smith et al. 2000), and many others. Reviews of classifier system applications are available in Lanzi et al. (2000); Lanzi and Riolo (2003), and Bull (2004).

Programs and Data

The major sources of information about classifier systems are the LCSWeb maintained by Alwyn Barry, which can be reached through, and www.learning-classifier-systems.org maintained by Xavier Llorà.

Several implementations of classifier systems are freely available online. The first standard implementation of Holland's classifier system in Pascal was described in Goldberg (1989), and it is available at http://www.illigal.org/; a C version of the same implementation, developed by Robert E. Smith, is available at http://www.etsimo.uniovi.es/ftp/pub/EC/CFS/src/. Another implementation of an extension of Holland's classifier system in C by Rick L. Riolo is available at http://www.cscs.umich.edu/Software/Contents.html. Implementations of Wilson's XCS 1995 are distributed by Alwyn Barry at the LCSWeb, by Martin V. Butz (at www.illigal.org), and by Pier Luca Lanzi (at xcslib.sf.net). Among the implementations of Pittsburgh classifier systems, the Samuel system is available from Alan C. Schultz at http://www.nrl.navy.mil/; Xavier Llorà distributes GALE (Genetic and Artificial Life Environment) a fine-grained parallel genetic algorithm for data mining at www.illigal.org/xllora.

Clause

A *clause* is a logical rule in a ▶ logic program. Formally, a clause is a disjunction of (possibly negated) literals, such as

$$\mathit{grandfather}(x, y) \vee \neg \mathit{father}(x, z) \vee \neg \mathit{parent}(z, y)$$

In the logic programming language ▶ Prolog this clause is written as

```
grandfather(X,Y) :- father(X,Z),
                    parent(Z,Y).
```

The part to the left of :- ("if") is the *head* of the clause, and the right part is its *body*. Informally, the clause asserts the truth of the head given the truth of the body. A clause with exactly one literal in the head is called a *Horn clause* or *definite clause*; logic programs mostly consist of definite clauses. A clause without a body is also called a *fact*; a clause without a head is also called a *denial*, or a *query* in a proof by refutation. The clause without head or body is called the *empty clause*: it signifies inconsistency or falsehood and is denoted □. Given a set of clauses, the *resolution* inference rule can be used to deduce logical consequences and answer queries (see ▶ First-Order Logic).

In machine learning, clauses can be used to express classification rules for structured individuals. For example, the following definite clause classifies a molecular compound as carcinogenic if it contains a hydrogen atom with charge above a certain threshold.

```
carcinogenic(M) :- atom(M,A1),
                   element(A1,h),
                   charge(A1,C1),
                   geq(C1,0.168).
```

Clause Learning

In ▶ speedup learning, clause learning is a ▶ deductive learning technique used for the purpose of ▶ intelligent backtracking in satisfiability solvers. The approach analyzes failures at backtracking points and derives clauses that must be satisfied by the solution. The clauses are added to the set of clauses from the original satisfiability problem and serve to prune new search nodes that violate them.

Click-Through Rate (CTR)

CTR measures the success of a ranking of search results, or advertisement placing. Given the number of *impressions*, the number of times a web result or ad has been displayed, and the number of *clicks*, the number of users who clicked on the result/advertisement, CTR is the number of clicks divided by the number of impressions.

Clonal Selection

The clonal selection theory (CST) is the theory used to explain the basic response of the adaptive immune system to an antigenic stimulus. It establishes the idea that only those cells capable of recognizing an antigenic stimulus will proliferate, thus being selected against those that do not. Clonal selection operates on both T-cells and B-cells. When antibodies on a B-cell bind with an antigen, the B-cell becomes activated and begins to proliferate. New B-cell clones are produced that are an exact copy of the parent B-cell, but then they undergo somatic hypermutation and produce antibodies that are specific to the invading antigen. The B-cells, in addition to proliferating or differentiating into *plasma cells*, can differentiate into long-lived B *memory cells*. Plasma cells produce large amounts of *antibody* which will attach themselves to the antigen and act as a type of *tag* for T-cells to pick up on and remove from the system. This whole process is known as *affinity maturation*. This process forms the basis of many artificial immune system algorithms such as AIRS and aiNET.

▶ Nearest Neighbor

Cluster Editing

The Cluster Editing problem is almost equivalent to Correlation Clustering on complete instances. The idea is to obtain a graph that consists only of cliques. Although Cluster Deletion requires us to delete the smallest number of edges to obtain such a graph, in Cluster Editing we are permitted to add as well as remove edges. The final variant is Cluster Completion in which edges can only be added: each of these problems can be restricted to building a specified number of cliques.

Cluster Ensembles

Cluster ensembles are an unsupervised ▶ ensemble learning method. The principle is to create multiple different clusterings of a dataset, possibly using different algorithms, then aggregate the opinions of the different clusterings into an ensemble result. The final ensemble clustering should be in theory more reliable than the individual clusterings.

Cluster Initialization

▶ *K*-Means Clustering

Cluster Optimization

▶ Evolutionary Clustering

Clustering

Clustering is a type of ▶ unsupervised learning in which the goal is to partition a set of ▶ examples into groups called clusters. Intuitively, the examples within a cluster are more similar to each other than to examples from other clusters. In order to measure the similarity between examples, clustering algorithms use various distortion or ▶ distance measures. There are two major types clustering approaches: generative and discriminative. The former assumes a parametric form of the data and tries to find the model parameters that maximize the probability that the data was generated by the chosen model. The latter represents graph-theoretic approaches that compute a similarity matrix defined over the input data.

Clustering from Data Streams

João Gama
University of Porto, Porto, Portugal

Abstract

Clustering is one of the most popular data mining techniques. In this article, we review the

relevant methods and algorithms for designing cluster algorithms under the data streams computational model, and discuss research directions in tracking evolving clusters.

Definition

Clustering is the process of grouping objects into different groups, such that the common properties of data in each subset are high and between different subsets are low. The data stream clustering problem is defined as *to maintain a continuously consistent good clustering of the sequence observed so far, using a small amount of memory and time*. The issues are imposed by the continuous arriving data points and the need to analyze them in real time. These characteristics require incremental clustering, maintaining cluster structures that evolve over time. Moreover, the data stream may evolve over time, and new clusters might appear, other disappears, reflecting the dynamics of the stream.

Main Techniques

Clustering data streams requires a process able to continuously cluster objects within memory and time restrictions (Gama 2010). Following Silva et al. (2013), algorithms for clustering data streams should ideally fulfill the following requirements:

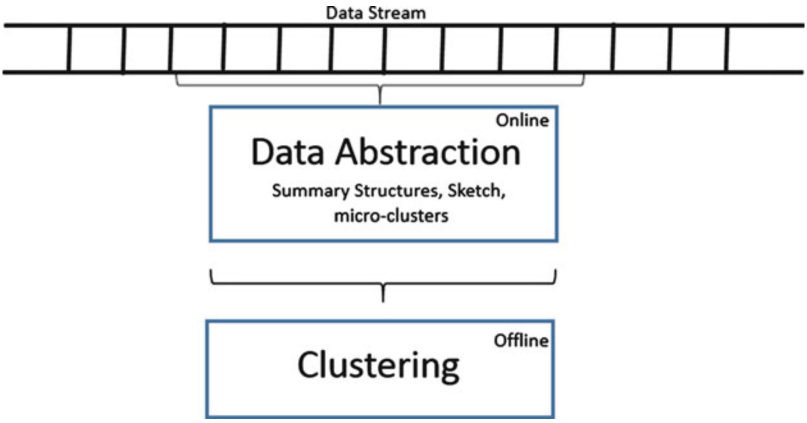
(i) provide timely results by performing fast and incremental processing of data objects;
(ii) rapidly adapt to changing dynamics of the data, which means algorithms should detect when new clusters may appear or others disappear;
(iii) scale to the number of objects that are continuously arriving;
(iv) provide a model representation that is not only compact, but that also does not grow with the number of objects processed (notice that even a linear growth should not be tolerated);
(v) rapidly detect the presence of outliers and act accordingly; and
(vi) deal with different data types, e.g., XML trees, DNA sequences, and GPS temporal and spatial information. Although these requirements are only partially fulfilled in practice, it is instructive to keep them in mind when designing algorithms for clustering data streams.

Major clustering approaches in data stream cluster analysis include:

- *Partitioning* algorithms: construct a partition of a set of objects into k clusters, which minimize some objective function (e.g., the sum of squared distances to the centroid representative). Examples include k-means (Farnstrom et al. 2000) and k-medoids (Guha et al. 2003);
- *Micro-clustering* algorithms: divide the clustering process into two phases, where the first phase is online and summarizes the data stream in local models (micro-clusters) and the second phase generates a global cluster model from the micro-clusters. Examples of these algorithms include BIRCH (Zhang et al. 1996), CluStream (Aggarwal et al. 2003), and ClusTree (Kranen et al. 2011).

Basic Concepts

Data stream clustering algorithms can be summarized into two main steps: data summarization step and clustering step, as illustrated in Fig. 1. The online abstraction step summarizes the data stream with the help of particular data structures in order to deal with space and memory constraints of stream applications. These data structures summarize the stream in order to preserve the meaning of the original objects without the need of storing them. Among the commonly employed data structures, we highlight the feature vectors (Zhang et al. 1996; Aggarwal et al. 2003), prototype arrays (Guha et al. 2003), coreset trees (Ackermann et al. 2012), and data grids (Gama et al. 2011).



Clustering from Data Streams, Fig. 1 A generic schema for clustering data streams

A powerful idea in clustering from data streams is the concept of *cluster feature – CF*. A cluster feature, or *micro-cluster*, is a compact representation of a set of points. A CF structure is a triple (N, LS, SS), used to store the sufficient statistics of a set of points:

- N is the number of data points;
- LS is a vector, of the same dimension of data points, that store the linear sum of the N points;
- SS is a vector, of the same dimension of data points, that store the square sum of the N points.

The properties of cluster features are:

- **Incrementality**

  If a point x is added to a cluster A, the sufficient statistics are updated as follows:

  $$LS_A \leftarrow LS_A + x; SS_A \leftarrow SS_A + x^2; N_A \leftarrow N_A + 1$$

- **Additivity**

  If A and B are disjoint sets, merging them is equal to the sum of their parts. The additive property allows us to merge subclusters incrementally:

  $$LS_C \leftarrow LS_A + LS_B; SS_C \leftarrow SS_A + SS_B; N_C \leftarrow N_A + N_B.$$

A CF entry has sufficient information to calculate the norms

$$L_1 = \sum_{i=1}^{n} |LS_{a_i} - LS_{b_i}| \text{ and}$$

$$L_2 = \sqrt{\sum_{i=1}^{n} (LS_{a_i} - LS_{b_i})^2}$$

and basic measures to characterize a cluster:

- **Centroid**, defined as the gravity center of the cluster:

  $$\vec{X}0 = \frac{LS}{N}$$

- **Radius**, defined as the average distance from member points to the centroid:

  $$R = \sqrt{\frac{SS}{N} - \frac{LS}{N}^2}.$$

- **Diameter**, defined as the largest distance between member points:

  $$R = \sqrt{\frac{2N \times SS - 2 \times LS^2}{N \times (N-1)}}.$$

When processing and summarizing continuously arriving stream data, the most recent observations are more important because they reflect the current state of the process generating the data. A popular approach in data stream clustering consists of defining a time window that covers the most recent data. The window models that have been used in the literature are the landmark model, sliding-window model, and damped model (Gama 2010).

Partitioning Clustering

K-means is the most widely used clustering algorithm. It constructs a partition of a set of objects into k clusters, that minimize some objective function, usually a squared error function, which imply round-shape clusters. The input parameter k is fixed and must be given in advance that limits its real applicability to streaming and evolving data.

Farnstrom et al. (2000) propose a *single-pass k-Means* algorithm. The main idea is to use a buffer where points of the dataset are kept in a compressed way. The data stream is processed in blocks. All available space on the buffer is filled with points from the stream. Using these points, find k-centers such that the sum of distances from data points to their closest center is minimized. Only the k-centroids (representing the clustering results) are retained, with the corresponding k-cluster features. Only the k-centroids (representing the clustering results) are retained, with the corresponding k-cluster features. In the next iterations, the buffer is initialized with the k-centroids, found in the previous iteration and the incoming data points from the stream. The *very fast k-means* algorithm (VFKM) (Domingos and Hulten 2001) uses the Hoeffding bound to determine the number of examples needed in each step of a k-means algorithm. VFKM runs as a sequence of k-means runs, with an increasing number of examples until the Hoeffding bound is satisfied.

Guha et al. (2003) present an analytical study on k-median clustering data streams. The proposed algorithm makes a single pass over the data stream and uses small space. It requires $O(nk)$ time and $O(n\epsilon)$ space where k is the number of centers, n is the number of points, and $\epsilon < 1$. They have proved that any k-median algorithm that achieves a constant factor approximation cannot achieve a better run time than $O(nk)$.

Micro-clustering

The idea of dividing the clustering process into two layers, where the first layer generates local models (micro-clusters) and the second layer generates global models from the local ones, is a powerful idea that has been used elsewhere.

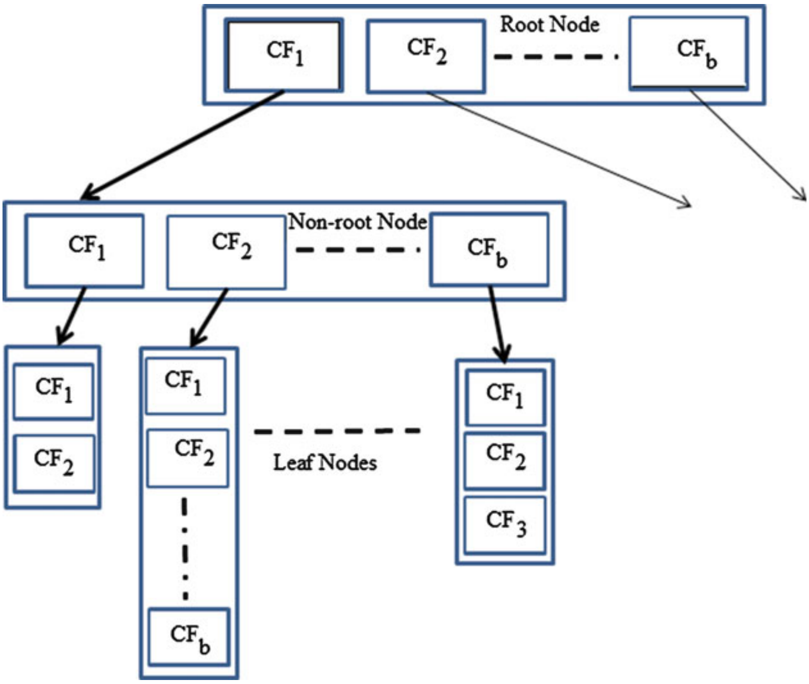
The BIRCH system (Zhang et al. 1996) builds a hierarchical structure of data, the CF-tree (see Fig. 2), where each node contains a set of cluster features. These CFs contain the sufficient statistics describing a set of points in the dataset and all information of the cluster features below in the tree. The system requires two user-defined parameters: b the branch factor or the maximum number of entries in each non-leaf node and T the maximum diameter (or radius) of any CF in a leaf node. The maximum diameter T defines the examples that can be *absorbed* by a CF. Increasing T, more examples can be absorbed by a micro-cluster and smaller CF-trees are generated.

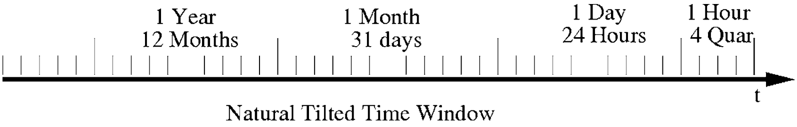
When an example is available, it traverses down the current tree from the root, till finding the appropriate leaf. At each non-leaf node, the example follows the *closest* CF path, with respect to norms L_1 or L_2. If the closest CF in the leaf cannot absorb the example, make a new CF entry. If there is no room for new leaf, split the parent node. A leaf node might be expanded due to the constrains imposed by B and T. The process consists of taking the two farthest CFs and creates two new leaf nodes. When traversing backup the CFs are updated.

Monitoring the Evolution of the Cluster Structure

The *CluStream* algorithm (Aggarwal et al. 2003) is an extension of the BIRCH system designed for data streams. Here, the CFs include temporal information: the time stamp of an example is treated as a feature. For each incoming data point, the distance to the centroids of existing CFs is computed. The data point is absorbed by an existing CF if the distance to the centroid falls

Clustering from Data Streams, Fig. 2 The clustering feature tree in BIRCH. **B** is the maximum number of CFs in a level of the tree





Clustering from Data Streams, Fig. 3 The figure presents a *natural tilted time window*. The most recent data is stored with high detail, while older data is stored in a compressed way. The degree of detail decreases with time

within the *maximum boundary* of the CF. The *maximum boundary* is defined as a factor t of the *radius* deviation of the CF; otherwise, the data point starts a new micro-cluster.

CluStream can generate approximate clusters for any user-defined time granularity. This is achieved by storing the CF at regular time intervals, referred to as snapshots. Suppose the user wants to find clusters in the stream based on a history of length h. The off-line component can analyze the snapshots stored at time t, the current time, and $(t - h)$ by using the addictive property of CF. An important problem is when to store the snapshots of the current set of micro-clusters. For example, the natural time frame stores snapshots each quarter, 4 quarters are aggregated in hours, 24 h are aggregated in days, etc. (Fig. 3). The aggregation level is domain dependent and explores the addictive property of CF. Along similar ideas, Kranen et al. (2011) present *ClusTree* that uses a weighted CF vector, which is kept into a hierarchical tree. *ClusTree* provides strategies for dealing with time constraints for anytime clustering, i.e., the possibility of interrupting the process of inserting new objects in the tree at any moment.

Tracking the Evolution of the Cluster Structure

Promising research lines are tracking change in clusters. Spiliopoulou et al. (2006) present system `MONIC`, for detecting and tracking change in clusters. MONIC assumes that a cluster is an object in a geometric space. It encompasses changes that involve more than one cluster, allowing for insights on cluster change in the whole clustering. The transition tracking mechanism is based on the degree of overlapping between the two clusters. The concept of *overlap* between two clusters, $\mathcal{X}$ and $\mathcal{Y}$, is defined as the normed number of common records weighted with the age of the records. Assume that cluster $\mathcal{X}$ was obtained at time t_1 and cluster $\mathcal{Y}$ at time t_2. The degree of overlapping between the two clusters is given by $overlap(X,Y) = \frac{\sum_{a \in X \cap Y} age(a,t_2)}{\sum_{x \in X} age(x,t_2)}$. The degree of overlapping allows inferring properties of the underlying data stream. Cluster transition at a given timepoint is a change in a cluster discovered at an earlier timepoint. MONIC considers *internal* and *external* transitions, which reflect the dynamics of the stream. Examples of cluster transitions include the cluster survives, the cluster is absorbed; a cluster disappears; and a new cluster emerges.

Coevolutionary Learning

R. Paul Wiegand
University of Central Florida, Orlando, FL, USA

Synonyms

Coevolution; Coevolutionary computation

Definition

Coevolutionary learning is a form of evolutionary learning (see ▶ Evolutionary Algorithms) in which the fitness evaluation is based on interactions between individuals. Since the evaluation of an individual is dependent on interactions with other evolving entities, changes in the set of entities used for evaluation can affect an individual's ranking in a population. In this sense, coevolutionary fitness is *subjective*, while fitness in traditional evolutionary learning systems typically uses an *objective* performance measure.

Motivation and Background

Ideally, coevolutionary learning systems focus on relevant areas of a search space by making adaptive changes between interacting, concurrently evolving parts. This can be particularly helpful when problem spaces are very large – infinite search spaces in particular. Additionally, coevolution is useful when applied to problems when no intrinsic objective measure exists. The interactive nature of evaluation makes them natural methods to consider for problems such as the search for game-playing strategies (Fogel 2001). Finally, some coevolutionary systems appear natural for search spaces which contain certain kinds of complex structures (Potter 1997; Stanley 2004), since search on smaller components in a larger structure can be emphasized. In fact, there is reason to believe that coevolutionary systems may be well suited for uncovering complex structures within a problem (Bucci and Pollack 2002).

Still, the dynamics of coevolutionary learning can be quite complex, and a number of pathologies often plague naïve users. Indeed, because of the subjective nature of coevolution, it can be easy to apply a particular coevolutionary learning system without a clear understanding of what kind of solution one expects a coevolutionary algorithm to produce. Recent theoretical analysis suggests that a clear concept of solution and a careful implementation of an evaluation process consistent with this concept can produce a coevolutionary system capable of addressing many problems (de Jong and Pollack 2004; Ficici 2004; Panait 2006; Wiegand 2003). Accordingly, a great deal of research in this area focuses on evaluation and progress measurement.

Structure of Learning System

Coevolutionary learning systems work in much the same way that an evolutionary learning system works: individuals encode some aspect of potential solutions to a problem, those representatives are altered during search using genetic-like operators such as mutation and crossover, and the search is directed by selecting better individuals as determined by some kind of fitness assessment. These heuristic methods gradually refine solutions by repeatedly cycling through such steps, using the ideas of heredity and survival of the fittest to produce new generations of individuals, with increased quality of solution. Just as in traditional evolutionary computation, there are many choices available to the engineer in designing such systems. The reader is referred to the chapters relating to evolutionary learning for more details.

However, there are some fundamental differences between traditional evolution and coevolution. In coevolution, measuring fitness requires evaluating the interaction between multiple individuals. Interacting individuals may reside in the same population or in different populations; the interactive nature of coevolution evokes notions of cooperation and competition in entirely new ways; the choices regarding how to best conduct evaluation of these interactions for the purposes of selection are particularly important; and there are unique coevolutionary issues surrounding representation. In addition, because of its interactive nature, the dynamics of coevolution can lead to some well-known pathological behaviors, and particularly careful attention to implementation choices to avoid such conditions is generally necessary.

Multiple Versus Single Population Approaches

Coevolution can typically be broadly classified as to whether interacting individuals reside in different populations or in the same population.

In the case of multipopulation coevolution, measuring fitness requires evaluating how individuals in one population interact with individuals in another. For example, individuals in each population may represent potential strategies for particular players of a game, they may represent roles in a larger ecosystem (e.g., predators and prey), or they may represent components that are fitted into a composite assembly with other component then applied to a problem. Though individuals in different populations interact for the purposes of evaluation, they are typically otherwise independent of one another in the coevolutionary search process.

In single population coevolution, an individual in the population is evaluated based on his or her interaction with other individuals in the same population. Such individuals may again represent potential strategies in a game, but evaluation may require them to trade off roles as to which player they represent in that game. Here, individuals interact not only for evaluation, but also implicitly compete with one another as resources used in the coevolutionary search process itself.

There is some controversy in the field as to whether this latter type qualifies as "coevolution." Evolutionary biologists often define coevolution exclusively in terms of multiple populations; however, in biological systems, fitness is always subjective, while the vast majority of computational approaches to evolutionary learning involve objective fitness assessment – and this subjective/objective fitness distinction creates a useful classification.

To be sure, there are fundamental differences between how single population and multipopulation learning systems behave (Ficici 2004). Still, single population systems that employ subjective fitness assessment behave a lot more like multipopulation coevolutionary systems than like objective fitness based evolution. Moreover, historically, the field has used the term coevolution whenever fitness assessment is based on interactions between individuals, and a large amount of that research has involved systems with only one population.

Competition and Cooperation

The terms *cooperative* and *competitive* have been used to describe aspects of coevolution learning in at least three ways.

First and less commonly, these adjectives can describe qualitatively observed behaviors of potential solutions in coevolutionary systems, the results of some evolutionary process (e.g., "tit-for-tat" strategies, Axelrod 1984).

Second, problems are sometimes considered to be inherently competitive or cooperative. Indeed, game theory provides some guidance for making such distinctions. However, since in many kinds of problems little may be known about the actual structure of the payoff functions involved, we may not actually be able to classify the problem as definitively competitive or cooperative.

The final and by far most common use of the term is to distinguish algorithms themselves. Cooperative algorithms are those in which interacting individuals succeed or fail together, while competitive algorithms are those in which individuals succeed at the expense of other individuals.

Because of the ambiguity of the terms, some researchers advocate abandoning them altogether, instead focusing distinguishing terminology on the form a potential solution takes. For example, using the term ▸ compositional coevolution to describe an algorithm designed to return a solution composed of multiple individuals (e.g., a multiagent team) and using the term ▸ test-based coevolution to describe an algorithm designed to return an individual who performs well against an adaptive set of tests (e.g., sorting network). This latter pair of terms is a slightly different, though probably more useful distinction than the cooperative and competitive terms.

Still, it is instructive to survey the algorithms based on how they have been historically classified.

Examples of competitive coevolutionary learning include simultaneously learning sorting networks and challenging data sets in a predator–prey type relationship (Hillis 1991). Here, individuals in one population representing potential sorting networks are awarded a fitness score based on how well they sort opponent data sets from the other population. Individuals in the second population represent potential data sets whose fitness is based on how well they distinguish opponent sorting networks.

Competitive coevolution has also been applied to learning game-playing strategies (Fogel 2001; Rosin and Belew 1996). Additionally, competition has played a vital part in the attempts to coevolve complex agent behaviors (Sims 1994). Finally, competitive approaches have been applied to a variety of more traditional machine learning problems, for example, learning classifiers in one population and challenging subsets of exemplars in the other (Paredis 1994).

Potter developed a relatively general framework for cooperative coevolutionary learning, applying it first to static function optimization and later to neural network learning (Potter 1997). Here, each population contains individuals representing a portion of the network, and evolution of these components occurs almost independently, in tandem with one another, interacting only to be assembled into a complete network in order to obtain fitness. The decomposition of the network can be static and a priori, or dynamic in the sense that components may be added or removed during the learning process.

Moriarty et al. take a different, somewhat more adaptive approach to cooperative coevolution of neural networks (Moriarty and Miikkulainen 1997). In this case, one population represents potential network *plans*, while a second is used to acquire node information. Plans are evaluated based on how well they solve a problem with their collaborating nodes, and the nodes receive a share of this fitness. Thus, a node is rewarded for participating more with successful plans, and thus receives fitness only indirectly.

Evaluation

Choices surrounding how interacting individuals in coevolutionary systems are evaluated for the purposes of selection are perhaps the most important choices facing an engineer employing these methods. Designing the evaluation method involves a variety of practical choices, as well as a broader eye to the ultimate purpose of the algorithm itself.

Practical concerns in evaluation include determining the number of individuals with whom to interact, how those individuals will be chosen for the interaction, and how the selection will operate on the results of multiple interactions (Wiegand 2003). For example, one might determine the fitness of an individual by pairing him or her with all other individuals in the other populations (or the same population for single population approaches) and taking the average or maximum value of such evaluations as the fitness assessment. Alternatively, one may simply use the single best individual as determined by a previous generation of the algorithm, or a combination of those approaches. Random pairings between individuals is also common. This idea can be extended to use tournament evaluation where successful individuals from pairwise interactions are promoted and further paired, assigning fitness based on how far an individual progresses in the tournament. Many of these methods have been evaluated empirically on a variety of types of problems (Angeline and Pollack 1993; Bull 1997; Wiegand 2003).

However, the designing of the evaluation method also speaks to the broader issue of how to best implement the desired ▶ solution concept, (a criterion specifying which locations in the search space are solutions and which are not) (Ficici 2004). The key to successful application of coevolutionary learning is to first elicit a clear and precise solution concept and then design an algorithm (an evaluation method in particular) that implements such a concept explicitly.

A successful coevolutionary learner capable of achieving reliable progress toward a particular solution concept often makes use of an archive of individuals and an update rule for that archive that insists the distance to a particular solution concept decrease with every change to the archive. For example, if one is interested in finding game strategies that satisfy Nash equilibrium constraints, one might consider comparing new individuals to an archive of potential individual strategies found so far that together represent a potential Nash mixed strategy (Ficici 2004). Alternatively, if one is interested in maximizing the sum of an individual's outcomes over all tests, one may likewise employ an archive of discovered tests that candidate solutions are able to solve (de Jong 2004).

It is useful to note that many coevolutionary learning problems are multiobjective in nature. That is, ▸ underlying objectives may exist in such problems, each creating a different ranking for individuals depending on the set of tests being considered during evaluation (Bucci and Pollack 2002). The set of all possible underlying objectives (were it known) is sufficient to determine the outcomes on all possible tests. A careful understanding of this can yield approaches that create ideal and minimal evaluation sets for such problems (de Jong and Pollack 2004).

By acknowledging the link between multiobjective optimization and coevolutionary learning, a variety of evaluation and selection methods based on notions of multiobjective optimization have been employed. For example, there are selection methods that use Pareto dominance between candidate solutions and their tests as their basis of comparison (Ficici 2004). Additionally, such methods can be combined with archive-based approaches to ensure monotonicity of progress toward a Pareto dominance solution concept (de Jong and Pollack 2004).

Representation

Perhaps the core representational question in coevolution is the role that an individual plays. In test-based coevolution, an individual typically represents a potential solution to the problem or a test for a potential solution, whereas in compositional coevolution individuals typically represent a candidate component for a composite or ensemble solution.

Even in test-based approaches, the true solution to the problem may be expressed as a population of individuals, rather than a single individual. The population may represent a mixed strategy while individuals represent potential pure strategies for a game. Engineers using such approaches should be clear of the form of the final solution produced by the algorithm, and that this form is consistent with the prescribed solution concept.

In compositional approaches, the key issues tend to surround about how the problem is decomposed. In some algorithms, this decomposition is performed a priori, having different populations represent explicit components of the problem (Potter 1997). In other approaches, the decomposition is intended to be somewhat more dynamic (Moriarty and Miikkulainen 1997; Potter 1997). Still more recent approaches seek to harness the potential of compositional coevolutionary systems to search open-ended representational spaces by gradually *complexifying* the representational space during the search (Stanley 2004).

In addition, a variety of coevolutionary systems have successfully dealt with some inherent pathologies by representing populations in spatial topologies, and restricting selection and interaction using geometric constraints defined by those topologies (Pagie 1999). Typically, these systems involve overlaying multiple grids of individuals, applying selection within some neighborhood in a given grid, and evaluating interactions between individuals in different grids using a similar type of cross-population neighborhood. The benefits of these systems are in part due to their ability to naturally regulate loss of diversity and spread of interaction information by explicit control over the size and shape of these neighborhoods.

Pathologies and Remedies

Perhaps the most commonly cited pathology is the so-called *loss of gradient* problem, in which one population comes to severely dominate the others, thus creating a situation in which individuals cannot be distinguished from one another. The populations become disengaged and evolutionary progress may *stall* or *drift* (Watson and Pollack 2001). Disengagement most commonly occurs when distinguishing individuals are lost in the evolutionary process (*forgetting*), and the solution to this problem typically involves somehow retaining potentially informative, though possibly inferior quality individuals (e.g., archives).

Intransitivities in the reward system can cause some coevolutionary systems to exhibit *cycling* dynamics (Watson and Pollack 2001), where reciprocal changes force the system to orbit some part of a potential search space. The remedy to this problem often involves creating coevolutionary systems that change in response to traits in several other populations. Mechanisms introduced to produce such effects include *competitive fitness sharing* (Rosin and Belew 1996).

Another challenging problem occurs when individuals in a coevolutionary systems *overspecialize* on one underlying objective at the expense of other necessary objectives (Watson and Pollack 2001). In fact, overspecialization can be seen as a form of disengagement on some subset of underlying objectives, and likewise the repair to this problem often involves retaining individuals capable of making distinctions in as many underlying objectives as possible (Bucci and Pollack 2003).

Finally, certain kinds of compositional coevolutionary learning algorithms can be prone to *relative overgeneralization*, a pathology in which components that perform reasonably well in a variety of composite solutions are favored over those that are part of an optimal solution (Wiegand 2003). In this case, it is typically possible to bias the evaluation process toward optimal values by evaluating an individual in a variety of composite assemblies and assigning the best objective value found as the fitness (Panait 2006).

In addition to pathological behaviors in coevolution, the subjective nature of these learning systems creates difficulty in measuring progress. Since fitness is subjective, it is impossible to determine whether these relative measures indicate progress or stagnation when the measurement values do not change much. Without engaging some kind of external or objective measure, it is difficult to understand what the system is really doing. Obviously, if an objective measure exists then it can be employed directly to measure progress (Watson and Pollack 2001).

A variety of measurement methodologies have been employed when objective measurement is not possible. One method is to compare current individuals against all ancestral opponents (Cliff and Miller 1995). Another predator/prey based method holds *master tournaments* between all the best predators and all the best prey found during the search (Nolfi and Floreano 1998). A similar approach suggests maintaining the best individuals from each generation in each population in a *hall of fame* for comparison purposes (Rosin and Belew 1996). Still other approaches seek to record the points during the coevolutionary search in which a new dominant individual was found (Stanley 2004). A more recent approach advises looking at the *population differential*, examining all the information from ancestral generations rather than simply selecting a biased subset (Bader and Pollack 2005). Conversely, an alternative idea is to consider how well the *dynamics* of the best individuals in different populations reflect the fundamental *best response* curves defined by the problem (Popovici 2006).

With a clear solution concept, an appropriate evaluation mechanism implementing that concept, and practical progress measures in place, coevolution can be an effective and versatile machine learning tool.

Collaborative Filtering

Collaborative Filtering (CF) refers to a class of techniques used in recommender systems, that recommend items to users that other users with similar tastes have liked in the past. CF methods are commonly sub-divided into *neighborhood-based* and *model-based* approaches. In neighborhood-based approaches, a subset of users are chosen based on their similarity to the active user, and a weighted combination of their ratings is used to produce predictions for this user. In contrast, model-based approaches assume an underlying structure to users' rating behavior, and induce predictive models based on the past ratings of all users.

University of Maryland, College Park, MD, USA

Synonyms

Iterative classification; Link-based classification

Definition

Many real-world ▶classification problems can be best described as a set of objects interconnected via links to form a network structure. The links in the network denote relationships among the instances such that the class labels of the instances are often correlated. Thus, knowledge of the correct label for one instance improves our knowledge about the correct assignments to the other instances it connects to. The goal of collective classification is to *jointly* determine the correct label assignments of all the objects in the network.

Motivation and Background

Traditionally, a major focus of machine learning is to solve classification problems: given a corpus of documents, classify each according to its topic label; given a collection of e-mails, determine which are spam; given a sentence, determine the part-of-speech tag for each word; given a handwritten document, determine the characters, etc. However, much of the work in machine learning makes an *independent and identically distributed* (IID) assumption and focuses on predicting the class label of each instance in isolation. In many cases, however, the class labels whose values need to be determined can benefit if we know the correct assignments to related class labels. For example, it is easier to predict the topic of a webpage if we know the topics of the webpages that link to it, the chance of a particular word being a verb increases if we know that the previous word in the sentence is a noun, knowing the rest of the characters in a word can make it easier to identify an unknown character, etc. In the last decade, many researchers have proposed techniques that attempt to classify samples in a joint or collective manner instead of treating each sample in isolation and reported significant gains in classification accuracy.

Theory/Solution

Collective classification is a combinatorial optimization problem, in which we are given a set of nodes, $\mathcal{V} = \{v_1, \ldots, v_n\}$, and a neighborhood function $\mathcal{N}$, where $\mathcal{N}_i \subseteq \mathcal{V}\backslash\{v_i\}$, which describes the underlying network structure. Each node in $\mathcal{V}$ is a random variable that can take a value from an appropriate domain, $\mathcal{L} = \{l_1, \ldots, l_q\}$. $\mathcal{V}$ is further divided into two sets of nodes: $\mathcal{X}$, the nodes for which we know the correct values (observed variables), and $\mathcal{Y}$, the nodes whose values need to be determined. Our task is to label the nodes $y_i \in \mathcal{Y}$ with one of a small number of predefined labels in $\mathcal{L}$.

Even though it is only in the last decade that collective classification has entered the collective conscience of machine learning researchers, the general idea can be traced further back (Besag 1986). As a result, a number of approaches have been proposed. The various approaches to collective classification differ in the kinds of information they aim to exploit to arrive at the correct classification and their mathematical underpinnings. We discuss each in turn.

Relational Classification

Traditional classification concentrates on using the observed attributes of the instance to be classified. Relational classification (Slattery and Craven 1998) attempts to go a step further by classifying the instance using not only the instance's own attributes but also the instance's neighbors' attributes. For example, in a hypertext classification domain where we want to classify webpages, not only would we use the webpage's own words but we would also look at the webpages linking to this webpage using hyperlinks and their words to arrive at the correct class label. Results obtained using relational classification have been mixed. For example, even though there have been reports of classification accuracy gains using such techniques, in certain cases, these techniques can harm classification accuracy (Chakrabarti et al. 1998).

Iterative Collective Classification with Neighborhood Labels

A second approach to collective classification is to use the class labels assigned to the neighbor instead of using the neighbor's observed attributes. For example, going back to our hypertext classification example, instead of using the linking webpage's words, we would, in this case, use its assigned labels to classify the current webpage. Chakrabarti et al. (1998) illustrated the use of this approach and reported impressive classification accuracy gains. Neville and Jensen (2000) further developed the approach, and referred to the approach as iterative classification, and studied the conditions under which it improved classification performance (Jensen et al. 2004). Techniques for feature construction from the neighboring labels were developed and studied (Lu and Getoor 2003), along with methods that make use of *only* the label information (Macskassy and Provost 2007), as well as a variety of strategies for when to commit the class labels (McDowell et al. 2007).

Algorithm 1 depicts pseudo-code for a simple version of the iterative classification algorithm (ICA). The basic premise behind ICA is extremely simple. Consider a node $Y_i \in \mathcal{Y}$ whose value we need to determine and suppose we know the values of all the other nodes in its neighborhood $\mathcal{N}_i$ (note that $\mathcal{N}_i$ can contain both observed and unobserved variables). Then, ICA assumes that we are given a local classifier f that takes the values of $\mathcal{N}_i$ as arguments and returns a label value for Y_i from the class label set $\mathcal{L}$. For local classifiers f that do not return a class label but a goodness/likelihood value given a set of attribute values and a label, we simply choose the label that corresponds to the maximum goodness/likelihood value; in other words, we replace f with $\mathrm{argmax}_{l \in \mathcal{L}} f$. This makes the local classifier f extremely flexible, and we can use anything ranging from a decision tree to a ▸ support vector machine (SVM). Unfortunately, it is rare in practice that we know all values in $\mathcal{N}_i$, which is why we need to repeat the process iteratively, in each iteration, labeling each Y_i using the current best estimates of $\mathcal{N}_i$ and the local classifier f and continuing to do so until the assignments to the labels stabilize.

Most local classifiers are defined as functions whose argument consists of a fixed-length vector of attribute values. A common approach to circumvent such a situation is to use an aggregation operator such as count, mode, or prop, which measures the proportion of neighbors with a given label. In Algorithm 1, we use $\vec{a}_i$ to denote the vector encoding the values in $\mathcal{N}_i$ obtained after aggregation. Note that in the first ICA iteration, all labels y_i are undefined, and to initialize them we simply apply the local classifier to the observed attributes in the neighborhood of Y_i; this is referred to as "bootstrapping" in Algorithm 1.

Researchers in collective classification (Macskassy and Provost 2007; McDowell et al. 2007; Neville and Jensen 2000) have extended the simple algorithm described above and developed a version of Gibbs sampling that is easy to imple-

Algorithm 1 Iterative classification algorithm

Iterative Classification Algorithm (ICA)

```
for each node $Y_i \in \mathcal{Y}$ do {bootstrapping}
    {compute label using only observed nodes in $\mathcal{N}_i$}
    compute $\vec{a}_i$ using only $\mathcal{X} \cap \mathcal{N}_i$
    $y_i \leftarrow f(\vec{a}_i)$
end for
repeat {iterative classification}
    generate ordering $\mathcal{O}$ over nodes in $\mathcal{Y}$
    for each node $Y_i \in \mathcal{O}$ do
        {compute new estimate of $y_i$}
        compute $\vec{a}_i$ using current assignments to $\mathcal{N}_i$
        $y_i \leftarrow f(\vec{a}_i)$
    end for
until all class labels have stabilized or a threshold number of iterations have elapsed
```

ment and faster than traditional Gibbs sampling approaches. The basic idea behind this algorithm is to assume, just like in the case of ICA, that we have access to a local classifier f that can sample for the best label estimate for Y_i given all the values for the nodes in $\mathcal{N}_i$. We keep doing this repeatedly for a fixed number of iterations (a period known as "burn-in"). After that, not only do we sample for labels for each $Y_i \in \mathcal{Y}$ but we also maintain count statistics as to how many times we sampled label l for node Y_i. After collecting a predefined number of such samples, we output the best label assignment for node Y_i by choosing the label that was assigned the maximum number of times to Y_i while collecting samples.

One of the benefits of both variants of ICA is fairly simple to make use of any local classifier. Some of the classifiers used included the following: naïve Bayes (Chakrabarti et al. 1998; Neville and Jensen 2000), ▸ logistic regression (Lu and Getoor 2003), ▸ decision trees, (Jensen et al. 2004) and weighted-vote relational neighbor (Macskassy and Provost 2007). There is some evidence to indicate that discriminately trained local classifiers such as logistic regression tend to produce higher accuracies than others; this is consistent with results in other areas.

Other aspects of ICA that have been the subject of investigation include the ordering strategy to determine in which order to visit the nodes to relabel in each ICA iteration. There is some evidence to suggest that ICA is fairly robust to a number of simple ordering strategies such as random ordering, visiting nodes in ascending order of diversity of its neighborhood class labels, and labeling nodes in descending order of label confidences (Getoor 2005). However, there is also some evidence that certain modifications to the basic ICA procedure tend to produce improved classification accuracies. For example, both (Neville and Jensen 2000) and (McDowell et al. 2007) propose a strategy where only a subset of the unobserved variables are utilized as inputs for feature construction. More specifically, in each iteration, they choose the top-k most confident predicted labels and use only those unobserved variables in the following iteration's predictions, thus ignoring the less confident predicted labels. In each subsequent iteration, they increase the value of k so that in the last iteration, all nodes are used for prediction. McDowell et al. report that such a "cautious" approach leads to improved accuracies.

Collective Classification with Graphical Models

In addition to the approaches described above, which essentially focus on local representations and propagation methods, another approach to collective classification is by first representing the problem with a high-level global ▸ graphical model and then using learning and inference techniques for the graphical modeling approach to arrive at the correct classifications. These proposals include the use of both directed ▸ graphical models (Getoor et al. 2001) and undirected graphical models (Lafferty et al. 2001; Taskar et al. 2002). See ▸ statistical relational learning and Getoor and Taskar (2007) for a survey of various graphical models that are suitable for collective classification. In general, these techniques can use both neighborhood labels and observed attributes of neighbors. On the other hand, due to their generality, these techniques also tend to be less efficient than the iterative collective classification techniques.

One common way of defining such a global model uses a *pairwise Markov random field* (pairwise MRF) (Taskar et al. 2002). Let $G = (\mathcal{V}, E)$ denote a graph of random variables as before where $\mathcal{V}$ consists of two types of random variables, the unobserved variables, $\mathcal{Y}$, which need to be assigned domain values from label set $\mathcal{L}$, and observed variables $\mathcal{X}$ whose values we know (see ▸ Graphical Models). Let Ψ denote a set of *clique potentials*. Ψ contains three distinct types of functions:

- For each $Y_i \in \mathcal{Y}$, $\psi_i \in \Psi$ is a mapping $\psi_i : \mathcal{L} \rightarrow \Re_{\geq 0}$, where $\Re_{\geq 0}$ is the set of nonnegative real numbers.
- For each $(Y_i, X_j) \in E$, $\psi_{ij} \in \Psi$ is a mapping $\psi_{ij} : \mathcal{L} \rightarrow \Re_{\geq 0}$.

- For each $(Y_i, Y_j) \in E$, $\psi_{ij} \in \Psi$ is a mapping $\psi_{ij} : \mathcal{L} \times \mathcal{L} \to \mathfrak{R}_{\geq 0}$.

Let $\mathbf{x}$ denote the values assigned to all the observed variables in $\mathcal{V}$, and let x_i denote the value assigned to X_i. Similarly, let $\mathbf{y}$ denote any assignment to all the unobserved variables in $\mathcal{V}$, and let y_i denote a value assigned to Y_i. For brevity of notation, we will denote by ϕ_i the clique potential obtained by computing $\phi_i(y_i) = \psi_i(y_i) \prod_{(Y_i, X_j) \in E} \psi_{ij}(y_i)$. We are now in a position to define a pairwise MRF.

Definition 1 A *pairwise Markov random field* (MRF) is given by a pair $\langle G, \Psi \rangle$ where G is a graph and Ψ is a set of clique potentials with ϕ_i and ψ_{ij} as defined above. Given an assignment $\mathbf{y}$ to all the unobserved variables $\mathcal{Y}$, the pairwise MRF is associated with the probability distribution $P(\mathbf{y}|\mathbf{x}) = \frac{1}{\mathcal{Z}(\mathbf{x})} \prod_{Y_i \in \mathcal{Y}} \phi_i(y_i) \prod_{(Y_i, Y_j) \in E} \psi_{ij}(y_i, y_j)$ where $\mathbf{x}$ denotes the observed values of $\mathcal{X}$ and $\mathcal{Z}(\mathbf{x}) = \sum_{\mathbf{y}'} \prod_{Y_i \in \mathcal{Y}} \phi_i\left(y'_i\right) \prod_{(Y_i, Y_j) \in E} \psi_{ij}\left(y'_i, y'_j\right)$.

Given a pairwise MRF, it is conceptually simple to extract the best assignments to each unobserved variable in the network. For example, we may adopt the criterion that the best label value for Y_i is simply the one corresponding to the highest marginal probability obtained by summing over all other variables from the probability distribution associated with the pairwise MRF. Computationally, however, this is difficult to achieve since computing one marginal probability requires summing over an exponentially large number of terms, which is why we need approximate inference algorithms. Hence, approximate inference algorithms are typically employed, the two most common being *loopy belief propagation* (LBP) and *mean-field relaxation labeling*.

Applications

Due to its general applicability, collective classification has been applied to a number of real-world problems. Foremost in this list is document classification. Chakrabarti et al. (1998) was one of the first to apply collective classification to corpora of patents linked via hyperlinks and reported that considering attributes of neighboring documents actually hurts classification performance. Slattery and Craven (1998) also considered the problem of document classification by constructing features from neighboring documents using an ▶ inductive logic programming rule learner. Yang et al. (2002) conducted an in-depth investigation over multiple datasets commonly used for document classification experiments and identified different patterns. Other applications of collective classification include object labeling in images (Hummel and Zucker 1983), analysis of spatial statistics (Besag 1986), iterative decoding (Berrou et al. 1993), part-of-speech tagging (Lafferty et al. 2001), classification of hypertext documents using hyperlinks (Taskar et al. 2002), link prediction (Getoor et al. 2002; Taskar et al. 2003b), optical character recognition (Taskar et al. 2003a), entity resolution in sensor networks (Chen et al. 2003), predicting disulfide bonds in protein molecules (Taskar et al. 2005), segmentation of 3D scan data (Anguelov et al. 2005), and classification of e-mail speech acts (Carvalho and Cohen 2005). Recently, there have also been attempts to extend collective classification techniques to the semi-supervised learning scenario (Lu and Getoor 2003b; Macskassy 2007; Xu et al. 2006).

Comparable Corpus

A comparable corpus (pl. corpora) is a document collection composed of two or more disjoint subsets, each written in a different language, such that documents in each subset are on a same topic as the documents in the others. The prototypical example of a comparable corpora is a collection of newspaper article written in different languages and reporting about the same events: while they will not be, strictly speaking, the translation of one another, they will share most of the semantic content. Some methods for cross-language text mining rely, totally or partially, on the statistical properties of comparable corpora.

Comparison Training

▸ Preference Learning

Competitive Coevolution

▸ Test-Based Coevolution

Competitive Learning

A *Competitive learning* is an ▸ artificial neural network learning process where different neurons or processing elements compete on who is allowed to learn to represent the current input. In its purest form competitive learning is in the so-called winner-take-all networks where only the neuron that best represents the input is allowed to learn. Since all neurons learn to better represent the kinds of inputs they already are good at representing, they become specialized to represent different kinds of inputs. For vector-valued inputs and representations, the input becomes quantized to the unit having the closest representation (model), and the representations are adapted to minimize the representation error using stochastic gradient descent.

Competitive learning networks have been studied as models of how receptive fields and feature detectors, such as orientation-selective visual neurons, develop in neural networks. The same process is at work in online ▸ K-means clustering, and variants of it in ▸ Self-Organizing Maps (SOM) and the EM algorithm of mixture models.

Complex Adaptive System

▸ Complexity in Adaptive Systems

Complexity in Adaptive Systems

Jun He

Abstract

The complexity in adaptive systems is classified into two types: internal complexity for model complexity and external complexity for data complexity. As an application, the two concepts are put into the background of learning and are used to explain statistical learning.

Synonyms

Adaptive system; Complex adaptive system

Definition

An adaptive system, or complex adaptive system, is a special case of complex systems, which is able to adapt its behavior according to changes in its environment or in parts of the system itself. In this way, the system can improve its performance through a continuing interaction with its environment. The concept of complexity in an adaptive system is used to analyze the interactive relationship between the system and its environment, which can be classified into two types: internal complexity for model complexity and external complexity for data complexity. The internal complexity is defined by the amount of input, information, or energy that the system receives from its environment. The external complexity refers to the complexity of how the system represents these inputs through its internal process.

Motivation and Background

Adaptive systems range from natural systems to artificial systems (Holland 1992, 1995; Mitchell 1992). Examples of natural systems include ant colonies, ecosystem, the brain, neural network and immune system, cell, and developing embryo; examples of artificial systems include the stock market, social system, manufacturing businesses, and human social group-based endeavor in a cultural and social system such as political parties or communities. All these systems have a common feature: they can adapt to their environment.

An adaptive system is adaptive in that way it has the capacity to change its internal structure for adapting the environment. It is complex in the sense that it interacts with their environment. The interaction between an adaptive system and its environment is dynamic and nonlinear. Complexity emerges from the interaction among the system and environment and the elements of the system, where the emergent macroscopic patterns are more complex than the sum of the these low-level (microscopic) elements encompassed in the system. Understanding the evolution and development of adaptive systems still faces many mathematical challenges (Levin 2003).

The concepts of external and internal complexity are used to analyze the relation between an adaptive system and its environment. The description given below is based on Jürgen Jost's work (Jost 2004), which introduced these two concepts and applied the theoretical framework to the construction of learning models, e.g., to design neural network architectures. In the following, the concepts are mainly applied to analyze the interaction between the system and its environment. The interaction among individual elements of the system is less discussed; however, the concepts can be explored in that situation too.

Theory

Adaptive System, Environment, and Regularities

The environment of an adaptive system is more complex than the system itself and its changes cannot be completely predictable for the system. However, the changes of the environment are not purely random and noisy; there exist regularities in the environment. An adaptive system can recognize these regularities; and depending on these regularities, the system will express them through its internal process in order to adapt to the environment.

The input that an adaptive system receives or extracts from its environment usually includes two parts: one is the part with regularities and another is that appears random to the system. The part of regularities is useful and meaningful. An adaptive system will represent these regularities by internal processes. But the part of random input is useless, and even at the worst it will be detrimental for an adaptive system. However, it will depend on the adaptive system's internal model of the external environment for how to determine which part of input is meaningful and regular and which part is random and devoid of meaning and structure.

An adaptive system will translate the external regularities into its internal ones, and only the regularities are useful to the system. The system tries to extract regularities as many as possible and to represent these regularities as efficiently as possible in order to make optimal use of its capacity.

The notions of external complexity and internal complexity are used to investigate these two complementary aspects conceptually and quantitatively. In terms of these notions, an adaptive system aims to increase their external complexity and reduce their internal complexity.

The two processes operate on their own time scale but are intricately linked and mutually dependent on each other. For example, the internal complexity will be only reduced if the external complexity is fixed. Under fixed inputs received from the external environment, an adaptive system can represent these inputs systems more efficiently and optimize its internal structure. If the external complexity is increased, e.g., additional new input is required to handle by the system, then it is necessary to increase its internal complexity.

The increase of internal complexity may occur through the creation of redundancy in the existing adaptive system, e.g., to duplicate some internal structures and then enable the system to handle more external input. Once the input is fixed, the adaptive then will represent the input as efficiently as possible and reduce the internal input. The decrease of internal complexity can be achieved through discarding some input as meaningless and irrelevant, e.g., leaving some regularities out, for the purpose.

Since the inputs relevant for the systems are those which can be reflected in the internal model, the external complexity is not equivalent to the amount of raw data received from the environment. In fact, it is only relevant to the inputs which can be processed in the internal model or observations in some adaptive systems. Thus the external complexity ultimately is decided by the internal model constructed by the system.

External and Internal Complexity

External complexity means data complexity, which is used to measure the amount of input received from the environment for the system to handle and process. Such a complexity can be measured by entropy in the term of information theory.

Internal complexity is model complexity, which is used to measure the complexity of a model for representing the input or information received by the system.

The aim of the adaptive system is to obtain an efficient model as simple as possible, with the capacity to handle as much input as possible. On the one hand, the adaptive system will try to maximize its external complexity and then to adapt to its environment in a maximal way and, on the other hand, to minimize its internal complexity and then to construct a model to process the input in the most efficient way.

These two aims sometimes seem conflicting, but such a conflict can be avoided when these two processes operate on different time scales. If given a model, the system will organize the input data and try to increase its ability to deal input from its environment and then increase its external complexity. If given the input, conversely, it tries to simplify its model which represents that input and thus to decrease the internal complexity. The meaning of the input is relevant to the time scale under investigation. On a short time scale, for example, the input may consist of individual signals, but on a long time scale, it will be a sequence of signals, which satisfies a probability distribution. A good internal model tries to express regularities in the input sequence, rather than several individual signals. And the decrease of internal complexity will happen on this time scale.

A formal definition of the internal and external complexity concepts is based on the concept of entropy from statistical mechanics and information theory. Given a model θ, the system can model data as with $X(\theta) = (X_1, \cdots, X_k)$, which is assumed to have an internal probability distribution $P(X(\theta))$ so that entropy can be computed. The external complexity is defined by

$$-\sum_{i=1}^{k} P(X_i(\theta)) \log_2 P(X_i(\theta)). \qquad (1)$$

An adaptive system tries to maximize the above external complexity.

The probability distribution $P(X(\theta))$ is for quantifying the information value of the data $X(\theta)$. The value of information can be described in other approaches, e.g., the length of the representation of the data in the internal code of the system (Rissanen 1989/1998). In this case, the optimal coding is a consequence of the minimization of internal complexity, and then the length of the representation of data $X_i(\theta)$ behaves like $\log_2 P(X(\theta))$ (Rissanen 1989/1998).

On a short time scale, for a given model θ, the system tries to increase the amount of meaningful input information $X(\theta)$. On a long time scale, when the input is given, e.g., when the system has gathered a set of input on a time scale with a stationary probability distribution of input patterns Ξ, then the model should be improved to handle the input as efficiently as possible and reduce the complexity of model. This complexity, or internal complexity, is defined by

$$-\sum_{i=1}^{k} P(\Xi_i \mid \theta) \log_2 P(\Xi_i \mid \theta) - \log_2 P(\theta), \quad (2)$$

with respect to the model θ.

If Rissanen's minimum description length principle (Rissanen 1989/1998) is applied to the above formula, then the optimal model will satisfy the following variation problem:

$$\min_{\theta} (-\log_2 P(\Xi \mid \theta) - \log_2 P(\theta)) . \quad (3)$$

Here in the above minimization problem, there are two objectives to minimize. The first term is to measure how efficiently the model represents or encodes the data and the second one to how complicated the model is. In computer science, this latter term corresponds to the length of the program required to encode the model.

The concepts of external and internal complexity can be applied into a system divided into subsystems. In this case, some internal part of the original whole system will become external to a subsystem. Thus the internal input of a subsystem consists of original external input and also input from the rest of the system, i.e., other subsystems.

Application: Learning

The discussion of these two concepts, external and internal complexity, can be put into the background of learning. In statistical learning theory (Vapnik 1998), the criterion for evaluating a learning process is the expected prediction error of future data by the model based on training data set with partial and incomplete information. The task is to construct a probability distribution drawn from an a priori specific class for representing the distribution underlying the input data received. Usually if a higher error is produced by a model on the training data, then a higher error will be expected on the future data. The error will depend on two factors: one is the accuracy of the model on the training data set and another is the simplicity of the model itself. The description of the data set can be split into two parts, the regular part, which is useful in construct the model, and the random part, which is a noise to the model.

The learning process fits very well into the theory framework of internal and external complexity. If the model is too complicated, it will bring the risk of over-fitting the training dada. In this case, some spurious or putative regularity is incorporated into the model, which will not appear in the future data. The model should be constrained within some model class with bounded complexity. This complexity in this context of statistical learning theory is measured by the Vapnik-Chervonenkis dimension (Vapnik 1998). Under the simplest form of statistical learning theory, the system aims at finding a representation with smallest error in a class with given complexity constraints; and then the model should minimize the expected error on future data and also over-fitting error.

The two concepts of over-fitting and leaving out regularities can be distinguished in the following sense. The former is caused by the noise in the data, i.e., the random part of the data, and this leads to putative regularities, which will not appear in the future data. The latter, leaving out regularities, means the system can forgo some part of regularities in the data, or it is possible to make data compression. Thus leaving out regularities can be used to simplify the model and reduce the internal complexity. However, a problem is still waiting for answer here, that is, what regularities in the data set are useful for data compression and also meaningful for future prediction and what parts are random to the model.

The internal complexity is the model complexity. If the internal complexity is chosen too small, then the model does not have enough capacity to represent all the important features of the data set. If the internal complexity is too large, on the other hand, then the model doesn't represent the data efficiently. The internal complexity is preferably minimized under appropriate constraints on the adequacy of the representation of data. This is consistent with Rissanen's principle of minimum description length (Rissanen 1989/1998), to represent the given data set in the most efficient way. Thus a good model is both to simplify the model itself and to represent the data efficiently.

The external complexity is the data complexity which should be large to represent the input accurately. This is related to Jaynes' principle of maximizing the ignorance (Jaynes 1957), where a model for representing data should have the maximal possible entropy under the constraint that all regularities can be reproduced. In this way, putative regularities could be eliminated in the model. However, this principle should be applied with some conditions; as argued by Gell-Mann and Lloyd (1996), it cannot eliminate the essential regularities in the data, and an overly complex model should be avoided.

For some learning system, only a selection of data is gathered and observed by the system. Thus a middle term, observation, is added between model and data. The concept of observation refers to the extraction of value of some specific quantity from a given data or data pool. What a system can observe depends on its internal structure and its general model of the environment. The system doesn't have direct access to the raw data, but through constructing a model of the environment solely on the basis of the values of its observation.

For such kind of learning system, Jaynes' principle (Jaynes 1957) is still applicable for increasing the external complexity. For the given observation made on a data set, the maximum entropy representation should be selected. However, this principle is still subject to the modification of Gell-Mann and Lloyd (1996) to the principle, where the model should not lose the essential regularities observed in the data.

In contrast, the observations should be selected to reduce the internal complexity. Given a model, if the observation can be made on a given data set, then these observations should be selected so as to minimize the resulting entropy of the model, with the purpose of minimizing the uncertainty left about the data. Thus it leads to reduce complexity.

In most cases, the environment is dynamic, i.e., the data set itself can be varied, then the external complexity should be maximized again. Thus the observation should be chosen for maximal information gain extracted from the data to increase the external complexity. Jaynes' principle (Jaynes 1957) can be applied as the same as in previous discussion. But in a longer time scale, when the input reaches some stationary distribution, the model should be simplified to reduce its internal complexity.

[2]Department of Mathematics, National University of Singapore, Singapore, Singapore

Definition

In ▸ inductive inference, the complexity of learning can be measured in various ways: by the number of hypotheses issued in the worst case until the correct hypothesis is found, by the number of data items to be consumed or to be memorized in order to learn in the worst case, by the Turing degree of oracles needed to learn the class under a certain criterion, and by the intrinsic complexity which is – like the Turing degrees in recursion theory – a way to measure the complexity of classes by using reducibilities between them.

Detail

We refer the reader to the article ▸ Inductive Inference for basic definitions in inductive inference and the notations used below. Let $\mathbb{N}$ denote the set of natural numbers. Let $\varphi_0, \varphi_1, \ldots$ denote a fixed acceptable numbering of the partial-recursive functions (Rogers 1967). Let $W_i = \text{domain}(\varphi_i)$.

Mind Changes and Anomalies

The first measure of complexity of learning can be considered as the number of mind changes needed before the learner converges to its final hypothesis in the **TxtEx** model of learning. The number of mind changes by a learner M on a text T can be counted as card $(\{m : ? \neq \text{M}(T[m]) \neq \text{M}(T[m+1])\})$. A learner M $\mathbf{TxtEx}_n$ learns a class $\mathcal{L}$ of languages if M **TxtEx** learns $\mathcal{L}$ and for all $L \in \mathcal{L}$, for all texts T for L, M makes at most n mind changes on T. $\mathbf{TxtEx}_n$ is defined as the collection of language classes which can be $\mathbf{TxtEx}_n$ identified (see Case and Smith (1983) for details).

Consider the class of languages $\mathcal{L}_n = \{L : \text{card}(L) \leq n\}$. It can be shown that $\mathcal{L}_{n+1} \in \mathbf{TxtEx}_{n+1} - \mathbf{TxtEx}_n$.

Now consider anomalous learning. A class $\mathcal{C}$ is $\mathbf{TxtEx}_b^a$ learnable if there is a learner, which makes at most b mind changes (where $b = *$ denotes that the number of mind changes is finite on each text for a language in the class, but not necessarily bounded by a constant) and whose final hypothesis is allowed to make up to a errors (where $a = *$ denotes finitely many errors). For these learning criteria, we get a two-dimensional hierarchy on what can be learnt. Let $\mathcal{C}_n = \{f : \varphi_{f(0)} =^n f\}$. For a total function f, let $L_f = \{\langle x, f(x) \rangle : x \in \mathbb{N}\}$, where $\langle \cdot, \cdot \rangle$ denotes a computable pairing function: a bijective mapping from $\mathbb{N} \times \mathbb{N}$ to $\mathbb{N}$. Let $\mathcal{L}_{\mathcal{C}} = \{L_f : f \in \mathcal{C}\}$. Then, one can show that $\mathcal{L}_{\mathcal{C}_{n+1}} \in \mathbf{TxtEx}_0^{n+1} - \mathbf{TxtEx}^n$. Similarly, if we consider the class $\mathcal{S}_n = \{f : \text{card}(\{m : f(m) \neq f(m+1)\}) \leq n\}$, then one can show that $\mathcal{L}_{\mathcal{S}_{n+1}} \in \mathbf{TxtEx}_{n+1}^0 - \mathbf{TxtEx}_n^*$ (we refer the reader to Case and Smith (1983) for a proof of the above).

Data and Time Complexity

Wiehagen (1986) considered the complexity of the number of data needed for learning. Regarding time complexity, one should note the result by Pitt (1989) that any **TxtEx**-learnable class of languages can be **TxtEx**-learnt by a learner that has time complexity (with respect to the size of the input) bounded by a linear function. This result is achieved by a delaying trick, where the learner just repeats its old hypothesis unless it has enough time to compute its later hypothesis. This seriously effects what one can say about time complexity of learning. One proposal made by Daley and Smith (1986) is to consider the total time used by the learner until its sequence of hypotheses converges, resulting in a possibly more reasonable measure of time in the complexity of learning.

Iterative and Memory-Bounded Learning

Another measure of complexity of learning can be considered when one restricts how much past data a learner can remember. Wiehagen (1976) introduced the concept of *iterative* learning in which the learner cannot remember any past data. Its new hypothesis is based only on its previous conjecture and the new datum it receives. In other words, there exists a recursive function F such that $\text{M}(T[n+1]) = F(\text{M}(T[n]), T(n))$, for all texts T and for all n. Here, $\text{M}(T[0])$ is some fixed value, say the symbol "?" which is used by the learner to denote the absence of a reasonable conjecture. It can be shown that being iterative restricts the learning capacity of learners. For example, let $L_e = \{2x : x \in \mathbb{N}\}$ and let $\mathcal{L} = \{L_e\} \cup \{\{S \cup \{2n+1\}\} : n \in \mathbb{N}, S \subseteq L_e$, and $\max(S) \leq n\}$; then $\mathcal{L}$ can be shown to be **TxtEx** learnable but not iteratively learnable.

Memory-bounded learning (see Lange and Zeugmann 1996) is an extension of memory-limited learning, where the learner is allowed to memorize up to some fixed number of elements seen in the past. Thus, M is an m-memory-bounded learner if there exists a function mem and two computable functions mF and F such that, for all texts T and all n:

- $mem(T[0]) = \emptyset$;
- $\mathrm{M}(T[n+1]) = F(\mathrm{M}(T[n]), mem(T[n]), T(n+1))$;
- $mem(T[n+1]) = mF(\mathrm{M}(T[n]), mem(T[n]), T(n+1))$;
- $mem(T[n+1]) - mem(T[n]) \subseteq \{T(n+1)\}$;
- $\mathrm{card}(mem(T[n])) \leq m$.

It can be shown that the criteria of inference based on **TxtEx** learning by m-memory-bounded learners form a proper hierarchy.

Besides memorizing some past elements seen, another way to address this issue is by giving feedback to the learner (see Case et al. 1999) on whether some element has appeared in the past data. A feedback learner is an iterative learner, which is additionally allowed to query whether certain elements appeared in earlier data. An n-feedback learner is allowed to make n such queries at each stage (when it receives the new input datum). Thus, M is an m-feedback learner if there exist computable functions Q and a F such that, for all texts T and all n:

- $Q(\mathrm{M}(T[n]), T(n))$ is defined and is a set of m elements
- If $Q(\mathrm{M}(T[n]), T(n)) = (x_1, x_2, \ldots, x_m)$, then $\mathrm{M}(T[n+1]) = F(\mathrm{M}(T[n]), T(n), y_1, y_2, \ldots, y_m)$, where $y_i = 1$ iff $x_i \in \mathrm{ctnt}(T[n])$.

Again, it can be shown that allowing more feedback gives greater learning power, and thus one can get a hierarchy based on the amount of feedback allowed.

Complexity of Final Hypothesis

Another possibility on complexity of learning is to consider the complexity or size of the final grammar output by the learner. Freivalds (1975) considered the case when the final program/grammar output by the learner is minimal: that is, there is no smaller index that accepts/generates the same language. He showed that this severely restricts the learning capacity of learners. Not only that, the learning capacity depends on the acceptable programming system chosen, unlike the case for most other criteria of learning such as **TxtEx** or **TxtBc**, which are independent of the acceptable programming system chosen. In particular, there are acceptable programming systems in which only classes containing finitely many infinite languages can be learnt using minimal final grammars (see Freivalds 1975; Jain and Sharma 1993). Chen (1982) considered a modification of such a paradigm where one considers convergence to nearly minimal grammars rather than minimal. That is, instead of requiring that the final grammars are minimal, one requires that they are within a recursive function h of minimal. Here h may depend on the class being learnt. Chen showed that this allows one to have the criteria of minimal learnability to be independent of the acceptable programming system chosen. However, one can show that some simple classes are not minimally learnable. An example of such a class is the class $\mathcal{L}_{\mathcal{C}}$ which is derived from $\mathcal{C} = \{f : \forall^\infty x[f(x) = 0]\}$, the class of all functions which are almost everywhere 0.

Intrinsic Complexity

Another way to consider complexity of learning is to consider relative complexity in a way similar to how one considers Turing reductions in computability theory. Such a notion is called intrinsic complexity of the class. This was first considered by Freivalds et al. (1995) for function learning. Jain and Sharma (1996) considered it for language learning, and the following discussion is from there.

An *enumeration operator* (see Rogers 1967), Θ, is an algorithmic mapping from SEQ into SEQ such that the following two conditions are satisfied:

- for all $\sigma, \tau \in$ SEQ, if $\sigma \subseteq \tau$, then $\Theta(\sigma) \subseteq \Theta(\tau)$;
- for all texts T, $\lim_{n\to\infty} |\Theta(T[n])| = \infty$.

By extension, we think of Θ as also mapping texts to texts such that $\Theta(T) = \bigcup_n \Theta(T[n])$. Furthermore, we define $\Theta(L) = \{\mathrm{ctnt}(\Theta(T)) : T$ is a text for $L\}$. Intuitively, $\Theta(L)$ denotes the set of languages to whose texts Θ maps texts of L. The reader should note the overloading of this notation because the type of the argument to Θ could be a sequence, a text, or a language.

One says that a sequence of grammars $g_0, g_1, \ldots$ is an acceptable **TxtEx** sequence for L if the sequence of grammars converges to a grammar for L.

$\mathcal{L}_1 \leq_{\mathrm{weak}} \mathcal{L}_2$ if there are two operators Θ and Ψ such that for all $L \in \mathcal{L}_1$, for all texts T for L, $\Theta(T)$ is a text for some $L' \in \mathcal{L}_2$ such that if $g_0, g_1, \ldots$ is an acceptable **TxtEx** sequence for L', then $\Psi(g_0, g_1, \ldots)$ is an acceptable **TxtEx** sequence for L.

Note that different texts for the same language L may be mapped by Θ to texts for different languages in $\mathcal{L}_2$ above. If we require that different texts for L are mapped to texts for the same language L' in $\mathcal{L}_2$, then we get a stronger notion of reduction called strong reduction: $\mathcal{L}_1 \leq_{\mathrm{strong}} \mathcal{L}_2$ if $\mathcal{L}_1 \leq_{\mathrm{weak}} \mathcal{L}_2$ and for all $L \in \mathcal{L}_1$, $\Theta(L)$ contains only one language, where Θ is as in the definition for $\leq_{\mathrm{weak}}$ reduction.

It can be shown that *FIN* is a complete class for **TxtEx** identification with respect to $\leq_{\mathrm{weak}}$ reduction (see Jain and Sharma 1996). Interestingly, it was shown that the class of pattern languages (Angluin 1980), the class $SD = \{L : W_{\min(L)} = L\}$, and the class $COINIT = \{\{x : x \geq n\} : n \in \mathbb{N}\}$ are all equivalent under $\leq_{\mathrm{strong}}$. Let $code$ be a bijective mapping from nonnegative rational numbers to natural numbers. Then, one can show that the class RINIT $= \{\{code(x) : 0 \leq x \leq r, x$ is a rational number$\} : 0 \leq r \leq 1, r$ is a rational number $\}$ is $\leq_{\mathrm{strong}}$ complete for **TxtEx** (see Jain et al. 2001).

Interestingly every finite directed acyclic graph can be embedded into the $\leq_{\mathrm{strong}}$ degree structure (Jain and Sharma 1997a). On the other hand, the degree structure is non-dense in the sense that there exist classes $\mathcal{L}_1$ and $\mathcal{L}_2$ such that $\mathcal{L}_1 <_{\mathrm{strong}} \mathcal{L}_2$, but for any class $\mathcal{L}$ such that $\mathcal{L}_1 \leq_{\mathrm{strong}} \mathcal{L} \leq_{\mathrm{strong}} \mathcal{L}_2$, either $\mathcal{L}_1 \equiv_{\mathrm{strong}} \mathcal{L}$ or $\mathcal{L} \equiv_{\mathrm{strong}} \mathcal{L}_2$. A similar result holds for $\leq_{\mathrm{weak}}$ reducibility (see Jain and Sharma 1997a).

Interesting connections between learning of elementary formal systems (Shinohara 1994), intrinsic complexity, and ordinal mind changes (Freivalds and Smith 1993) were shown in Jain and Sharma (1997b).

Learning Using Oracles

Another method to measure complexity of learning is to see how powerful an oracle (given to the learning machine) has to be to make a class learnable. It can be shown that an oracle A permits to explanatorily learn the class of all recursive functions iff A is high (Adleman and Blum 1991). Furthermore, an oracle is trivial, that is, does not give additional learning power for explanatory learning of function classes iff the oracle has 1-generic Turing degree and is Turing reducible to the halting problem (Slaman and Solovay 1991). The picture is a bit different in the general case of learning languages. For every oracle A, there is an oracle B and a class, which is **TxtEx** learnable using the oracle B but not using the oracle A (Jain and Sharma 1993). Note that there are also classes of languages like Gold's class of all finite languages plus the set of natural numbers which are not **TxtEx** learnable using any oracle. Furthermore, for oracles above the halting problem, **TxtEx** learning and **TxtBc** learning using these oracles coincide.

Definition

Measures of the complexity of learning have been developed for a number of purposes including

▶ Inductive Inference, ▶ PAC Learning, and ▶ Query-Based Learning. The complexity is usually measured by the largest possible usage of resources that can occur during the learning of a member of a class. Depending on the context, one measures the complexity of learning either by a single number/ordinal for the whole class or by a function in a parameter n describing the complexity of the target to be learned. The actual measure can be the number of mind changes, the number of queries submitted to a teacher, the number of wrong conjectures issued, the number of errors made, or the number of examples processed until learning succeeds. In addition to this, one can equip the learner with an oracle and determine the complexity of the oracle needed to perform the learning process. Alternatively, in complexity theory, instead of asking for an NP-complete oracle to learn a certain class, the result can also be turned into the form "this class is unlearnable unless RP = NP" or something similar. (Here RP is the class of decision problems solvable by a randomized polynomial time algorithm, and NP is the class of decision problems solvable by a nondeterministic polynomial time algorithm, and both algorithms never give "yes" answer for an instance of the problem with "no" answer.)

Detail

In ▶ PAC Learning, one usually asks how many examples are needed to learn the concept, where the number of examples needed mainly depends on the Vapnik-Chervonenkis dimension of the class to be learned, the error permitted, and the confidence required. Furthermore, for certain classes of finite Vapnik-Chervonenkis dimension, learnability can still fail when the learner is required to be computable in polynomial time; hence, there is, besides the dimension, also a restriction stemming from the computational complexity of problems such as the complexity of finding concepts consistent with all data observed so far.

For ▶ Query-Based Learning, one common criterion to be looked at is the number of queries made during the learning process. If a class contains 2^n different $\{0,1\}$-valued functions f and one is required to learn the class using membership queries, that is, by asking queries of the form whether $f(x) = 0$ or $f(x) = 1$, then there is a function f on which the learner needs at least n queries until it knows which of the given functions f is; for some classes consisting of 2^n functions, the number of queries needed can be much worse – as much as $2^n - 1$. A well-known result of Angluin is that one can learn the class of all regular languages with polynomially many equivalence and membership queries measured with respect to the number of states of the smallest deterministic finite automaton accepting the language to be learned. Further research has been done dealing with which query algorithms can be implemented by a polynomial time learner and which need for polynomial time learning, in addition to the teacher informing on the target concept, also some oracle supplying information that cannot be computed in polynomial time. See the entry ▶ Query-Based Learning for an overview of these results.

For ▶ Inductive Inference, most complexity measures are measures applying to the overall class and not just a parameterized version. When learning the class of all sets with up to n elements, the learner might first issue the conjecture $\emptyset$ and then revise (up to n times) its hypothesis when a new datum is observed; such a measure is called the mind change complexity of learning. Mind change complexity has been generalized to measure the complexity by recursive ordinals or the notation of these. Furthermore, one can measure the long-term memory of past data observed either by a certain number of examples remembered or by the number of bits stored on a tape describing the long-term memory of the learner. Besides these quantitative notions, a further frequently studied question is the following: Which oracles support the learning process in a way that some classes become learnable using the oracle, but are unlearnable without using any oracle? An example of such a type of result is that the class of all recursive functions can be learned if and only if the learner has access to a high oracle, that is, an oracle that permits to compute a function which dominates (i.e., grows faster than) every recursive function. See the entry ▶ Complexity of Inductive Inference for more information.

Definition

Concept drift occurs when the values of hidden variables change over time. That is, there is some unknown context for ▶ concept learning and when that context changes, the learned concept may no longer be valid and must be updated or relearned.

Motivation and Background

Prediction in real-world domains is complicated by potentially unstable phenomena that are not known in advance to the learning system. For example, financial market behavior can change dramatically with changes in contract prices, interest rates, inflation rates, budget announcements, and political and world events. Thus, concept definitions that may have been learned in one context become invalid in a new context. This *concept drift* can be due to changes in context and is often directly reflected by one or more attributes. When changes in context are not reflected by any known attributes they can be said to be *hidden*. Hidden changes in context cause problems for any predictive approach that assumes concept stability.

Structure of the Learning System

Machine learning approaches can be broadly categorized as either ▶ batch Learning or ▶ incremental learning. Batch systems learn offline by examining a large collection of instances *en masse* and form a single concept. Incremental systems evolve and change a concept definition as new observations are processed (Schlimmer and Granger 1986a; Aha et al. 1991; Kolter and Maloof 2003).

The most common approach to learning in domains with hidden changes in context has been to use an incremental learning approach in which the importance of older items is progressively decayed. A popular implementation of this, originally presented in Kubat (1989), is to use a window of recent instances from which concept updates are derived. Other examples of this approach include Widmer and Kubat (1996), Kubat and Widmer (1995), Kilander and Jansson (1993), and Salganicoff (1993). Swift adaptation to changes in context can be achieved by dynamically varying the window size in response to changes in accuracy and concept complexity (Widmer and Kubat 1996).

There are many domains in which the context can be expected not only to change but for earlier contexts to hold again at some time in the future. That is, contexts can repeat in domains such as financial prediction, dynamic control, and underrepresented data mining tasks. In these domains, prediction accuracy can be improved by storing knowledge about past contexts for reuse. FLORA3 (Widmer and Kubat 1993) addresses domains in which contexts recur by storing and retrieving concepts that appear stable as the learner traverses the series of input data.

In many situations, there is no constraint to learn incrementally. For example, many organizations maintain large data bases of historical data that are suitable for data mining. These data bases may hold instances that belong to a number of contexts but do not have this context explicitly recorded. Many of these data bases may incorporate time as an essential attribute, for example, financial records and stock market price data. Interest in mining datasets of this nature suggests the need for systems that can learn global concepts and are sensitive to changing and hidden contexts. Systems such as FLORA3 also imply that an off-line recognition of stable concepts can be useful for ▶ on-line prediction.

An alternative to on-line learning for domains with hidden changes in context is to examine the data *en masse* in an attempt to directly identify concepts associated with stable, hidden contexts. Some potential benefits of such an approach are:

1. Context specific (known as local) concepts could be used as part of a multiple model online predictive system.
2. Local concepts could be verified by experts, or used to improve domain understanding.
3. A model of the hidden context could be induced using context characteristics such as context duration, order, and stability. The model could also use existing attributes and domain feedback if available.
4. Stable contexts identified could be used as target characteristics for selecting additional attributes from the outside world as part of an iterative data mining process.

Splice (Harries et al. 1998) is a ▶ meta-learning system that implements a context sensitive batch learning approach. Splice is designed to identify intervals with stable hidden context, and to induce and refine local concepts associated with hidden contexts.

Identifying Context Change

In many domains with hidden changes in context, time can be used to differentiate hidden contexts. Most machine learning approaches to these domains do not explicitly represent time as they assume that current context can be captured by focusing on recent examples. The implication is that hidden context will be reflected in contiguous intervals of time. For example, an attempt to build a system to predict changes in the stock market could produce the following ▶ decision tree:

$$\begin{array}{l}
\text{Year} \quad > 2002 \\
\qquad \text{Year} < 2005 \\
\qquad\qquad \text{Attribute A} \;=\; \text{true}: \;\text{Market Rising} \\
\qquad\qquad \text{Attribute A} \;=\; \text{false}: \;\text{Market Falling} \\
\qquad \text{Year} \geq 2005 \\
\qquad\qquad \text{Attribute B} \;=\; \text{true}: \;\text{Market Rising} \\
\qquad\qquad \text{Attribute B} \;=\; \text{false}: \;\text{Market Falling}
\end{array}$$

This tree contains embedded knowledge about two intervals of time: in one of which, 2002–2004, attribute A is predictive; in the other, 2005 onward, attribute B is predictive. As time (in this case, year) is a monotonically increasing attribute, future classification using this decision tree will only use attribute B. If this domain can be expected to have recurring hidden context, information about the prior interval of time could be valuable.

The decision tree in the example above contains information about changes in context. We define context as:

> Context is any attribute whose values are largely independent but tend to be stable over contiguous intervals of another attribute known as the environmental attribute.

The ability of decision trees to capture context is associated with the fact that decision tree algorithms use a form of context-sensitive feature selection (CSFS). A number of machine learning algorithms can be regarded as using CSFS including decision tree algorithms (Quinlan 1993), rule induction algorithms (Clark and Niblett 1989), and ▶ ILP systems (Quinlan 1990). All of these systems produce concepts containing local information about context.

When contiguous intervals of time reflect a hidden attribute or context, we call time the environmental attribute. The environmental attribute is not restricted to time alone as it could be any ordinal attribute over which instances of a hidden context are liable to be contiguous. There is also no restriction, in principle, to one dimension. Some alternatives to time as environmental attributes are dimensions of space, and space–time combinations.

Given an environmental attribute, we can utilize a CSFS machine learning algorithm to gain information on likely hidden changes in context. The accuracy of the change points found will be dependent upon at least hidden context duration, the number of different contexts, the complexity of each local concept, and noise.

The CSFS identified context change points can be expected to contain errors of the following types:

1. ▸ Noise or serial correlation errors. These would take the form of additional incorrect change points.
2. Errors due to the repetition of tests on time in different parts of the concept. These would take the form of a group of values clustered around the actual point where the context changed.
3. Errors of omission, change points that are missed altogether.

The initial set of identified context changes can be refined by contextual ▸ clustering.

This process combines similar intervals of the dataset, where the similarity of two intervals is based upon the degree to which a partial model is accurate on both intervals.

Recent Advances

With the increasing amount of data being generated by organizations, recent work on concept drift has focused on mining from high volume ▸ data streams (Hulten et al. 2001; Wang et al. 2003; Kolter and Maloof 2003; Mierswa et al. 2006; Chu and Zaniolo 2004; Gaber et al. 2005). Methods such as Hulten et al.'s, combine decision tree learning with incremental methods for efficient updates, thus avoiding relearning large decision trees. Koltzer and Maloof also use incremental methods combined in an ▸ ensemble.

Concept Learning

Claude Sammut
The University of New South Wales, Sydney,
NSW, Australia

Synonyms

Categorization; Classification learning

Definition

The term *concept learning* is originated in psychology, where it refers to the human ability to learn categories for object and to recognize new instances of those categories. In machine learning, concept is more formally defined as "inferring a boolean-valued function from training examples of its inputs and outputs" (Mitchell 1997).

Background

Bruner et al. (1956) published their book *A Study of Thinking*, which became a landmark in psychology and would later have a major impact on machine learning. The experiments reported by Bruner, Goodnow, and Austin were directed toward understanding a human's ability to categorize and how categories are learned.

> We begin with what seems a paradox. The world of experience of any normal man is composed of a tremendous array of discriminably different objects, events, people, impressions... But were we to utilize fully our capacity for registering the differences in things and to respond to each event encountered as unique, we would soon be overwhelmed by the complexity of our

> environment…The resolution of this seeming paradox…is achieved by man's capacity to categorize. To categorize is to render discriminably different things equivalent, to group objects and events and people around us into classes…The process of categorizing involves…an act of invention…If we have learned the class "house" as a concept, new exemplars can be readily recognised. The category becomes a tool for further use. The learning and utilization of categories represents one of the most elementary and general forms of cognition by which man adjusts to his environment.

The first question that they had to deal with was that of representation: what is a concept? They assumed that objects and events could be described by a set of attributes and were concerned with how inferences could be drawn from attributes to class membership. Categories were considered to be of three types: conjunctive, disjunctive, and relational.

> …when one learns to categorize a subset of events in a certain way, one is doing more than simply learning to recognise instances encountered. One is also learning a rule that may be applied to new instances. The concept or category is basically, this "rule of grouping" and it is such rules that one constructs in forming and attaining concepts.

The notion of a rule as an abstract representation of a concept influenced research in machine learning. For example, ▸ decision tree learning was used as a means of creating a cognitive model of concept learning (Hunt et al. 1966). This model later inspired Quinlan's development of ID3 (Quinlan 1983).

The learning experience may be in the form of examples from a trainer or the results of trial and error. In either case, the program must be able to represent its observations of the world, and it must also be able to represent hypotheses about the patterns it may find in those observations. Thus, we will often refer to the ▸ observation language and the ▸ hypothesis language. The observation language describes the inputs and outputs of the program and the hypothesis language describes the internal state of the learning program, which corresponds to its theory of the concepts or patterns that exist in the data.

The input to a learning program consists of descriptions of objects from the universe and, in the case of ▸ supervised learning, an output value associated with the example. The universe can be an abstract one, such as the set of all natural numbers, or the universe may be a subset of the real world. No matter which method of representation we choose, descriptions of objects in the real world must ultimately rely on measurements of some properties of those objects. These may be physical properties such as size, weight, and color or they may be defined for objects, for example, the length of time a person has been employed for the purpose of approving a loan. The accuracy and reliability of a learned concept depends on the accuracy and reliability of the measurements.

A program is limited in the concepts that it can learn by the representational capabilities of both observation and hypothesis languages. For example, if an attribute/value list is used to represent examples for an induction program, the measurement of certain attributes and not others clearly places bounds on the kinds of patterns that the learner can find. The learner is said to be *biased* by its observation language (see ▸ Language Bias). The hypothesis language also places constraints on what may and may not be learned. For example, in the language of attributes and values, relationships between objects are difficult to represent. Whereas, a more expressive language, such as first-order logic, can easily be used to describe relationships.

Unfortunately, representational power comes at a price. Learning can be viewed as a search through the space of all sentences in a language for a sentence that best describes the data. The richer the language, the larger is the search space. When the search space is small, it is possible to use "brute force" search methods. If the search space is very large, additional knowledge is required to reduce the search.

Rules, Relations, and Background Knowledge

In the early 1960s, there was no discipline called "machine learning." Instead, learning was considered to be part of "pattern recognition," which had not yet split from AI. One of the main problems addressed at that time was how to represent patterns so that they could be recognized easily. Symbolic description languages were developed to be expressive and learnable.

Banerji (1960, 1962) first devised a language, which he called a "description list," which utilized an object's attributes to perform pattern recognition. Pennypacker, a masters student of Banerji at the Case Institute of Technology, implemented the recognition procedure and also used Bruner, Goodnow, and Austin's *Conservative Focussing Strategy* to learn conjunctive concepts (Pennypacker 1963). Bruner, Goodnow, and Austin describe the strategy as follows:

> ...this strategy may be described as finding a positive instance to serve as a focus, then making a sequence of choices each of which alters but one attribute value [of the focus] and testing to see whether the change yields a positive or negative instance. Those attributes of the focus which, when changed, still yield positive instance are *not* part of the concept. Those attributes of the focus that yield negative instances when changed *are* features of the concept.

The strategy is only capable of learning *conjunctive concepts*, that is, the concept description can only consist of a simple conjunction of tests on attribute values. Recognizing the limitations of simple attribute/value representations, Banerji (1964) introduced the use of predicate logic as a description language. Thus, Banerji was one of the earliest advocates of what would, many years later, become *Inductive Logic Programming*.

In the 1970s, a series of algorithms emerged that developed concept learning further. Winston's ARCH program (Winston, Learning structural descriptions from examples. PhD Thesis, MIT Artificial Intelligence Laboratory, 1970, unpublished) was influential as one of the first widely known concept learning programs. Michalski (1973, 1983) devised the Aq family of learning algorithms that set some of the early benchmarks for learning programs. Early relational learning programs were developed by Hayes-Roth (1973), Hayes-Roth and McDermott (1977), and Vere (1975, 1977).

Banerji emphasized the importance of a description language that could "grow." That is, its descriptive power should increase as new concepts are learned. These concepts become background knowledge for future learning. A simple example from Banerji (1980) illustrates the use of background knowledge. There is a language for describing instances of a concept and another for describing concepts. Suppose we wish to represent the binary number, 10, by a left-recursive binary tree of digits "0" and "1":

$$[\text{head}: \ [\text{head}: \ 1; \ \text{tail}: \ \text{nil}]; \text{tail}: 0]$$

"head" and "tail" are the names of attributes. Their values follow the colon. The concepts of binary digit and binary number are defined as

$$\begin{aligned} x \in digit &\equiv x = 0 \vee x = 1 \\ x \in num &\equiv (tail(x) \in digit \\ &\quad \wedge head(x) = nil) \\ &\quad \vee (tail(x) \in digit \\ &\quad \wedge head(x) \in num) \end{aligned}$$

Thus, an object belongs to a particular class or concept if it satisfies the logical expression in the body of the description. Note that the concept above is *disjunctive*. Predicates in the expression may test the membership of an object in a previously learned concept and can express *relations* between objects. Cohen and Sammut (1982) devised a learning system based on Banerji's ideas of a growing concept description language and this was further extended by Sammut and Banerji (1986).

Concept Learning and Noise

One of the most severe drawbacks of early concept learning systems was that they assumed that data sets were not noisy. That is, all attribute values and class labels in the training data are assumed to be correct. This is unrealistic in most real applications. Thus, concept learning systems began incorporating statistical measures to minimize the effects of noise and to estimate error rates (Breiman et al. 1984; Cohen 1995; Quinlan 1986, 1993).

Learning to classify objects from training examples has gone on to become one of the central themes of machine learning research. As the robustness of classification systems has increased, they have found many applications, particularly in data mining but in a broad range of other areas.

Confirmation Theory

The branch of philosophy concerned with how (and indeed whether) evidence can confirm a hypothesis, even though typically it does not entail it. A distinction is sometimes drawn between *total confirmation*: how well confirmed a hypothesis is, given all available evidence and *weight-of-evidence*: the amount of extra confirmation added to the total confirmation of a hypothesis by a particular piece of evidence. Confirmation is often measured by the probability of a hypothesis conditional on evidence.

Confusion Matrix

Kai Ming Ting
Federation University, Mount Helen, VIC, Australia

Definition

A confusion matrix summarizes the classification performance of a ▶ classifier with respect to some ▶ test data. It is a two-dimensional matrix, indexed in one dimension by the true class of an object and in the other by the class that the classifier assigns. Table 1 presents an example of confusion matrix for a three-class classification task, with the classes A, B, and C.

The first row of the matrix indicates that 13 objects belong to the class A and that 10 are correctly classified as belonging to A, two misclassified as belonging to B, and one as belonging to C.

Confusion Matrix, Table 1 An example of a three-class confusion matrix

Actual class		Assigned class		
		A	*B*	*C*
	A	10	2	1
	B	0	6	1
	C	0	3	8

Confusion Matrix, Table 2 The outcomes of classification into positive and negative classes

Actual class		Assigned class	
		Positive	Negative
	Positive	TP	FN
	Negative	FP	TN

A special case of the confusion matrix is often utilized with two classes, one designated the *positive* class and the other the *negative* class. In this context, the four cells of the matrix are designated as ▶ *true positives* (TP), ▶ *false positives* (FP), ▶ *true negatives* (TN), and ▶ *false negatives* (FN), as indicated in Table 2.

A number of measures of classification performance are defined in terms of these four classification outcomes.

▶ *Specificity* = ▶ *True negative rate* = TN/(TN + FP)

▶ *Sensitivity* = ▶ *True positive rate* = ▶ *Recall* = TP/ (TP + FN)

▶ *Positive predictive value* = ▶ *Precision* = TP/(TP + FP)

▶ *Negative predictive value* = TN/(TN + FN)

Conjunctive Normal Form

Bernhard Pfahringer
University of Waikato, Hamilton, New Zealand

Conjunctive normal form (CNF) is an important normal form for propositional logic. A logic formula is in conjunctive normal form if it is a single conjunction of disjunctions of (possibly negated) literals. No more nesting and no other negations are allowed. Examples are:

$$a$$
$$\neg b$$
$$a \wedge b$$
$$(a \vee \neg b) \wedge (c \vee d)$$
$$\neg a \wedge (b \vee \neg c \vee d) \wedge (a \vee \neg d)$$

Any arbitrary formula in propositional logic can be transformed into conjunctive normal form by application of the laws of distribution, De Morgan's laws, and by removing double negations. It is important to note that this process can lead to exponentially larger formulas which implies that the process in the worst case runs in exponential time. An example for this behavior is the following formula given in ▸ disjunctive normal form (DNF), which is linear in the number of propositional variables in this form. When transformed into conjunctive normal form (CNF), its size is exponentially larger.

DNF: $(a_0 \wedge a_1) \vee (a_2 \wedge a_3) \vee \ldots \vee (a_{2n} \wedge a_{2n+1})$
CNF: $(a_0 \vee a_2 \vee \ldots \vee a_{2n}) \wedge (a_1 \vee a_2 \vee \ldots \vee a_{2n}) \wedge \ldots \wedge (a_1 \vee a_3 \vee \ldots \vee a_{2n+1})$

Connections Between Inductive Inference and Machine Learning

John Case[1] and Sanjay Jain[2]
[1]University of Delaware, Newark, DE, USA
[2]School of Computing, National University of Singapore, Singapore, Singapore

Abstract

Inductive inference is a branch of computational learning theory which deals with learning in the limit. Though this topic deals with mostly theoretical work, it has provided some results which can be of use to practical machine learning. Some of these works include the work multitask or context-sensitive learning, learnability of elementary formal systems, behavioral cloning, learning to coordinate, geometrical clustering, and so on. The results in these areas also often give insights into limitations of science.

Definition

Inductive inference is a theoretical framework to model learning in the limit. Here we will discuss some results in inductive inference, which have relevance to machine learning community.

The mathematical/theoretical area called ▸ inductive inference is also known as *computability theoretic learning* and *learning in the limit* (Jain et al. 1999; Odifreddi 1999) typically *but, as will be seen below, not always* involves a situation depicted in (1) just below.

$$\text{Data}\quad d_0, d_1, d_2, \ldots \xrightarrow{\text{In}} M \xrightarrow{\text{Out}} \text{Programs}\quad e_0, e_1, e_2, \ldots . \tag{1}$$

Let $\mathbb{N}$ = the set of nonnegative integers. Strings, including program strings, computer reals, and other data structures, inside computers, are finite bit strings and, hence, can be coded into $\mathbb{N}$. Therefore, mathematically at least, it is without loss of mathematical generality that we sometimes use the data type $\mathbb{N}$ where standard practice would use a different type.

In (1), $d_0, d_1, d_2, \ldots$ can be, e.g., the successive values of a function $f : \mathbb{N} \rightarrow \mathbb{N}$ or the elements of a (formal) language $L \subseteq \mathbb{N}$ in some order, M is a machine, the e_i's are from some hypothesis space of programs, and, for M's *successful* learning, later e_i's exactly or approximately compute the f or L.

Such learning is *offline*: in successful cases, one comes away with programs for past and future data. For the related problem of *online extrapolation* of next values for a function f, *suitable* e_i's may *be* the values of $f(i)$'s based on having seen *strictly* prior values of f.

Detail

We will discuss the off-line case until we say otherwise. It is typical in applied machine learning to present to a learner whatever data one has and to obtain *one* corresponding program hopefully for predicting these data and future data. In inductive inference the case where only one program is output is called *one-shot* learning. More typically, in inductive inference, one allows for *mind changes*, i.e., for a succession of output programs, as one receives successively more input data, with the later programs hopefully eventually being useful for predictions. Typically, one does not get success on one's first conjecture/output program, but, rather, one may achieve success eventually or, as it is said, *in the limit* after some sequence of trial and error. It is helpful at this juncture to present a problem for which this latter approach makes more sense than the one-shot approach.

We will consider some different criteria of successful learning of f or L by M. For example, **Ex**-style criteria will require that all but finitely many of the e_i's are *syntactically* the same *and* do a reasonable job of computing the f or L. **Bc**-style criteria are more relaxed, more powerful, but less useful (Bārzdiņš 1974; Case and Lynes 1982; Case and Smith 1983): they do not require almost all e_i's be the same syntactically.

Here is a well-known regression technique from, e.g., Hildebrand (1956), for exactly "curve-fitting" polynomials. It is the method involving calculating *forward differences*. We express it as a learning machine M_0 and illustrate with its being fed an *example* data sequence generated by a cubic polynomial

$$x^3 - 2x^2 + 2x + 3. \qquad (2)$$

Connections Between Inductive Inference and Machine Learning, Table 1 Example sequence and its iterated forward differences

Sequence:	3		4		7		18		43
1st Diffs:		1		3		11		25	
2nd Diffs:			2		8		14		
3rd Diffs:				6		6			

See Hildebrand (1956), for how to recover the polynomials themselves.

M_0, fed a finite data sequence of natural numbers, first looks for iterated forward differences to become (apparently) constant and then outputs a rule/program, which uses the (apparent) constant to extrapolate the data sequence for any desired prediction. For example, were M_0 given the data sequence in the top row of Table 1, it would calculate 6 to be the apparent constant after *three* differencings, so M_0 then outputs the following informal rule/program.

> ► To generate the level 0 sequence, at level 0, start with 3; at level 1, start with 1; at level 2, start with 2; add the apparent constant 6 from level 3 to get successive level 2 data items; add successive level 2 items to get successive level 1 data items; *finally*, add successive level 1 items to get as many successive level 0 data items as needed for prediction.

This program, eventually output by M_0 when its input the whole top row of Table 1, correctly predicts the elements of the cubic polynomial, on successive values in $\mathbb{N}$ – the whole sequence $3, 4, 7, 18, 43, 88, 159, \ldots$. Along the way, though, just after the first data point, M_0 thinks the apparent constant is 0; just after the second that it is 1; just after the third that it is 2; and only after more of the data points does it converge for this cubic polynomial to the apparent (and, on *this* example, actual) constant 6. In general, M_0, on a polynomial of degree m, *changes its mind* up to m times until converging to its final program (of course on $f(x) = 2^x$, M_0 never converges, and each level of forward differences is just the sequence f again.).

Hence, M_0 above **Ex**-learns, e.g., the integer polynomials $f : N \rightarrow N$, but it does not in general one-shot learn these polynomials – since the data alone do not disclose the degree of a generating polynomial.

In this entry we survey some results from inductive inference but with an eye to topics having something to say regarding or to applied machine learning. In some cases, the theoretical results lend mathematical support to preexisting empirical observations about the efficacy of known machine learning techniques. In other cases, the theoretical results provide some, typically abstract, suggestions for the machine learning practitioner. In some of these cases, some of the suggestions apparently pay off in others, intriguingly, we do not know yet.

Multitask or Context-Sensitive Learning

In empirical, applied machine learning, *multitask* or *context-sensitive learning* involves trying to learn Y by first (de Garis 1990a,b; Fahlman 1991; Thrun 1996; Thrun and Sullivan 1996; Tsung and Cottrell 1989; Waibel 1989a,b) *or* simultaneously (Caruana 1993, 1996; Matwin and Kubat 1996; Bartlmae et al. 1997; Dietterich et al. 1995; Mitchell et al. 1994; Pratt et al. 1991; Sejnowski and Rosenberg 1986) trying to learn also X – even in cases where there may be no inherent interest in learning X. There is, in many cases, an apparent *empirical* advantage in doing this for some X, Y. It can happen that Y is not apparently or easily learnable by itself but is learnable if one learns X first or simultaneously in some case X itself can be a sequence of tasks $X_1, \ldots, X_n$. Here the X_is may need to be learned sequentially or simultaneously to learn Y. For example, to teach a robot to drive a car, it is useful to train it also to predict the center of the road markings (see, e.g., Baluja and Pomerleau 1995; Caruana 1996). For another example, an experimental system to predict the value of German *Daimler* stock performed better when it was modified to track simultaneously the German stock index DAX (Bartlmae et al. 1997). The value of the Daimler stock here was the primary or target concept and the value of the DAX – a related concept – provided useful auxiliary context.

Angluin et al. (1989) shows *mathematically* that, in effect, there are (mathematical) learning scenarios for which it was *provable* that Y could not be learned without learning X *first* , and, in other scenarios (Angluin et al. 1989; Kinber et al. 1995), Y could not be learned without *simultaneously* learning X. These *mathematical* results provide a kind of evidence that the *empirical* observations as to the *apparent* usefulness of multitask or context-sensitive learning *may* not be illusionary, luck, or a mere accident of happening to use some data sets but not others.

For illustration, here is a particularly simple theoretical example needing to be learned *simultaneously* and similar to examples in Angluin et al. (1989). Let $\mathcal{R}$ be the set of all computable functions mapping $\mathbb{N}$ to $\mathbb{N}$. We use numerical names in $\mathbb{N}$ for programs. Let

$$\mathcal{S} = \{(f, g) \in \mathcal{R} \times \mathcal{R} \mid f(0) \text{ is a program for } g \wedge g(0) \text{ is a program for } f\}. \tag{3}$$

We say (p, q) is a program for $(f, g) \in \mathcal{R} \times \mathcal{R}$ iff p is a program for f and q is a program for g.

Consider a machine M which, if, as in (1), M is fed $d_0, d_1, \ldots$, but *where* each d_i is $(f(i), g(i))$, then M outputs each $e_i = (g(0), f(0))$. Clearly, M one-shot learns $\mathcal{S}$. It can be easily shown that the component f's and g's *for* $(f, g) \in \mathcal{S}$ are not *separately* even **Bc**-learnable. It is important to note that, perhaps quite unlike real-world problems, the definition of this example $\mathcal{S}$ employs a simple self-referential coding trick: useful programs are coded into values of the functions at argument zero. A number of inductive inference results have been proved by means of (sometimes more complicated) self-referential coding tricks (see, e.g., Case 1994). Bārzdiņš indirectly (see Zeugmann 1986) provided a kind of informal robustness idea in his attempt to be rid of such coding tricks in inductive inference. More formally, Fulk (1990) considered a learnability result involving a witnessing class $\mathcal{C}$ of (tuples of) functions to be *robust* iff each computable scrambling of $\mathcal{C}$ also witnesses the learnability result (the allowed computable scramblers are the *general recursive operators* of (Rogers 1967), but we omit the formal details herein.) Example: A simple shift scrambler converting each f to f', where $f'(x) = f(x + 1)$, would eliminate the coding tricks just above – since the values of f at argument zero would be lost in this scrambling. Some inductive inference results hold robustly and some not (see, e.g., Fulk 1990; Jain et al. 1999, 2001; Jain 1999;

Case et al. 2000). Happily, the $\mathcal{S} \subseteq \mathcal{R} \times \mathcal{R}$ above (i.e., learnable, but its components not) can be replaced by a more complicated class $\mathcal{S}'$ that *robustly* witnesses the same result. This is better *theoretical* evidence that the empirically noticed efficacy of multitask or context-sensitive learning is not just an accident. It is residually important to note that (Jain et al. 2001) shows, though, that the computable scramblers cannot get rid of more sophisticated coding tricks they called topological. $\mathcal{S}'$ mentioned just above turns out to *employ* this latter kind of coding trick. It is hypothesized in Case et al. (2000) that nature likely employs some sophisticated coding tricks itself. For a separate informal argument about coding tricks of nature, see Case (1999). Ott and Stephan (2002) introduce a finite invariance constraint on top of robustness. This so-called hyperrobustness does destroy all coding tricks, and the result about the *theoretical* efficacy of multitask or context-sensitive learning is *not* hyperrobust. However, hyperrobustness, perhaps, leaves unrealistically sparse structure.

Final note: Machine learning is an engineering endeavor. However, philosophers of science as well as practitioners in classical scientific disciplines should likely be considering the relevance of multitask or context-sensitive inductive inference to their endeavors.

Special Cases of Inductive Logic Programming

In this section we discuss some *learning in the limit* results for *elementary formal systems (EFSs)* (Smullyan 1961). Essentially, EFSs are programs in a string rewriting system. It is well known (Arikawa et al. 1992) that EFSs are essentially (pure) logic programs over strings. Hence, the results have possible relevance for ▶ inductive logic programming (ILP) (Muggleton and De Raedt 1994; Lavrač and Džeroski 1994; Bratko and Muggleton 1995; Mitchell 1997).

First we will discuss some important special cases based on Angulin's *pattern languages* (Angluin 1980).

A *pattern language* is (by definition) one generated by all the positive length substitution instances in a *pattern*, such as,

$$abXYcbbZXa \tag{4}$$

— where the variables (for substitutions) are depicted in upper case and the constants/terminals in lower case and are from, say, the alphabet {a,b,c}. Just below is an EFS or logic program based on this example pattern.

$$abXYcbbZXa \leftarrow . \tag{5}$$

It must be understood, though, that in (5) and in the next example EFS below, only positive length strings are allowed to be substituted for the variables.

Angluin (1980) showed the **Ex**-learnability of the class of pattern languages from positive data. For these results, in the paradigm of (1) above $d_0, d_1, d_2, \ldots$ is a listing or presentation of some formal language L over a finite nonempty alphabet, and the e_i's are programs that generate languages. In particular, for Angluin's M, for L a pattern language, the e_i's are patterns, and, for each presentation of L, all but finitely many of the corresponding e_i's are the same *correct* pattern for L.

Much work has been done on the learnability of pattern languages, e.g., Salomaa (1994a,b), Case et al. (2001), and on bounded finite unions thereof, e.g., Shinohara (1983), Wright (1989), Kilpeläinen et al. (1995), Brazma et al. (1996), and Case et al. (1999).

Regarding bounded finite unions of pattern languages, an *n-pattern language* is the union of the pattern languages for some n patterns $P_1, \ldots, P_n$. Each n-pattern language is also **Ex**-learnable from positive data (see Wright 1989). An EFS or logic program corresponding to the n-patterns $P_1, \ldots, P_n$ and generating the corresponding n-pattern language is just below.

$$\begin{gathered} P_1 \leftarrow . \\ \vdots \\ P_n \leftarrow . \end{gathered}$$

Pattern language learning algorithms have been successfully applied toward some problems in molecular biology; see, e.g., Shimozono et al. (1994), Shinohara and Arikawa (1995).

Lange and Wiehagen (1991) present an interesting *iterative* (Wiehagen 1976) algorithm learning the class of pattern languages – from positive data only and with fair polynomial time constraints (for examples of fair vs. unfair polynomial time learning, see Case and Kötzing 2009). *Iterative learners* are **Ex**-learners for which each output depends only on its just prior output (if any) and the input data element currently seen. Their algorithm works in polynomial time (actually quadratic time) in the length of the latest data item and the previous hypothesis. Furthermore, the algorithm has a linear set of good examples, in the sense that if the input data contains these good examples, then the algorithm already converges to the correct hypothesis. The number of good examples needed is at most $|P| + 1$, where P is a pattern generating the data $d_0, d_1, d_2, \ldots$ for the language being learned. This algorithm may be useful in practice due to its fast run time and being able to converge quickly, *if* enough good data is available early. Furthermore, due to iterativeness, it does not need to store previous data!

Zeugmann (1998) considers *total* learning time up to convergence of the algorithm just discussed in the just prior paragraph. Note that, for arbitrary presentations, $d_0, d_1, d_2, \ldots$, of a pattern language, this time can be unbounded. In the best case, it is polynomial in the length of a generating pattern P, where $d_0, d_1, d_2, \ldots$ is based on using P to get good examples early – in fact the time taken in the best case is $\Theta(|P|^2 log_s(s + k))$, where P is the pattern, s is the alphabet size, and k is the number of variables in P. Much more interesting is the case of *average time* taken up to convergence. The probability distribution (called *uniform* by Zeugmann) considered is as follows. A variable X is replaced by a string w with probability $\frac{1}{(2s)^{|w|}}$ (i.e., all strings of length r together have probability 2^{-r}, and the distribution is uniform among strings of length r). Different variables are replaced independently of each other. In this case the average total time up to convergence is $O(2^k k^2 s|P|^2 log_s(ks))$. The main thing is that for average case on probabilistic data (as can be expected in real life, though not necessarily with this kind of uniform distribution), the algorithm converges pretty fast and computations are done efficiently.

A number of papers consider **Ex**-learning of EFSs (Krishna Rao 1996; Krishna Rao and Sattar 1998; Krishna Rao 2000, 2004, 2005) including with various bounds on the number of mind changes until syntactic convergence to correct programs (Jain and Sharma 1997, 2002). The EFSs considered are patterns, n-patterns, those with a constant bound on the length of clauses, and some with constant bounds on search trees. The mind change bounds are typically more dynamic than those given by constants: they involve counting down from finite representations (called *notations*) for infinite constructive ordinals. *An example* of this kind of bound: one can algorithmically, based on some input parameters, decide how many mind changes will be allowed. In *other* examples, the decision as to how many mind changes will be allowed can be algorithmically revised some constant number of times. It is possible that not yet created special cases of some of these algorithms could be made feasible enough for practice.

Learning Drifting Concepts

A drifting concept to be learned is one which is a moving target (see ▸ Concept Drift). In some machine learning applications, concept drift must be dealt with (Bartlett et al. 1996; Blum and Chalasani 1992; Devaney and Ram 1994; Freund and Mansour 1997; Helmbold and Long 1994; Kubat 1992; Wrobel 1994; Widmer and Kubat 1996). An inductive inference contribution is (Case et al. 2001) in which it is shown, for online *extrapolation* by computable martingale betting strategies, upper bounds on the "speed" of the moving target that permit success at all. Here success is to make unbounded amounts of "money" betting on correctness of one's extrapolations. Here is an illustrative result from

(Case et al. 2001). For the pattern languages considered in the previous section, only *positive* length strings of terminals can be substituted for a variable in an associated pattern. The (difficult to learn) *pattern languages with erasing* are just the languages obtained by also allowing the substitution of the empty string for variables in a pattern. For our example, we restrict the terminal alphabet to be {0,1}. With each pattern language with erasing L (over this terminal alphabet), we associate its characteristic function χ_L, which is 1 on terminal strings in L and 0 on those not in L. For ε denoting the empty string, and for the terminal strings in length-lexicographical order, $\varepsilon, 0, 1, 00, 01, 10, 11, 000, \ldots$, we would input a χ_L itself to a potential extrapolating machine as the bit string, $\chi_L(\varepsilon), \chi_L(0), \chi_L(1), \chi_L(00), \chi_L(01), \ldots$. Let $\mathcal{E}$ be the class of these characteristic functions. Pick a positive integer constant p. To model *drift with permanence* p, we imagine that a potential extrapolator for $\mathcal{E}$ receives successive bits from a member of $\mathcal{E}$ but keeps switching to the next bits of another, etc., *but* it must see at least p bits in a row of each member of $\mathcal{E}$ it sees before it can see the next bits of another. p is, then, a speed limit on drift. The result is that some suitably clever computable martingale betting strategy is successful at extrapolating $\mathcal{E}$ with drift permanence (speed limit on drift) of $p = 7$.

Behavioral Cloning

Kummer and Ott (1996) and Case et al. (2002) studied learning in the limit of winning control strategies for *closed computable games*. These games nicely model *reactive* process-control problems. Included are such example process-control games as regulating temperature of a room to be in a desired interval, forever after no more than some *fixed* number of moves between the thermostat and processes disturbing the temperature (Roughly, *closed computable games* are those so that one can tell algorithmically when one has lost. A temperature control game that requires stability forever after some *undetermined* finite number of moves is *not* a closed computable game. For a more formal treatment, see Cenzer and Remmel (1992), Maler et al. (1995), Thomas (1995), and Kummer and Ott (1996).

In machine learning, there are cases where one wants to teach a machine some motor skill possessed by human experts and where these human experts do not have access to verbalizable knowledge about how they perform expertly. Piloting an aircraft or expert operation of a swinging shipyard crane provide examples, and machine learning employs, in these cases, ▸ *behavioral cloning*, which uses direct performance data from the experts (Bain and Sammut 1999; Bratko et al. 1998; Šuc 2003).

Case et al. (2002) study the effects on learning in the limit *closed computable games* where the learning procedures also had access to the *behavioral performance* (but not the algorithms) of masters/experts at the games. For example, it is showed that, in some cases, there is better performance cloning $n + 1$ disparate masters over cloning only n. For a while it was not known *in machine learning* how to clone multiple experts even after Case et al. (2002) was known to some; however, independently of Case et al. (2002), and later, Dorian Šuc (2003) found a way to clone behaviorally more than one human expert simultaneously (for the free-swinging shipyard crane problem) – by having more than one level of feedback control, *and* he got enhanced performance from cloning the multiple experts!

Learning to Coordinate

Montagna and Osherson (1999) begin the study of learning in the limit to *coordinate* (digital) moves between at least two agents.

The machines of Montagna and Osherson (1999) are, in effect, general extrapolating devices (Montagna and Osherson 1999; Case et al. 2005). Technically, and without loss of generality of the results, we restrict the moves of each coordinator to bits, i.e., zeros and ones. *Coordination* is achieved between two coordinators iff each, reacting to the bit sequence of the other, eventually (in the limit) matches it bit for bit. Montagna and Osherson (1999) give an example of two people who show up in a park each day at one of noon (bit 0) or 6pm (bit 1); each *silently* watches the other's past behavior, and each *tries*, based on the past behavior of the other, to show up eventually exactly when the other shows up. If they manage it, they have learned to coordinate.

A *blind* coordinator is one that reacts only to the *presence* of a bit from another process, *not* to *which* bit the other process has played (Montagna and Osherson 1999).

Case et al. (2005) developed and studied the notion of probabilistically correct algorithmic coordinators. Next is a sample of theorems to the effect that just a few random bits can enhance learning to coordinate.

Theorem 1 (Case et al. 2005) *Suppose* $0 \leq p < 1$. *There exists a class of deterministic algorithmic coordinators* $\mathcal{C}$ *such that:*

(1) No *deterministic algorithmic coordinator can coordinate with all of* $\mathcal{C}$
(2) For k *chosen so that* $1-2^{-k} \geq p$, *there exists a blind,* probabilistic *algorithmic coordinator* **PM**, *such that:*
  (i) For each member of $\mathcal{C}$, **PM** *can coordinate with with probability* $1-2^{-k} \geq p$
  (ii) **PM** *is* k-memory limited *in the sense of (Osherson et al. 1986, P. 66); more specifically,* **PM** *needs to remember whether it is outputting one of its first* k *bits* — which are its only random bits *(e.g., for* $p = \frac{255}{256}$, *a mere* $k = 8$ *random bits suffice.).*

Regarding possible eventual applicability: Maye et al. (2007) cite finding deterministic chaos but *not* randomness in the behavior of *animals*. Hence, animals may not be exploiting random bits in learning anything, including to coordinate. However, one might build artifactual devices to exploit randomness, say, from radioactive decay, including, then, for enhancing learning to coordinate.

Learning Geometric Clustering

Case et al. (2006) showed that learnability in the limit of ▸ *clustering*, with or without additional information, depends strongly on geometric constraints on the shape of the clusters. In this approach the hypothesis space of possible clusters is pre-given in each setting. It was hoped to obtain thereby insight into the difficulty of clustering when the clusters are restricted to preassigned *geometrically* defined classes.

This is interestingly complementary to the *conceptual clustering* approach (see, e.g., Pitt and Reinke 1988; Mishra et al. 2004) where one restricts the possible clusters to have good "verbal" descriptions in some language.

Clustering of many of the geometric classes investigated was shown to *require* information *in addition* to a presentation, $d_0, d_1, d_2, \ldots$, of the set of points to be clustered. For example, for clusters as convex hulls of finitely many points in a rational vector space, clustering can be done – but with the number of clusters as additional information. Let $\mathcal{S}$ consist of all polygons including their interiors – in the rational two-dimensional plane *without intersections and degenerated angles*. (Attention was restricted to spaces of rationals since 1. computer reals are rationals, 2. this avoids the uncountability of the set of reals, and 3. this avoids dealing with *un*computable real points.) The class $\mathcal{S}$ *can* be clustered – but with the number of vertices of the polygons of the clusters involved as additional information.

Correspondingly, then, it was shown that the class $\mathcal{S}'$ containing $\mathcal{S}$ *together with* all such polygons but with one hole (the nondegenerate differences of two members in $\mathcal{S}$) can*not* be clustered with the number of vertices as additional information, yet $\mathcal{S}'$ can be clustered with *area* as additional information – and this even in higher dimensions and with any number of holes (Case et al. 2006).

It remains to be seen if some forms of geometrically constrained clustering can be usefully complementary to, say, conceptually/verbally constrained clustering.

Insights for Limitations of Science

We briefly treat below in some problems regarding parsimonious, refutable, and consistent hypotheses.

It is common wisdom in science that one should fit parsimonious explanations, hypotheses, or programs to data. In machine learning, this has been successfully applied, e.g., (Wallace and Dowe 1999; Wallace 2005).

Curiously, though, there are many results in inductive inference in which we see sometimes severe *degradations* of learning power caused by demanding *parsimonious* predictive programs (see, e.g., Freivalds 1975; Kinber 1977; Chen 1982; Case et al. 1996; Ambainis et al. 2004).

It is an interesting problem to resolve the seeming, likely not actual contradiction between the just prior two paragraphs.

Popper's Refutability (1962) asserts that hypotheses in science should be subject to refutation. Besides the well-known difficulties of Duhem–Quine (Harding 1976) of knowing which component hypothesis to throw out when a compound hypothesis badly fails to make correct predictions, inductive inference theorems have provided very different difficulties. Case and Smith (1983) outline cases of usefully *in*complete (hence wrong) hypothesis that cannot be refuted, and Case and Suraj (2007) (see also Case 2007) provide cases of inductively inferable higher order hypothesis not totally subject to refutation in cases where ordinary hypotheses subject to full refutation cannot be inductively inferred.

While Duhem–Quine may impact machine learning eventually, it remains to be seen about the inductive inference results of the just prior paragraph.

Requiring ▸ inductive inference procedures always to output an hypothesis in various senses *consistent* with (e.g., not ignoring) the data on which that hypothesis is based seems like mere common sense. However, from Bārzdiņš (1974a), Blum and Blum (1975), Wiehagen (1976), and Case et al. (2004), we see that strict adherence to various consistency principles can severely attenuate the learning power of inductive inference machines. Furthermore, interestingly, *even when inductive inference is polytime constrained*, we see similar counterintuitive results to the effect that a kind of consistency can strictly attenuate learning power (Wiehagen and Zeugmann 1994).

A machine learning analog might be Breiman's bagging (Breiman 1996) and random forests (Breiman 2001), where data is purposely ignored. However, in these cases, the purpose of ignoring data is to avoid overfitting to noise.

It remains to be seen, whether, in applied machine learning involving cases of practically noiseless data, one can also obtain some advantage in ignoring some consistency principles. Again the potential lesson from inductive inference is abstract and provides only a hint of something to work out in real machine learning problems.

Consensus Clustering

Synonyms

Clustering aggregation; Clustering ensembles

Definition

In Consensus Clustering we are given a set of n objects V, and a set of m clusterings $\{C_1, C_2, \ldots, C_m\}$ of the objects in V. The aim is to find a single clustering C that *disagrees* least with the input clusterings, that is, C minimizes

$$D(C) = \sum_{C_i} d(C, C_j),$$

for some metric d on clusterings of V. Meilă (2003) proposed the principled *variation of information* metric on clusterings, but it has been difficult to analyze theoretically. The Mirkin metric is the most widely used, in which $d(C, C')$ is the number of pairs of objects (u, v) that are clustered together in C and apart in C', or vice versa; it can be calculated in time $O(mn)$.

We can interpret each of the clusterings C_i in Consensus Clustering as evidence that pairs ought be put together or separated. That is, w^i_{uv} is the number of C_i in which $C_i[u] = C_i[v]$ and w^-_{uv} is the number of C_i in which $C_i[u] \neq C_i[v]$. It is clear that $w^+_{uv} + w^-_{uv} = m$ and that Consensus clustering is an instance of Correlation clustering in which the w^-_{uv} weights obey the triangle inequality.

Constrained Clustering

Kiri L. Wagstaff
Pasadena, CA, USA

Definition

Constrained clustering is a semisupervised approach to ▸ clustering data while incorporating domain knowledge in the form of constraints. The constraints are usually expressed as pairwise statements indicating that two items must, or cannot, be placed into the same cluster. Constrained clustering algorithms may enforce every constraint in the solution, or they may use the constraints as guidance rather than hard requirements.

Motivation and Background

▸ Unsupervised learning operates without any domain-specific guidance or preexisting knowledge. Supervised learning requires that all training examples be associated with labels. Yet it is often the case that existing knowledge for a problem domain fits neither of these extremes. Semisupervised learning methods fill this gap by making use of both labeled and unlabeled data. Constrained clustering, a form of semisupervised learning, was developed to extend clustering algorithms to incorporate existing domain knowledge, when available. This knowledge may arise from labeled data or from more general rules about the concept to be learned.

One of the original motivating applications was noun phrase coreference resolution, in which noun phrases in a text must be clustered together to represent distinct entities (e.g., "Mr. Obama" and "the President" and "he", separate from "Sarah Palin" and "she" and "the Alaska governor"). This problem domain contains several natural rules for when noun phrases should (such as appositive phrases) or should not (such as a mismatch on gender) be clustered together. These rules can be translated into a collection of pairwise constraints on the data to be clustered.

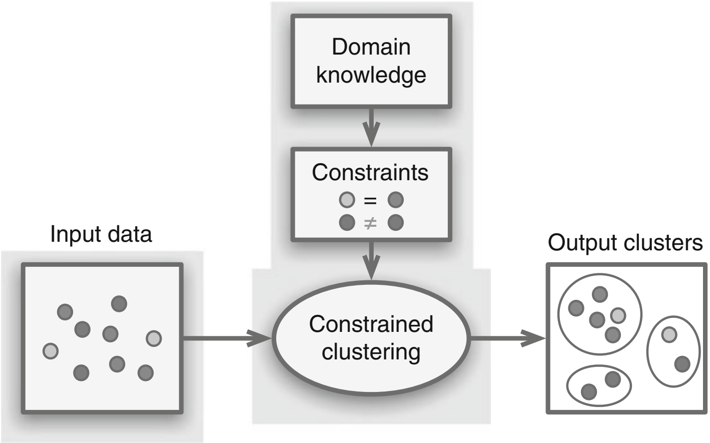
Constrained clustering algorithms have now been applied to a rich variety of domain areas, including hyperspectral image analysis, road lane divisions from GPS data, gene expression microarray analysis, video object identification, document clustering, and web search result grouping.

Structure of the Learning System

Constrained clustering arises out of existing work with unsupervised clustering algorithms. In this description, we focus on clustering algorithms that seek a partition of the data into disjoint clusters, using a distance or similarity measure to place similar items into the same cluster. Usually, the desired number of clusters, k, is specified as an input to the algorithm. The most common clustering algorithms are k-means (MacQueen 1967) and expectation maximization or EM (Dempster et al. 1977) (Fig. 1).

A constrained clustering algorithm takes the same inputs as a regular (unsupervised) clustering algorithm and also accepts a set of pairwise constraints. Each constraint is a must-link or ▸ cannot-link constraint. The must-link constraints form an equivalence relation, which permits the inference of additional transitively implied must-links as well as additional entailed cannot-link constraints between items from distinct must-link cliques. Specifying a significant number of pairwise constraints might be tedious for large data sets, so often they may be generated from a manually labeled subset of the data or from domain-specific rules.

The algorithm may interpret the constraints as hard constraints that must be satisfied in the output or as soft preferences that can be violated, if necessary. The former approach was used in the first constrained clustering algorithms, COP-COBWEB (Wagstaff and Cardie 2000) and COP-kmeans (Wagstaff et al. 2001). COP-kmeans accommodates the constraints by restricting item assignments to exclude any constraint violations. If a solution that satisfies the constraints is not found, COP-kmeans terminates without a solution. Later, algorithms such as PCK-means and MPCK-means (Bilenko et al. 2004) permitted the violation of constraints when necessary by introducing a violation penalty. This is useful when the constraints may contain noise or internal inconsistencies, which are especially relevant in real-world domains. Constrained versions of other clustering algorithms such as EM (Shental et al. 2004) and spectral clustering (Kamvar et al. 2003) also exist. Penalized probabilistic clustering (PPC) is a modified version of EM that interprets the constraints as (soft) probabilistic priors on the relationships between items (Lu and Leen 2005).



Constrained Clustering, Fig. 1 The constrained clustering algorithm takes in nine items and two pairwise constraints (one must-link and one cannot-link). The output clusters respect the specified constraints

In addition to constraining the assignment of individual items, constraints can be used to learn a better distance metric for the problem at hand (Bar-Hillel et al. 2005; Klein et al. 2002; Xing et al. 2003). Must-link constraints hint that the effective distance between those items should be low, while cannot-link constraints suggest that their pairwise distance should be high. Modifying the metric accordingly permits the subsequent application of a regular clustering algorithm, which need not explicitly work with the constraints at all. The MPCK-means algorithm fuses these approaches together, providing both constraint satisfaction and metric learning simultaneously (Basu et al. 2004; Bilenko et al. 2004).

More information about subsequent advances in constrained clustering algorithms, theory, and novel applications can be found in a compilation edited by Basu et al. (2008).

Programs and Data

The MPCK-means algorithm is available in a modified version of the Weka machine learning toolkit (Java) at http://www.cs.utexas.edu/users/ml/risc/code/.

Constraint-Based Mining

Siegfried Nijssen
Katholieke Universiteit Leuven, Leuven,
Belgium

Definition

Constraint-based mining is the research area studying the development of data mining algorithms that search through a pattern or model space restricted by constraints. The term is usually used to refer to algorithms that search for patterns only. The most well-known instance of constraint-based mining is the mining of ▸ frequent patterns. Constraints are needed in pattern mining algorithms to increase the efficiency of the search and to reduce the number of patterns that are presented to the user, thus making knowledge discovery more effective and useful.

Motivation and Background

Constraint-based pattern mining is a generalization of frequent itemset mining. For an introduction to frequent itemset mining, see ▸ Frequent Pattern. A constraint-based mining problem is specified by providing the following elements:

- A database $\mathcal{D}$, usually consisting of independent transactions (or instances)
- A ▸ hypothesis space $\mathcal{L}$ of patterns
- A constraint $q(\theta, \mathcal{D})$ expressing criteria that a pattern θ in the hypothesis space should fulfill on the database

The general constraint-based mining problem is to find the set

$$\mathrm{Th}(\mathcal{D}, \mathcal{L}, q) = \{\theta \in \mathcal{L} | q(\theta, \mathcal{D}) = \mathrm{true}\}.$$

Alternative problem settings are obtained by making different choices for $\mathcal{D}, \mathcal{L}$ and q. For instance,

- If the database and hypothesis space consist of itemsets, and the constraint checks if the support of a pattern exceeds a predefined threshold in data, the frequent itemset mining problem is obtained (see ▸ Frequent Pattern)
- If the database and the hypothesis space consist of graphs or trees instead of itemsets, a graph mining or a tree mining problem is obtained. For more information about these topics, see ▸ Graph Mining and ▸ Tree Mining
- Additional syntactic constraints can be imposed

An overview of important types of constraints is given below.

One can generalize the constraint-based mining problem beyond pattern mining. Also models, such as ▸ Decision Trees, could be seen as languages of interest. In the broadest sense, topics such as ▸ Constrained Clustering, ▸ Cost-Sensitive Learning, and even learning ▸ Support Vector Machines (SVMs) may be seen as constraint-based mining problems. However, it is currently not common to categorize these topics as *constraint-based mining*; in practice, the term refers to constraint-based *pattern* mining.

From the perspective of constraint-based mining, the knowledge discovery process can be seen as a process in which a user repeatedly specifies constraints for data mining algorithms; the data mining system is a solver that finds patterns or models that satisfy the constraints.

This approach to data mining is very similar to querying relational databases. Whereas relational databases are usually queried using operations such as projections, selections, and joins, in the constraint-based mining framework data is queried to find patterns or models that satisfy constraints that cannot be expressed in these primitives. A database which supports constraint-based mining queries, stores patterns and models, and allows later reuse of patterns and models, is sometimes also called an *inductive database* (Imielinski and Mannila 1996).

Structure of the Learning System

Constraints

Frequent pattern mining algorithms can be generalized along several dimensions.

One way to generalize pattern mining algorithms is to allow them to deal with arbitrary coverage relations, which determine when a pattern matches a transaction in the data. In the example of mining itemsets, the subset relation determines the coverage relation. The coverage relation is at the basis of constraints such as minimum support; an alternative coverage relation would be the superset relation.

From the coverage relation follows a generality relationship. A pattern θ_1 is defined to be more specific than a pattern θ_2 (denoted by $\theta_1 \succ \theta_2$) if any transaction that is covered by θ_1 is also covered by θ_2 (see ▸ Generalization). In frequent itemset mining, itemset I_1 is more general than itemset I_2 if and only $I_1 \subseteq I_2$.

Generalization and coverage relationships can be used to identify the following types of constraints.

Monotonic and Anti-Monotonic Constraints

An essential property which is exploited in ▸ frequent pattern mining, is that allsubsets of a frequent pattern are also frequent. This is a property that can begeneralized:

- A constraint is called *monotonic* if any generalization of a pattern that satisfies the constraint, also satisfies the constraint
- A constraint is called *anti-monotonic* if any specialization of a pattern that satisfies the constraint, also satisfies the constraint

In some publications, the definitions of monotonic and anti-monotonic are used reversely.

The following are examples of monotonic constraints:

- Minimum support
- Syntactic constraints, for instance: a constraint that requires that patterns specializing a given pattern x are excluded a constraint requiring patterns to be small given a definition of pattern size
- Disjunctions or conjunctions of monotonic constraints
- Negations of anti-monotonic constraints

The following are examples of anti-monotonic constraints:

- Maximum support
- Syntactic constraints, for instance, a constraint that requires that patterns generalizing a given pattern x are excluded
- Disjunctions or conjunctions of anti-monotonic constraints
- Negations of monotonic constraints

Succinct Constraints

Constraints that can be pushed in the mining process by adapting the pattern space or data, are called succinct constraints. An example of a succinct constraint is the monotonic constraint that an itemset should contain the item A. This constraint could be dealt with by deleting all transactions that do not contain A. For any frequent itemset found in the new dataset, it is now known that the item A can be added to it.

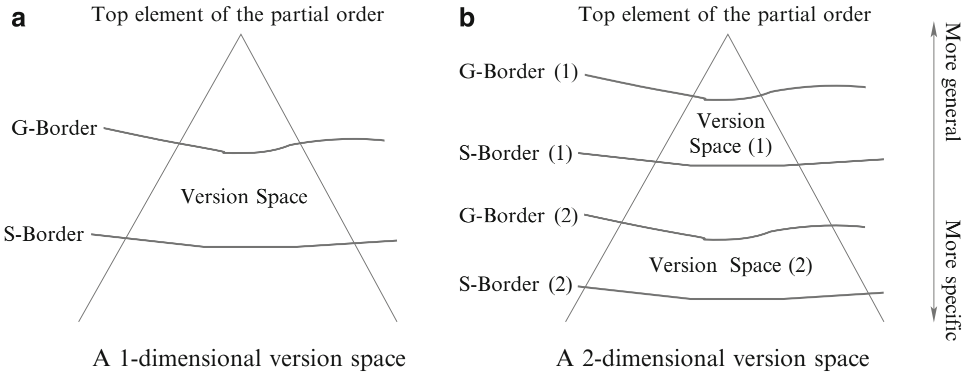
Convertible Constraints

Some constraints that are not monotonic, can still be *convertible* monotonic (Pei and Han 2002). A constraint is convertible monotonic if for every pattern θ one least general generalization θ' can be identified such that if θ satisfies the constraint, then θ' also satisfies the constraint. An example of a convertible constraint is a maximum average cost constraint. Assume that every item in an itemset has a cost as defined by a function $c(i)$. The constraint $c(I) = \sum_{i \in I} c(i)/|I| \leq maxcost$ is not monotonic. However, for every itemset I with $c(I) \leq maxcost$, if an item i is removed with $c(i) = \max_{i \in I} c(i)$, an itemset with $c(I - \{i\}) \leq c(I) \leq maxcost$ is obtained.

Maximum average cost has the desirable property that no access to the data is needed to identify the generalization that should satisfy the constraints. If it is not possible to identify the necessary least general generalization before accessing the data, the convertible constraint is also sometimes called weak (anti-)monotone (Zhu et al. 2007).

Boundable Constraints

Constraints on non-monotonic measures for which a monotonic bound exist, are called boundable. An example of such a constraint is a minimum accuracy constraint in a database with binary class labels. Assume that every itemset is interpreted as a rule **if** I **then** 1 **else** 2 (thus, class label 1 is predicted if a transaction contains itemset I, or class label 2 otherwise; see ▸ Supervised Descriptive Rule Induction). A minimum accuracy constraint can be formalized by the formula $(\mathrm{fr}(I, D_1) + |D_2| - \mathrm{fr}(I, D_2))/|D| \geq minacc$, where D_k is the



Constraint-Based Mining, Fig. 1 Version spaces

database containing only the examples labeled with class label k. It can be derived from this that

$$\mathrm{fr}(I, D_1) \geq |D| minacc - |D_2| +$$
$$\mathrm{fr}(I, D_2) \geq |D| minacc - |D_2|.$$

In other words, if a high accuracy is desirable, a minimum number of examples of class 1 is required to be covered, and a minimum frequency constraint can thus be derived. Therefore, minimum support can be used as a bound for minimum accuracy.

The principle of deriving bounds for non-monotonic measures can be applied widely (Bayardo et al. 1999; Morishita and Sese 2000).

Borders

If constraints are not restrictive enough, the number of patterns can be huge. Ignoring statistics about patterns such as their exact frequency, the set of patterns can be represented more compactly only by listing the patterns in the *border*(s) (Mannila and Toivonen 1997), similar to the idea of ▶ version spaces. An example of a border is the set of maximalfrequent itemsets (see ▶ Frequent Pattern). Borders can be computed for othertypes of both monotonic and anti-monotonic constraints as well. There areseveral complications compared to the simple frequent pattern miningsetting:

- If there is an anti-monotonic constraint, such as maximum support, not only is it needed to compute a border for the most specific elements in the set (S-Set), but also a border for the least general elements in the set (G-Set)
- If the formula is a disjunction of conjunctions, the result of a query becomes a union of version spaces, which is called a multi-dimensional version space (see Fig. 1) (De Raedt et al. 2002); the G-Set of one version space may be more general than the G-Set of another version space

Both the S-Set and the G-Set can be represented by listing elements just within the version space (the positive border), or elements just outside the version space (the negative border). For instance, the positive border of the G-Set consists of those patterns which are part of the version space, and for which no generalizations exist which are part of the version space.

Similarly, there may exist several representations of multi-dimensional version spaces; optimizing the representation of multi-dimensional version spaces is analogous to optimizing queries in relational databases (De Raedt et al. 2002).

Borders form a *condensed representations*, that is, they compactly represent the solution space; see ▶ Frequent Pattern.

Algorithms

For many of the constraints specified in the previous section specialized algorithms have been developed in combination with specific hypothesis spaces. It is beyond the scope of this chapter to discuss all these algorithms; only the most common ideas are provided here.

The main idea is that ▸ Apriori can easily be updated to deal with general monotonic constraints in arbitrary hypothesis spaces. The concept of a specialization refinement operator is essential to operateon other hypothesis spaces than itemsets. A specialization operator $\rho(\theta)$ computes a set of specializations in the hypothesis space for a given input pattern. In pattern mining, this operator should have the following properties:

- Completeness: every pattern in the hypothesis space should be reachable by repeated application of the refinement operator starting from the most general pattern in the hypothesis space
- Nonredundancy: every pattern in the hypothesis space should be reachable in only one way starting from the most general pattern in the hypothesis space

In itemset mining, optimal refinement is usually obtained by first ordering the items (for instance, alphabetically, or by frequency), and then adding items that are higher in the chosen order to a set than the items already in the set. For instance, for the itemset $\{A, C\}$, the specialization operator returns $\rho(\{A, C\}) = \{\{A, C, D\}, \{A, C, E\}\}$, assuming that the domain of items $\{A, B, C, D, E\}$ is considered. Other refinement operators are needed while dealing with other hypothesis spaces, such as in ▸ graph mining.

The search in Apriori proceeds breadth-first. Each level, the specialization operator is applied on patterns satisfying the monotonic constraints to generate candidates for the next level. For every new candidate it is checked whether its generalizations satisfy the monotonic constraints. To create a set of generalizations, a generalization refinement operator can be used. In frequent itemset mining, usually single items are removed from the itemset to generate generalizations.

More changes are required to deal with *anti-monotonic* constraints. A simple way of dealing with both monotonic and anti-monotonic constraints is to first compute all patterns that satisfy the monotonic constraints, and then to prune the patterns that fail to satisfy the anti-monotonic constraints. More challenging is to "push" anti-monotonic constraints in the mining process. An observation which is often exploited is that generalizations of patterns that do not satisfy the anti-monotonic constraint need not be considered. Well-known strategies are:

- In a breadth-first setting: traverse the lattice in reverse order for monotonic constraints, after the patterns have been determined satisfying the anti-monotonic constraints (De Raedt et al. 2002)
- In a depth-first setting: during the search for patterns, try to guess the largest pattern that can still be reached, and prune a branch in the search if the pattern does not satisfy the monotonic constraint on this pattern (Bucila et al. 2003; Kifer et al. 2003)

It is beyond the scope of this chapter to discuss how to deal with other types of constraints; however, it should be pointed out that not all combinations of constraints and hypothesis spaces have been studied; it is not obvious whether all constraints can be pushed usefully in a pattern search for any hypothesis space, for instance, when boundable constraints in more complex hypothesis spaces (such as graphs) are involved. Research in this area is ongoing.

Synonyms

Clustering with advice; Clustering with constraints; Clustering with qualitative information; Clustering with side information

Definition

In its rawest form, *correlation clustering* is graph optimization problem. Consider a ▶ clustering C to be a mapping from the elements to be clustered, V , to the set $\{1, \ldots, |V|\}$, so that u and v are in the same cluster if and only if $C[u] = C[v]$. *Given* a collection of items in which each pair (u, v) has two weights w^+_{uv} and w^-_{uv}, we must *find* a clustering C that minimizes

$$\sum_{C[u]=C[v]} w^-_{uv} + \sum_{C[u]\neq C[v]} w^+_{uv}, \qquad (1)$$

or, equivalently, maximizes

$$\sum_{C[u]=C[v]} w^+_{uv} + \sum_{C[u]\neq C[v]} w^-_{uv}. \qquad (2)$$

Note that although w^+_{uv} and w^-_{uv} may be thought of as positive and negative evidence towards coassociation, the actual weights are nonnegative.

Motivation and Background

The notion of *clustering with advice*, that is nonmetric-driven relations between items, had been studied in other communities (Ferligoj and Batagelj 1982) prior to its appearance in theoretical computer science. Traditional clustering problems, such as k-median and k-center, assume that there is some type of distance measure (metric) on the data items, and often specify the number of clusters that should be formed. In the clustering with advice framework, however, the number of clusters to be built need not be specified in advance: it can be an outcome of the objective function. Furthermore, instead of, or in addition to, a distance function, we are given advice as to which pairs of items are similar. The two weights w^+_{uv} and w^-_{uv} correspond to external advice about whether the pair should be clustered together or separately. Bansal et al. (2002) introduced the problem to the theoretical computer science and machine-learning communities. They were motivated by database consistency problems, in which the same entity appeared in different forms in various databases. Given a collection of such records from multiple databases, the aim is to cluster together the records that appear to correspond to the same entity. From this viewpoint, the log odds ratio from some classifier,

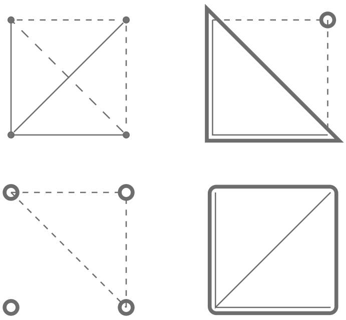
$$\log\left(\frac{\Pr(\text{same})}{\Pr(\text{different})}\right),$$

corresponds to a label w_{uv} for the pair. In many applications only one of the $+$ and $-$ weights for the pair is nonzero, that is

$$(w^+_{uv}, w^-_{uv}) = \begin{cases} (w_{uv}, 0) & \text{for } w_{uv} \geq 0 \\ (0, -w_{uv}) & \text{for } w_{uv} \leq 0. \end{cases}$$

In addition, if every pair has weight ±1, then the instance is called *complete*, otherwise it is referred to as *general*. Demaine et al. (2006) suggest the following motivation. Suppose we have a set of guests at a party. Each guest has preferences for whom they would like to sit with, and for whom they would like to avoid. We must group the guests into tables in a way that enhances the amicability of the party.

The notion of producing good clusterings when given inconsistent advice first appeared in the work of Ben et al. (1999). A canonical example of inconsistent advice is this: items u and v are similar, items v and y are similar, but u and y are dissimilar. It is impossible to find a clustering that satisfies all the advice. Figure 1 shows a very simple example of inconsistent advice. In addition, although Correlation clustering is an NP-hard problem, recent algorithms for clustering with advice *guarantee* that their solutions are only a specified factor worse than the optimal: that is, they are *approximation algorithms*.



Correlation Clustering, Fig. 1 *Top left* is a toy *clustering with advice* example showing three similar pairs (*solid edges*) and three dissimilar pairs (*dashed edges*). *Bottom left* is a clustering solution for this example with four singleton clusters, while *bottom right* has one cluster. *Top right* is a partitioning into two clusters that appears to best respect the advice

Theory

In setting out the correlation clustering framework, Bansal et al. (2002) noted that the following algorithm produces a 2-approximation for the maximization problem:

> If the total of the positive weights exceeds the total of the negative weights then, place all the items in a single cluster; otherwise, make each item a singleton cluster.

They then showed that complete instances are NP-hard to optimize, and how to minimize the penalty (1) with a constant factor approximation. The constant for this combinatorial algorithm was rather large. The algorithm relied heavily on the completeness of the instance; it iteratively *cleans* clusters until every cluster is *δ-clean*. That is, for each item at most a fraction $\delta (0 < \delta < 1)$ of the other items in its cluster have a negative relation with it, and at most δ outside its cluster a positive relation. Bansal et al. also demonstrated that the minimization problem on general instances is APX-hard: there is some constant, larger than 1, below which approximation is NP-hard. Finally, they provided a polynomial time approximation scheme (PTAS) for maximizing (2) in complete instances.

The constant factor for minimizing (1) on complete instances was improved to 4 by Charikar et al. (2003). They employed a region-growing type procedure to round the solution of a linear programming relaxation of the problem:

$$\begin{aligned}&\text{maximize}\\&\quad\sum_{ij} w_{ij}^{+}\cdot x_{ij} + w_{ij}^{-}\cdot(1-x_{ij})\\&\text{subject to}\\&\quad x_{ik} \le x_{ij} + x_{jk} \quad \text{for all } i,j,k\\&\quad x_{ij} \in [0,1] \qquad\quad \text{for all } i,j\end{aligned} \tag{3}$$

In this setting, $x_{ij} = 1$ implies i and j's separation, while $x_{ij} = 0$ implies coclustering, with values in between representing partial evidence. In practice solving this linear program is very slow and has huge memory demands (Bertolacci and Wirth 2007). Charikar et al. also showed that this version of problem is APX-hard.

For the maximization problem (2), they showed that instances with general weights were APX-hard and provided a rounding of the following semidefinite program (SDP) that yields a 0.7664 factor approximation algorithm.

$$\begin{aligned}&\text{maximize}\\&\quad\sum_{+(ij)} w_{ij}(v_i\cdot v_j) + \sum_{-(ij)} w_{ij}(1-v_i\cdot v_j)\\&\text{subject to}\\&\quad v_i\cdot v_i = 1 \quad \text{for all } i\\&\quad v_i\cdot v_j \ge 0 \quad \text{for all } i,j\end{aligned} \tag{4}$$

In this case we interpret $v_i \cdot v_j = 1$ as evidence that i and j are in the same cluster, but $v_i \cdot v_j = 0$ as evidence toward separation.

Emanuel and Fiat (2003) extended the work of Bansal et al. by drawing a link between Correlation Clustering and the Minimum Multicut problem. This reduction to Multicut provided an $O(\log n)$ approximation algorithm for minimizing general instances of Correlation Clustering. Interestingly, Emanuel and Fiat also showed that there was reduction in the opposite direction: an optimal solution to Correlation Clustering induced an optimal solution to Minimum Multicut.

Demaine and Immorlica (2003) also drew the link from Correlation Clustering to Minimum multicut and its $O(\log n)$ approximation algorithm. In addition, they described an $O(r^3)$-approximation algorithm for graphs that exclude the complete bipartite graph $K_{r,r}$ as a minor.

Swamy (2004), using the same SDP (4) as Charikar et al., but different rounding techniques, showed how to maximize (2) within factor 0.7666 in general instances.

The factor 4 approximation for minimization (1) of complete instances was lowered to 2.5 by Ailon et al. (2005). Using the *distances* obtained by solving the linear program (3), they repeat the following steps:

> form a cluster around random item i by including each (unclustered) j with probability $1 - x_{ij}$; set the cluster aside.

Since solving the linear program is highly resource hungry, Ailon et al. provided a combinatorial alternative: add j to i's cluster if $w_{ij}^{+} > w_{ij}^{-}$. Not only is this algorithm very fast, it is actually a factor 3 approximation.

Recently, Tan (2007) has shown that the $79/80 + \epsilon$ inapproximability for maximizing (2) on general weighted graphs extends to general unweighted graphs.

A further variant in the Correlation Clustering family of problems is the maximization of (2)–(1), known as *maximizing correlation*. Charikar and Wirth (2004) proved an $\Omega(1/\log n)$ approximation for the general problem of maximizing

$$\sum_{i=1}^{n}\sum_{j=1}^{n} a_{ij}x_i x_j, \qquad \text{s.t } x_i \in \{-1,1\} \text{ for all } i, \tag{5}$$

for a matrix A with null diagonal entries, by rounding the canonical SDP relaxation. This effectively maximized correlation with the requirement that two clusters be formed; it was not hard to extend this to general instances. The gap between the vector SDP solution and the integral solution to maximizing the quadratic program (5) was in fact shown to be $\Theta(1/\log n)$ in general (Alon et al. 2006). However, in other instances such as those with a bounded number of nonzero weights for each item, a constant factor approximation was possible. Arora et al. (2005) went further and showed that it is *quasi*-NP-hard to approximate the maximization to a factor better than $\Omega(1/\log^{\gamma} n)$ for some $\gamma > 0$.

Shamir et al. (2004) showed that ▸ Cluster Editing and p-Cluster Editing, in which p clusters must be formed, are NP-complete (for $p \geq 2$). Gramm et al. (2004) took an innovative approach to solving the Clustering Editing problem exactly. They had previously produced an $O(2.27k + n^3)$ time hand-made search tree algorithm, where k is the number of edges that need to be modified. This "awkward and error-prone work" was then replaced with a computer program that itself designed a search tree algorithm, involving automated case analysis, that ran in $O(1.92^k + n^3)$ time.

Kulis et al. (2005) unify various forms of clustering, correlation clustering, spectral clustering, and clustering with constraints in their kernel-based approach to k-means. In this, they have a general objective function that includes penalties for violating pairwise constraints and for having points spread far apart from their cluster centers, where the *spread* is measured in some high-dimensional space.

Applications

The work of Demaine and Immorlica (2003) on Correlation Clustering was closely linked with that of Bejerano et al. on Location Area Planning. This problem is concerned with the allocation of cells in a cellular network to clusters known as *location areas*. There are costs associated with traffic between the location areas (cuts between clusters) and with the size of clusters themselves (related to paging phones within individual cells). These costs drive the clustering solution in opposite directions, on top of which there are constraints on cells that must (or cannot) be in the same cluster. The authors show that the same $O(\log n)$ region-growing algorithm for minimizing Correlation Clustering and Multicut applies to Location Area Planning.

Correlation clustering has been directly applied to the coreference problem in natural language processing and other instances in which there are multiple references to the same object (Daume 2006; McCallum and Wellner 2005). Assuming some sort of undirected graphical model, such as a Conditional Random Field, algorithms for correlation clustering are used to partition a graph whose edge weights corresponding to log-potentials between node pairs. The machine learning community has applied some of the algorithms for Correlation clustering to problems such as email clustering and image segmentation. With similar applications in mind, Finley and Joachims (2005) explore the idea of adapting the pairwise input information to fit example clusterings given by a user. Their objective function is the same as Correlation Clustering (2), but their main tool is the ▸ Support Vector Machine.

There has been considerable interest in the ▸ consensus clustering problem, which is an excellent application of Correlation clustering techniques. Gionis et al. (2005) note several sources of motivation for the Consensus Clustering; these include identifying the correct number of clusters and improving clustering robustness. They adapt Charikar et al.'s region-growing algorithm to create a three-approximation that performs reasonably well in practice, though not as well as local search techniques. Gionis et al. also suggest using sampling as a tool for handling large data sets. Bertolacci and Wirth (2007) extended this study by implementing Ailon et al.'s algorithms with sampling, and therefore a variety of ways of developing a full clustering from the clustering of the sample. They noted that LP-based methods performed best, but placed a significant strain on resources.

Applications of Clustering with Advice

The ► *k*-means clustering algorithm is perhaps the most-used clustering technique: Wagstaff et al. incorporated constraints into a highly cited *k*-means variant called COP-KMEANS. They applied this algorithm to the task of identifying lanes of traffic based on input GPS data.

In the constrained-clustering framework, the constraints are usually assumed to be consistent (noncontradictory) and hard. In addition to the usual must- and cannot-link constraints, Davidson and Ravi (2005) added constraints enforcing various requirements on the distances between points in particular clusters. They analyzed the computational feasibility of the problem of establishing the (in) feasibility of a set of constraints, for various constraint types. Their constrained *k*-means algorithms were used to help a robot discover objects in a scene.

Cost-Sensitive Learning

Charles X. Ling and Victor S. Sheng
The University of Western Ontario, London, ON, Canada

Synonyms

Cost-sensitive classification; Learning with different classification costs

Definition

Cost-Sensitive Learning is a type of learning that takes the misclassification costs (and possibly other types of cost) into consideration. The goal of this type of learning is to minimize the total cost. The key difference between cost-sensitive learning and cost-insensitive learning is that cost-sensitive learning treats different misclassifications differently. That is, the cost for labeling a positive example as negative can be different from the cost for labeling a negative example as positive. Cost-insensitive learning does not take misclassification costs into consideration.

Motivation and Background

Classification is an important task in inductive learning and machine learning. A classifier, trained from a set of training examples with class labels, can then be used to predict the class labels of new examples. The class label is usually discrete and finite. Many effective classification algorithms have been developed, such as ▶ naïve Bayes, ▶ decision trees, ▶ neural networks, and ▶ support vector machines. However, most classification algorithms seek to minimize the error rate: the percentage of the incorrect prediction of class labels. They ignore the difference between types of misclassification errors. In particular, they implicitly assume that all misclassification errors have equal cost.

In many real-world applications, this assumption is not true. The differences between different misclassification errors can be quite large. For example, in medical diagnosis of a certain cancer (where having cancer is regarded as the positive class, and non-cancer (healthy) as negative), misdiagnosing a cancer patient as healthy (the patient is actually positive but is classified as negative; thus it is also called "false negative") is much more serious (thus expensive) than a false-positive error. The patient could lose his/her life because of a delay in correct diagnosis and treatment. Similarly, if carrying a bomb is positive, then it is much more expensive to miss a terrorist who carries a bomb onto a flight than searching an innocent person.

Cost-sensitive learning takes costs, such as the misclassification cost, into consideration. Turney (2000) provides a comprehensive survey of a large variety of different types of costs in data

Cost-Sensitive Learning, Table 1 An example of cost matrix for binary classification

	Actual negative	Actual positive
Predict negative	$C(0,0)$, or *TP*	$C(0,1)$, or *FN*
Predict positive	$C(1,0)$, or FP	$C(1,1)$, or TP

mining and machine learning, including misclassification costs, data acquisition cost (instance costs and attribute costs), ▶ active learning costs, computation cost, human–computer interaction cost, and so on. The misclassification cost is singled out as the most important cost, and it has received the most attention in recent years.

Theory

The theory of cost-sensitive learning (Elkan 2001; Zadrozny and Elkan 2001) describes how the misclassification cost plays its essential role in various cost-sensitive learning algorithms.

Without loss of generality, binary classification is assumed (i.e., positive and negative class) in this paper. In cost-sensitive learning, the costs of false positive (actual negative but predicted as positive; denoted as *FP*), false negative (*FN*), true positive (*TP*), and true negative (*TN*) can be given in a cost matrix, as shown in Table 1. In the table, the notation $C(i,j)$ is also used to represent the misclassification cost of classifying an instance from its actual class j into the predicted class i (1 is used for positive, and 0 for negative). These misclassification cost values can be given by domain experts, or learned via other approaches. In cost-sensitive learning, it is usually assumed that such a cost matrix is given and known. For multiple classes, the cost matrix can be easily extended by adding more rows and more columns.

Note that $C(i,i)$ (*TP* and *TN*) is usually regarded as the "benefit" (i.e., negated cost) when an instance is predicted correctly. In addition, cost-sensitive learning is often used to deal with datasets with very imbalanced class distributions (see ▶ Class Imbalance Problem) (Japkowicz and Stephen 2002). Usually (and without loss of generality), the minority or rare class is regarded as the positive class, and it is often more expensive to misclassify an actual positive example into negative, than an actual negative example into positive. That is, the value of $FN = C(0,1)$ is usually larger than that of $FP = C(1,0)$. This is true for the cancer example mentioned earlier (cancer patients are usually rare in the population, but predicting an actual cancer patient as negative is usually very costly) and the bomb example (terrorists are rare).

Given the cost matrix, an example should be classified into the class that has the minimum expected cost. This is the minimum expected cost principle. The expected cost $R(i|x)$ of classifying an instance x into class i (by a classifier) can be expressed as:

$$R(i|x) = \sum_j P(j|x)C(j,i), \qquad (1)$$

where $P(j|x)$ is the probability estimation of classifying an instance into class j. That is, the classifier will classify an instance x into positive class if and only if:

$$P(0|x)C(1,0) + P(1|x)C(1,1) \leq P(0|x)C(0,0) \\ + P(1|x)C(0,1)$$

This is equivalent to:

$$P(0|x)C(1,0) - C(0,0) \leq P(1|x) \\ (C(0,1) - C(1,1))$$

Thus, the decision (of classifying an example into positive) will not be changed if a constant is added into a column of the original cost matrix. Thus, the original cost matrix can always be converted to a simpler one by subtracting $C(0,0)$ to the first column, and $C(1,1)$ to the second column. After such conversion, the simpler cost matrix is shown in Table 2. Thus, any given cost-matrix can be converted to one with $C(0,0) = C(1,1) = 0$. (Here it is assumed that the misclassification cost is the same for all examples. This property is a special case of the one discussed in Elkan (2001).) In the rest of the paper, it will be assumed that $C(0,0) = C(1,1) = 0$. Under this

Cost-Sensitive Learning, Table 2 A simpler cost matrix with an equivalent optimal classification

	True negative	True positive
Predict negative	0	$C(0,1) - C(1,1)$
Predict positive	$C(1,0) - C(0,0)$	0

assumption, the classifier will classify an instance x into positive class if and only if:

$$P(0|x)C(1,0) \leq P(1|x)C(0,1)$$

As $P(0|x) = 1 - P(1|x)$, a threshold p^* can be obtained for the classifier to classify an instance x into positive if $P(1|x) \geq p^*$, where

$$P^* = \frac{C(1,0)}{C(1,0) + C(0,1)}. \qquad (2)$$

Thus, if a cost-insensitive classifier can produce a posterior probability estimation $p(1|x)$ for each test example x, one can make the classifier cost-sensitive by simply choosing the classification threshold according to (2), and classify any example to be positive whenever $P(1|x) \geq p^*$. This is what several cost-sensitive meta-learning algorithms, such as *Relabeling*, are based on (see later for details). However, some cost-insensitive classifiers, such as C4.5, may not be able to produce accurate probability estimation; they return a class label without a probability estimate. *Empirical Thresholding* (Sheng and Ling 2006) does not require accurate estimation of probabilities – an accurate ranking is sufficient. It simply uses ▸ cross-validation to search for the best probability value $p*$ to use as a threshold.

Traditional cost-insensitive classifiers are designed to predict the class in terms of a default, fixed threshold of 0.5. Elkan (2001) shows that one can "rebalance" the original training examples by sampling, such that the classifiers with the 0.5 threshold is equivalent to the classifiers with the p^* threshold as in (2), in order to achieve cost-sensitivity. The rebalance is done as follows. If all positive examples (as they are assumed as the rare class) are kept, then the number of negative examples should be multiplied by $C(1,0)/C(0,1) = FP/FN$. Note that as usualy $FP < FN$, the multiple is less than 1. This is, thus, often called "under-sampling the majority class." This is also equivalent to "proportional sampling," where positive and negative examples are sampled by the ratio of:

$$p(1)FN : p(0)FP \qquad (3)$$

where $p(1)$ and $p(0)$ are the prior probability of the positive and negative examples in the original training set. That is, the prior probabilities and the costs are interchangeable: doubling $p(1)$ has the same effect as doubling *FN*, or halving *FP* (Drummond and Holte 2000). Most sampling meta-learning methods, such as costing (Zadrozny et al. 2003), are based on (3) above (see later for details).

Almost all meta-learning approaches are either based on (2) or (3) for the thresholding- and sampling-based meta-learning methods, respectively, to be discussed in the next section.

Structure of Learning System

Broadly speaking, cost-sensitive learning can be categorized into two categories. The first one is to design classifiers that are cost-sensitive in themselves. They are called the direct method. Examples of direct cost-sensitive learning are ICET (Turney 1995) and cost-sensitive decision tree (Drummond and Holte 2000; Ling et al. 2004). The other category is to design a "wrapper" that converts any existing cost-insensitive (or cost-blind) classifiers into cost-sensitive ones. The wrapper method is also called cost-sensitive meta-learning method, and it can be further categorized into thresholding and sampling. Here is a hierarchy of the cost-sensitive learning and some typical methods. This paper will focus on cost-sensitive meta-learning that considers the misclassification cost only.

Cost-Sensitive learning

– Direct methods
  - ICET (Turney 1995)
  - Cost-sensitive decision trees (Drummond and Holte 2000; Ling et al. 2004)

- Meta-learning
  - Thresholding
    - MetaCost (Domingos 1999)
    - CostSensitiveClassifier (CSC in short) (Witten and Frank 2005)
    - Cost-sensitive naïve Bayes (Chai et al. 2004)
    - Empirical Thresholding (ET in short) (Sheng and Ling 2006)
  - Sampling
    - Costing (Zadrozny et al. 2003)
    - Weighting (Ting 1998)

Direct Cost-Sensitive Learning

The main idea of building a direct cost-sensitive learning algorithm is to directly introduce and utilize misclassification costs into the learning algorithms. There are several works on direct cost-sensitive learning algorithms, such as ICET (Turney 1995) and cost-sensitive decision trees (Ling et al. 2004).

ICET (Turney 1995) incorporates misclassification costs in the fitness function of genetic algorithms. On the other hand, cost-sensitive decision tree (Ling et al. 2004), called CSTree here, uses the misclassification costs directly in its tree building process. That is, instead of minimizing entropy in attribute selection as in C4.5, CSTree selects the best attribute by the expected total cost reduction. That is, an attribute is selected as a root of the (sub) tree if it minimizes the total misclassification cost.

Note that as both ICET and CSTree directly take costs into model building, they can also take easily attribute costs (and perhaps other costs) directly into consideration, while meta cost-sensitive learning algorithms generally cannot.

Drummond and Holte (2000) investigate the cost-sensitivity of the four commonly used attribute selection criteria of decision tree learning: accuracy, Gini, entropy, and DKM. They claim that the sensitivity of cost is highest with the accuracy, followed by Gini, entropy, and DKM.

Cost-Sensitive Meta-Learning

Cost-sensitive meta-learning converts existing cost- insensitive classifiers into cost-sensitive ones without modifying them. Thus, it can be regarded as a middleware component that preprocesses the training data, or post-processes the output, from the cost-insensitive learning algorithms.

Cost-sensitive meta-learning can be further classified into two main categories: *thresholding* and *sampling*, based on (2) and (3) respectively, as discussed in the theory section.

Thresholding uses (2) as a threshold to classify examples into positive or negative if the cost-insensitive classifiers can produce probability estimations. *MetaCost* (Domingos 1999) is a *thresholding* method. It first uses bagging on decision trees to obtain reliable probability estimations of training examples, relabels the classes of training examples according to (2), and then uses the relabeled training instances to build a cost-insensitive classifier. *CSC* (Witten and Frank 2005) also uses (2) to predict the class of test instances. More specifically, *CSC* uses a cost-insensitive algorithm to obtain the probability estimations $P(j|x)$ of each test instance. (CSC is a meta-learning method and can be applied to any classifiers.) Then it uses (2) to predict the class label of the test examples. Cost-sensitive naïve Bayes (Chai et al. 2004) uses (2) to classify test examples based on the posterior probability produced by the naïve Bayes.

As seen, all *thresholding*-based meta-learning methods rely on accurate probability estimations of $p(1|x)$ for the test example x. To achieve this, Zadrozny and Elkan (2001) propose several methods to improve the calibration of probability estimates. *ET* (Empirical Thresholding) (Sheng and Ling 2006) is a thresholding-based meta-learning method. It does not require accurate estimation of probabilities – an accurate ranking is sufficient. *ET* simply uses cross-validation to search the best probability from the training instances as the threshold, and uses the searched threshold to predict the class label of test instances.

On the other hand, *sampling* first modifies the class distribution of the training data according to (3), and then applies cost-insensitive classifiers on the sampled data directly. There is no need for the classifiers to produce probability estimations, as long as they can classify positive or negative examples accurately. Zadrozny et al. (2003) show that proportional sampling with replacement produces duplicated cases in the training, which in turn produces overfitting in model building. Instead, Zadrozny et al. (2003) proposes to use "rejection sampling" to avoid duplication. More specifically, each instance in the original training set is drawn once, and accepted into the sample with the accepting probability $C(j,i)/Z$, where $C(j,i)$ is the misclassification cost of class i, and Z is an arbitrary constant such that $Z \geq \max C(j,i)$. When $Z = \max_{ij} C(j,i)$, this is equivalent to keeping all examples of the rare class, and sampling the majority class without replacement according to $C(1,0)/C(0,1)$ – in accordance with (3). Bagging is applied after rejection sampling to improve the results further. The resulting method is called *Costing*.

Weighting (Ting 1998) can also be viewed as a sampling method. It assigns a normalized weight to each instance according to the misclassification costs specified in (3). That is, examples of the rare class (which carries a higher misclassification cost) are assigned, proportionally, high weights. Examples with high weights can be viewed as example duplication – thus oversampling. *Weighting* then induces cost-sensitivity by integrating the instances' weights directly into C4.5, as C4.5 can take example weights directly in the entropy calculation. It works whenever the original cost-insensitive classifiers can accept example weights directly. (Thus, it can be said that *Weighting* is a semi meta-learning method.) In addition, *Weighting* does not rely on bagging as *Costing* does, as it "utilizes" all examples in the training set.

Abstract

Covariance matrix is a generalization of covariance between two univariate random variables. It is composed of the pairwise covariance between components of a multivariate random variable. It underpins important stochastic processes such as Gaussian process, and in practice it provides key characterizations between multiple random factors.

Definition

It is convenient to define a covariance matrix by using multivariate random variables (*mrv*): $\mathbf{X} = (X_1, \ldots, X_d)^\top$. For univariate random variables X_i and X_j, their covariance is defined as

$$\mathrm{Cov}(X_i, X_j) = \mathbb{E}\left[(X_i - \mu_i)\left(X_j - \mu_j\right)\right],$$

where μ_i is the mean of X_i: $\mu_i = \mathbb{E}[X_i]$. As a special case, when $i = j$, then we get the variance of X_i, $\mathrm{Var}(X_i) = \mathrm{Cov}(X_i, X_i)$. Now in the setting of *mrv*, assuming that each component random variable X_i has finite variance under its marginal distribution, the covariance matrix $\mathrm{Cov}(\mathbf{X}, \mathbf{X})$ can be defined as a d-by-d matrix whose (i, j)th entry is the covariance:

$$\begin{aligned}(\mathrm{Cov}(\mathbf{X}, \mathbf{X}))_{ij} &= \mathrm{Cov}\left(X_i, X_j\right) \\ &= \mathbb{E}\left[(X_i - \mu_i)\left(X_j - \mu_j\right)\right].\end{aligned}$$

And its inverse is also called precision matrix.

It is easy to rewrite the element-wise definition into the matrix form:

$$\mathrm{Cov}(\mathbf{X}, \mathbf{X}) = \mathbb{E}\left[(\mathbf{X} - \mathbb{E}[\mathbf{X}])(\mathbf{X} - \mathbb{E}[\mathbf{X}])^\top\right], \tag{1}$$

which naturally generalizes the variance of univariate random variables: $\mathrm{Var}(X) = \mathbb{E}[(X - \mathbb{E}[X])^2]$.

Moreover, it is also straightforward to extend the covariance of a single *mrv* $\mathbf{X}$ to two *mrv*'s $\mathbf{X}$ (d dimensional) and $\mathbf{Y}$ (s dimensional), under the name cross covariance. It quantifies how much the component random variables in $\mathbf{X}$ and $\mathbf{Y}$ change together. The cross-covariance matrix is defined as a $d \times s$ matrix $\mathrm{Cov}(\mathbf{X}, \mathbf{Y})$ whose (i, j)th entry is

$$(\mathrm{Cov}(\mathbf{X}, \mathbf{Y}))_{ij} = \mathrm{Cov}(X_i, Y_j) \tag{2}$$

$$= \mathbb{E}\left[(X_i - \mathbb{E}[X_i])\left(Y_j - \mathbb{E}[Y_j]\right)\right]. \tag{3}$$

$\mathrm{Cov}(\mathbf{X}, \mathbf{Y})$ can also be written in the matrix form as

$$\mathrm{Cov}(\mathbf{X}, \mathbf{Y}) = \mathbb{E}\left[(\mathbf{X} - \mathbb{E}[\mathbf{X}])(\mathbf{Y} - \mathbb{E}[\mathbf{Y}])^\top\right],$$

where the expectation is with respect to the joint distribution of $(\mathbf{X}, \mathbf{Y})$. Obviously, $\mathrm{Cov}(\mathbf{X}, \mathbf{Y})$ becomes $\mathrm{Cov}(\mathbf{X}, \mathbf{X})$ when $\mathbf{Y} = \mathbf{X}$.

Motivation and Background

The covariance between two univariate random variables measures how much they change together, and as a special case, the covariance of a random variable with itself is exactly its variance. It is important to note that covariance is an unnormalized measure of the correlation between the random variables.

As a generalization to multivariate random variables $\mathbf{X} = (X_1, \ldots, X_d)^\top$, the covariance matrix is a d-by-d matrix whose (i, j)th component is the covariance between X_i and X_j.

In many applications, it is important to characterize the relations between a set of factors, hence the covariance matrix plays an important role in practice, especially in machine learning.

Theory

Properties

Covariance $\mathrm{Cov}(\mathbf{X},\mathbf{X})$ has the following properties:

1. Positive semi-definiteness. It follows from Eq. (1) that $\mathrm{Cov}(\mathbf{X},\mathbf{X})$ is positive semi-definite. $\mathrm{Cov}(\mathbf{X},\mathbf{X}) = \mathbf{0}$ if, and only if, $\mathbf{X}$ is constant almost surely, i.e., there exists a constant $\boldsymbol{x}$ such that $\Pr(\mathbf{X} \neq \boldsymbol{x}) = 0$. $\mathrm{Cov}(\mathbf{X},\mathbf{X})$ is not positive definite if, and only if, there exists a constant $\boldsymbol{\alpha}$ such that $\langle \boldsymbol{\alpha}, \mathbf{X} \rangle$ is constant almost surely.
2. Relating cumulant to moments: $\mathrm{Cov}(\mathbf{X},\mathbf{X}) = \mathbb{E}[\mathbf{X}\mathbf{X}^\top] - \mathbb{E}[\mathbf{X}]\mathbb{E}[\mathbf{X}]^\top$.
3. Linear transform: If $\mathbf{Y} = \mathbf{A}\mathbf{X} + \mathbf{b}$ where $\mathbf{A} \in \mathbb{R}^{s\times d}$ and $\mathbf{b} \in \mathbb{R}^s$, then $\mathrm{Cov}(\mathbf{Y},\mathbf{Y}) = \mathbf{A}\mathrm{Cov}(\mathbf{X},\mathbf{X})\mathbf{A}^\top$.

Cross-covariance $\mathrm{Cov}(\mathbf{X},\mathbf{Y})$ has the following properties:

1. Symmetry: $\mathrm{Cov}(\mathbf{X},\mathbf{Y}) = \mathrm{Cov}(\mathbf{Y},\mathbf{X})$.
2. Linearity: $\mathrm{Cov}(\mathbf{X}_1 + \mathbf{X}_2, \mathbf{Y}) = \mathrm{Cov}(\mathbf{X}_1,\mathbf{Y}) + \mathrm{Cov}(\mathbf{X}_2,\mathbf{Y})$.
3. Relating to covariance: If $\mathbf{X}$ and $\mathbf{Y}$ have the same dimension, then $\mathrm{Cov}(\mathbf{X}+\mathbf{Y}, \mathbf{X}+\mathbf{Y}) = \mathrm{Cov}(\mathbf{X},\mathbf{X}) + \mathrm{Cov}(\mathbf{Y},\mathbf{Y}) + 2\mathrm{Cov}(\mathbf{Y},\mathbf{X})$.
4. Linear transform: $\mathrm{Cov}(\mathbf{A}\mathbf{X}, \mathbf{B}\mathbf{Y}) = \mathbf{A}\mathrm{Cov}(\mathbf{X}, \mathbf{Y})\mathbf{B}$.

It is highly important to note that $\mathrm{Cov}(\mathbf{X},\mathbf{Y}) = 0$ is a necessary but not sufficient condition for $\mathbf{X}$ and $\mathbf{Y}$ to be independent.

Correlation Coefficient

Entries in the covariance matrix are sometimes presented in a normalized form by dividing each entry by its corresponding standard deviations. This quantity is called the correlation coefficient, represented as ρ_{X_i,X_j}, and defined as

$$\rho_{X_i,X_j} = \frac{\mathrm{Cov}(X_i,X_j)}{\mathrm{Cov}(X_i,X_i)^{1/2}\mathrm{Cov}(X_j,X_j)^{1/2}}.$$

The corresponding matrix is called the correlation matrix, and for Γ_X set to $\mathrm{Cov}(\mathbf{X},\mathbf{X})$ with all non-diagonal entries zeroed, and Γ_Y likewise, then the correlation matrix is given by

$$\mathrm{Corr}(\mathbf{X},\mathbf{Y}) = \Gamma_X^{-1/2}\mathrm{Cov}(\mathbf{X},\mathbf{Y})\Gamma_Y^{-1/2}.$$

The correlation coefficient takes on values between $[-1, 1]$.

Parameter Estimation

Given observations $\boldsymbol{x}_1, \ldots, \boldsymbol{x}_n$ of a *mrv* $\mathbf{X}$, an unbiased estimator of $\mathrm{Cov}(\mathbf{X},\mathbf{X})$ is

$$S = \frac{1}{n-1}\sum_{i=1}^{n}(\boldsymbol{x}_i - \bar{\boldsymbol{x}})(\boldsymbol{x}_i - \bar{\boldsymbol{x}})^\top,$$

where $\bar{\boldsymbol{x}} = \frac{1}{n}\sum_{i=1}^{n}\boldsymbol{x}_i$. The denominator $n-1$ reflects the fact that the mean is unknown and the sample mean is used in place. Note the maximum likelihood estimator in this case replaces the denominator $n-1$ by n.

Conjugate Priors

Covariance matrix is used to define the Gaussian distribution. In this case, the inverse Wishart distribution is the conjugate prior for the covariance matrix. Since the gamma distribution is a 1-D version of the Wishart distribution, hence in the 1-D case, the gamma is the conjugate prior for precision matrix.

Applications

Several key uses of the covariance matrix are reviewed here.

Correlation and Least Squares Approximation

In many machine learning problems, we often need to quantify the correlation of two *mrv*s which may be from two different spaces. For example, we may want to study how much the image stream of a movie is correlated with the comments it receives. For simplicity, we consider a r-dimensional *mrv* $\mathbf{X}$ and a s-dimensional *mrv* $\mathbf{Y}$. To study their correlation, suppose we have n pairs of observations $\{(\boldsymbol{x}_i, \boldsymbol{y}_i)\}_{i=1}^n$ drawn *iid* from certain underlying joint distribution of $(\mathbf{X}, \mathbf{Y})$. Let $\bar{\boldsymbol{x}} = \frac{1}{n}\sum_{i=1}^n \boldsymbol{x}_i$ and $\bar{\boldsymbol{y}} = \frac{1}{n}\sum_{i=1}^n \boldsymbol{y}_i$ and stack $\{\boldsymbol{x}_i\}$ and $\{\boldsymbol{y}_i\}$ into $\tilde{X} = (\boldsymbol{x}_1, \ldots, \boldsymbol{x}_n)^\top$ and $\tilde{Y} = (\boldsymbol{y}_1, \ldots, \boldsymbol{y}_n)^\top$, respectively. Then the cross-covariance matrix $\mathrm{Cov}(\mathbf{X}, \mathbf{Y})$ can be estimated by $\frac{1}{n}\sum_{i=1}^n (\boldsymbol{x}_i - \bar{\boldsymbol{x}})(\boldsymbol{y}_i - \bar{\boldsymbol{y}})^\top$. To quantify the cross correlation by a real number, we need to apply some norm of the cross-covariance matrix, and the simplest one is the Frobenius norm: $\|A\|_F^2 = \sum_{ij} A_{ij}^2$. Therefore we obtain a measure of cross correlation:

$$\left\| \frac{1}{n}\sum_{i=1}^n (\boldsymbol{x}_i - \bar{\boldsymbol{x}})(\boldsymbol{y}_i - \bar{\boldsymbol{y}})^\top \right\|_F^2 = \frac{1}{n} H\tilde{X}\tilde{X}^\top H\tilde{Y}\tilde{Y}^\top, \tag{4}$$

where $H_{ij} = \delta_{ij} - \frac{1}{n}$ and $\delta_{ij} = 1$ if $i = j$ and 0 otherwise. It is important to notice that (a) in this measure, inner product is performed only in the space of $\mathbf{X}$ and $\mathbf{Y}$ separately, i.e., no transformation between $\mathbf{X}$ and $\mathbf{Y}$ is required, and (b) the data points affect the measure only via inner products $\boldsymbol{x}_i^\top \boldsymbol{x}_j$ as the (i, j)th entry of $\tilde{X}\tilde{X}^\top$ (and similarly for $\boldsymbol{y}_i$). Hence we can endow new inner products on $\mathbf{X}$ and $\mathbf{Y}$, which eventually allows us to apply kernels, e.g., Gretton et al. (2005). In a nutshell, kernels (Schölkopf and Smola 2002) redefine the inner product $\boldsymbol{x}_i^\top \boldsymbol{x}_j$ by mapping $\boldsymbol{x}_i$ to a richer feature space via $\phi(\boldsymbol{x}_i)$ and then compute the inner product there: $k(\boldsymbol{x}_i, \boldsymbol{x}_j) := \phi(\boldsymbol{x}_i)^\top \phi(\boldsymbol{x}_j)$. Since the measure in Eq. (4) only needs inner products, one can even directly define k without explicitly specifying ϕ. This allows us to (a) implicitly use a rich feature space whose dimension can be infinitely high and (b) apply this measure of independence to non-Euclidean spaces as long as a kernel $k(\boldsymbol{x}_i, \boldsymbol{x}_j)$ can be defined on it.

Interestingly, this measure can be equivalently motivated by least square linear regression. That is, we look for a linear transform $T : \mathbb{R}^d \to \mathbb{R}^s$ which minimizes

$$\frac{1}{n}\sum_{i=1}^n \|(\boldsymbol{y}_i - \bar{\boldsymbol{y}}) - T(\boldsymbol{x}_i - \bar{\boldsymbol{x}})\|^2 .$$

And one can show that its minimum objective value is exactly equal to Eq. (4) up to a constant, as long as all $\boldsymbol{y}_i - \bar{\boldsymbol{y}}$ and $\boldsymbol{x}_i - \bar{\boldsymbol{x}}$ have unit length. In practice, this can be achieved by normalization. Or, the measure in Eq. (4) itself can be normalized by replacing the covariance matrix with the correlation matrix.

Principal Component Analysis

The covariance matrix plays a key role in principal component analysis (PCA). Assume we are given n *iid* observations $\boldsymbol{x}_1, \ldots, \boldsymbol{x}_n$ of a *mrv* $\mathbf{X}$, and let $\bar{\boldsymbol{x}} = \frac{1}{n}\sum_i \boldsymbol{x}_i$. PCA tries to find a set of orthogonal directions $\boldsymbol{w}_1, \boldsymbol{w}_2, \ldots$, such that the projection of $\mathbf{X}$ to the direction $\boldsymbol{w}_1$, $\boldsymbol{w}_1^\top \mathbf{X}$ has the highest variance among all possible directions in the d-dimensional space. After subtracting from $\mathbf{X}$ the projection to $\boldsymbol{w}_1$, $\boldsymbol{w}_2$ is chosen as the highest variance projection direction for the remainder. This procedure goes on, giving $\boldsymbol{w}_3, \ldots, \boldsymbol{w}_d$.

To find $\boldsymbol{w}_1 := \mathrm{argmax}_{\boldsymbol{w}} \mathrm{Var}(\boldsymbol{w}^\top \mathbf{X})$, we need an empirical estimate of $\mathrm{Var}(\boldsymbol{w}^\top \mathbf{X})$. Estimating $\mathbb{E}[(\boldsymbol{w}^\top \mathbf{X})^2]$ by $\boldsymbol{w}^\top \left(\frac{1}{n}\sum_i \boldsymbol{x}_i \boldsymbol{x}_i^\top\right) \boldsymbol{w}$ and $\mathbb{E}[\boldsymbol{w}^\top \mathbf{X}]$ by $\frac{1}{n}\sum_i \boldsymbol{w}^\top \boldsymbol{x}_i$, we get

$$\boldsymbol{w}_1 = \mathrm{argmax}_{\boldsymbol{w}:\|\boldsymbol{w}_1\|=1} \boldsymbol{w}^\top S \boldsymbol{w}, \quad \text{where}$$

$$S = \frac{1}{n}\sum_{i=1}^n (\boldsymbol{x}_i - \bar{\boldsymbol{x}})(\boldsymbol{x}_i - \bar{\boldsymbol{x}})^\top,$$

i.e., S is $\frac{n}{n-1}$ times the unbias empirical estimate of the covariance of $\mathbf{X}$, based on samples $\boldsymbol{x}_1, \ldots, \boldsymbol{x}_n$. $\boldsymbol{w}_1$ turns out to be exactly the eigenvector of S corresponding to the greatest eigenvalue.

Note that PCA is independent of the distribution of $\mathbf{X}$. More details on PCA can be found at Jolliffe (2002).

Gaussian Processes

Gaussian processes are another important framework in machine learning that relies on the covariance matrix. It is a distribution over functions $f(\cdot)$ from certain space $\mathcal{X}$ to $\mathbb{R}$, such that for any $n \in \mathbb{N}$ and any n points $\{\boldsymbol{x}_i \in \mathcal{X}\}_{i=1}^n$, the set of values of f evaluated at $\{\boldsymbol{x}_i\}_i$, $\{f(x_1), \ldots, f(x_n)\}$, will have an n-dimensional Gaussian distribution. Different choices of the covariance matrix of the multivariate Gaussian lead to different stochastic processes such as

Wiener process, Brownian motion, Ornstein-Uhlenbeck process, etc. In these cases, it makes more sense to define a covariance function $C : \mathcal{X} \times \mathcal{X} \mapsto \mathbb{R}$, such that given any set $\{\boldsymbol{x}_i \in \mathcal{X}\}_{i=1}^n$ for any $n \in \mathbb{N}$, the n-by-n matrix $\left(C(\boldsymbol{x}_i, \boldsymbol{x}_j)\right)_{ij}$ is positive semi-definite and can be used as the covariance matrix. This further allows straightforward kernelization of a Gaussian process by using the kernel function as the covariance function.

Although the space of functions is infinite dimensional, the marginalization property of multivariate Gaussian distributions guarantees that the user of the model only needs to consider the observed $\boldsymbol{x}_i$ and ignore all the other possible $\boldsymbol{x} \in \mathcal{X}$. This important property says that for a *mrv* $\mathbf{X} = (\mathbf{X}_1^\top, \mathbf{X}_2^\top)^\top \sim \mathcal{N}(\boldsymbol{\mu}, \Sigma)$, the marginal distribution of $\mathbf{X}_1$ is $\mathcal{N}(\boldsymbol{\mu}_1, \Sigma_{11})$, where Σ_{11} is the submatrix of Σ corresponding to $\mathbf{X}_1$ (and similarly for $\boldsymbol{\mu}_1$). So taking into account the random variable $\mathbf{X}_2$ will not change the marginal distribution of $\mathbf{X}_1$.

Covering Algorithm

Johannes Fürnkranz
Knowledge Engineering Group, TU Darmstadt,
Darmstadt, Deutschland
Department of Information Technology,
University of Leoben, Leoben, Austria

Abstract

The covering algorithm is the dominant approach to classification ▸ rule learning. Its distinguishing feature is the idea to learn one rule at a time, successively removing all training examples that are covered by the learned rules.

Synonyms

Separate-and-conquer learning

Method

Most covering algorithms operate in a ▸ concept learning framework, i.e., they assume a set of positive and negative training examples. Adaptations to the multi-class case are typically performed via ▸ class binarization, learning different ▸ rule sets for binary problems. Some algorithms, most notably CN2 (Clark and Niblett 1989; Clark and Boswell 1991), learn multi-class rules directly by optimizing overall possible classes in the head of the rule. In this case, the resulting theory is interpreted as a ▸ decision list. In the following, we will assume a two-class problem with a positive and a negative class.

The Covering algorithm starts with an empty theory. If there are any positive examples in the training set, it calls the subroutine FindBestRule for learning a single rule that

```
procedure COVERING(Examples, Classifier)

Input: Examples, a set of positive and negative examples
for a class $c$.

// initialize the classifier
$Classifier = \emptyset$

//loop until no more positive examples are covered
while POSITIVE(Examples) $\neq \emptyset$ do

    // find the best rule for the current examples
    $Rule$ = FINDBESTRULE(Examples)

    // check if we need more rules
    if RULESTOPPINGCRITERION(Classifier,Rule,
      Examples)
    then  break while

    // remove covered examples and add rule to rule set
    $Examples = Examples \setminus$ COVER(Rule,Examples)
    $Classifier = Classifier \cup Rule$

endwhile

// post-process the rule set (e.g., pruning)
$Classifier$ = POSTPROCESSING (Classifier)

Output: Classifier
```

will cover a subset of the positive examples (and possibly some negative examples as well). All covered examples are then separated from the training set, the learned rule is added to the theory, and another rule is learned from the remaining examples. Rules are learned in this way until no positive examples are left or until the RULESTOPPINGCRITERION fires. In the simplest case, the stopping criterion is a check whether there are still remaining positive examples that need to be covered. The resulting theory may also undergo some POSTPROCESSING, e.g., a separate pruning and re-induction phase as in RIPPER (Cohen 1995).

A more extensive survey of this family of algorithms can be found in Fürnkranz (1999a).

Credit Assignment

Claude Sammut

Synonyms

Structural credit assignment; Temporal credit assignment

Definition

When a learning system employs a complex decision process, it must assign credit or blame for the outcomes to each of its decisions. Where it is not possible to directly attribute an individual outcome to each decision, it is necessary to apportion credit and blame between each of the combinations of decisions that contributed to the outcome. We distinguish two cases in the credit assignment problem. *Temporal credit assignment* refers to the assignment of credit for outcomes to actions. *Structural credit assignment* refers to the assignment of credit for actions to internal decisions. The first subproblem involves determining when the actions that deserve credit were taken and the second involves assigning credit to the internal structure of actions (Sutton 1984).

Motivation

Consider the problem of learning to balance a pole that is hinged on a cart (Michie and Chambers 1968; Anderson and Miller 1991). The cart is constrained to run along a track of finite length and a fixed force can be applied to push the cart left or right. A controller for the pole and cart system must make a decision whether to push left or right at frequent, regular time intervals, for example, 20 times a second. Suppose that this controller is capable of learning from trial-and-error. If the pole falls over, then it must determine which actions it took helped or hurt its performance. Determining that action is the problem of *temporal credit assignment*. Although the actions are directly responsible for the outcome of a trial, the internal process for choosing the action indirectly affects the outcome. Assigning credit or blame to those internal processes that lead to the choice of action is the *structural credit assignment* problem. In the case of pole balancing, the learning system will typically keep statistics such as how long, on average, the pole remained balanced after taking a particular action in a particular state, or after a failure, it may count back and determine the average amount of time to failure after taking a particular action in a particular state. Using these statistics, the learner attempts to determine the best action for a given state.

The above example is typical of many problems in ▸ reinforcement learning (Sutton and Barto 1998), where an agent interacts with its environment and through that interaction, learns to improve its performance in a task. Although Samuel (1959) was the first to use a form of reinforcement learning in his checkers playing program, Minsky (1961) first articulated the credit assignment, as follows:

> Using devices that also learn which events are associated with reinforcement, i.e., reward, we can build more autonomous "secondary reinforcement" systems. In applying such methods to complex problems, one encounters a serious difficulty – in distributing credit for success of a complex strategy among the many decisions that were involved.

The BOXES algorithm of Michie and Chambers (1968) learned to control a pole balancer and performed credit assignment but the problem of credit assignment later became central to reinforcement learning, particularly following the work of Sutton (1984). Although credit assignment has become most strongly identified with reinforcement learning, it may appear in any learning system that attempts to assess and revise its decision-making process.

Structural Credit Assignment

The setting for our learning system is that we have an agent that interacts with an environment. The environment may be a virtual one, as in game playing, or it may be physical, as in a robot performing some task. The agent receives input, possibly through sensing devices, that allows it to characterize the state of the world. Somehow, the agent must map these inputs to appropriate responses. These responses may change the state of the world. In reinforcement learning, we assume that the agent will receive some reward signal after an action or sequence of actions. Its job is to maximize these rewards over time.

Structural credit assignment is associated with generalization over the input space of the agent. For example, a game player may have to respond to a very large number of potential board positions or a robot may have to respond to a stream of camera images. It is infeasible to learn a complete mapping from every possible input to every possible output. Therefore, a learning agent will typically use some means of grouping input signals. In the case of the BOXES pole balancer, Michie and Chambers discretized the state space. The state is characterized by the cart's position and velocity and the pole's angle and angular velocity. These parameters create a four-dimensional space, which was broken into three regions (left, center, right) for the pole angle, five for the angular velocity, and three for the cart position and velocity. These choices were arbitrary and other combinations also worked.

Having divided the input space into non-overlapping regions, Michie and Chambers associated a push-left and push-right action with each region, or box. The learning algorithm maintains a score for each action and chooses the next action based on that score. BOXES was an early, and simple example, of creating an internal representation for mapping inputs to outputs. The problem with this method is that the structure of the decision-making system is fixed at the start and the learner is incapable of changing the representation. This may be needed if, for example, the subdivisions that were chosen do not correspond to a real decision boundary. A learning system that could adapt its representation has an advantage, in this case.

The BOXES representation can be thought of as a lookup table that implements a function that maps an input to an output. The fixed lookup table can be replaced by a function approximator that, given examples from the desired function, generalizes from them to construct an approximation of that function. Different function approximation techniques can be used. For example, Moore's (1990) function approximator was a ▶ nearest-neighbor algorithm, implemented using kd-tree to improve efficiency. Other function approximation methods may also be used, e.g., Albus' CMAC algorithm (1975), ▶ locally weighted regression (Atkeson et al. 1997), ▶ perceptrons Rosenblatt (1962), multi-layer networks (Hinton et al. 1985), ▶ radial basis functions, etc. Structural credit assignment is also addressed in the creation of hierarchical representations. See ▶ hierarchical reinforcement learning. Other approaches to structural credit assignment include ▶ Value function approximation (Bertsekas and Tsitsiklis 1996) and automatic basis generation (Mahadevan 2009). See the entry on ▶ Gaussian Processes for examples of recent Bayesian and kernel method based approaches to solving the credit assignment problem.

Temporal Credit Assignment

In the pole balancing example described above, the learning system receives a signal when the pole has fallen over. How does it know which actions leading up to the failure contributed to the fall? The system will receive a high-level punishment in the event of a failure or a reward in tasks where there is a goal to be achieved. In either case, it makes sense to assign the greatest credit or blame to the most recent actions and assign progressively less to the preceding actions. Each time a learning trial is repeated, the value of an action is updated so that if it leads to another action of higher value, its weight is increased. Thus, the reward or punishment propagates back through the sequence of decisions taken by the system. The credit assignment problem was addressed by Michie and Chambers, in the BOXES, algorithm but many other solutions have subsequently been proposed. See the entries on ▶ Q-learning (Watkins 1989, 1992) and ▶ temporal difference learning (Barto et al. 1983; Sutton 1984).

Although temporal credit assignment is usually associated with reinforcement learning, it also appears in other forms of learning. In learning by imitation or ▶ behavioral cloning, an agent observes the actions of another agent and tries to learn from traces of behaviors. In this case, the learner must judge which actions of the other agent should receive credit or blame. Plan learning also encounters the same problem (Benson 1995; Wang 1996), as does ▶ explanation-based learning (Mitchell et al. 1986; Dejong and Mooney 1986; Laird et al. 1987).

To illustrate the connection with explanation-based learning, we use one of the earliest examples of this kind of learning, Mitchell and Utgoff's, LEX program (Mitchell et al. 1983). The program was intended to learn heuristics for performing symbolic integration. Given a mathematical expression that included an integral sign, the program tried to transform the expression into one they did not. The standard symbolic integration operators were known to the program but not when it is best to apply them. The task of the learning system was to learn the heuristics for when to apply the operators. This was done by experimentation. If no heuristics were available, the program attempted a brute force search. If the search was successful, all the operators applied, leading to the success were assumed to be positive examples for a heuristic, whereas operators applied during a failed attempt became negative examples. Thus, LEX performed a simple form of credit assignment, which is typical of any system that learns how to improve sequences of decisions.

▶ Genetic algorithms can also be used to evolve rules that perform sequences of actions (Holland 1986). When situation-action rules are applied in a sequence, we have a credit assignment problem that is similar to when we use a reinforcement learning. That is, how do we know which rules were responsible for success or failure and to what extent? Grefenstette (1988) describes a *bucket brigade* algorithm in which rules are given strengths that are adjusted to reflect credit or blame. This is similar to temporal difference learning except that in the bucket brigade the strengths apply to rules rather than states. See Classifier Systems and for a more comprehensive survey of bucket brigade methods, see Goldberg (1989).

Transfer Learning

After a person has learned to perform some task, learning a new, but related, task is usually easier because knowledge of the first learning episode is *transferred* to the new task. *Transfer Learning* is particularly useful for acquiring new concepts or behaviors when given only a small amount for training data. It can be viewed as a form of credit assignment because successes or failures in previous learning episodes bias future learning. Reid (2004, 2007) identifies three forms of ▶ inductive bias involved in transfer learning for rules: language bias, which determines what kinds of rules can be constructed by the learner; the search bias, which determines the order in which rules will be searched; and the evaluation bias, which determines how the quality of the rules will be assessed. Note that learning language bias is a form of structural credit assignment. Similarly, where rules are applied sequentially, evaluation bias becomes temporal credit assignment. Taylor and Stone (2009) give a comprehensive survey of transfer in ▶ reinforcement learning, in which they describe a variety of techniques for transferring the structure of an RL task from one case to another. They also survey methods for transferring evaluation bias.

Transfer learning can be applied in many different settings. Caruana (1997) developed a system for transferring inductive bias in ▶ neural networks performing multitask learning and more recent research has been directed toward transfer learning in ▶ Bayesian Networks (Niculescu and Caruana 2007).

Cross-Language Document Categorization

Document Categorization is the task consisting in assigning a document to zero, one or more categories in a predefined taxonomy. *Cross-language document categorization* describes the specific case in which one is interested in automatically categorize a document in a same taxonomy regardless of the fact that the document is written in one of several languages. For more details on the methods used to perform this task see ▶ cross-lingual text mining.

Cross-Language Information Retrieval

Cross-language information retrieval (CLIR) is the task consisting in recovering the subset of a document collection D relevant to a query q, in the special case in which D contains documents written in more than one language. Generally, it is additionally assumed that the subset of relevant documents must be returned as an ordered list, in decreasing order of relevance. For more details on methods and applications see ▶ cross-lingual text mining.

Cross-Language Question Answering

Question answering is the task consisting in finding in a document collection the answer to a question. CLCat is the specific case in which the question and the documents can be in different languages. For more details on the methods used to perform this task see ▶ cross-lingual text mining.

Cross-Lingual Text Mining

Nicola Cancedda and Jean-Michel Renders
Xerox Research Centre Europe, Meylan, France

Definition

Cross-lingual text mining is a general category denoting tasks and methods for accessing the information in sets of documents written in several languages, or whenever the language used to express an information need is different from the language of the documents. A distinguishing feature of cross-lingual text mining is the necessity to overcome some language translation barrier.

Motivation and Background

Advances in mass storage and network connectivity make enormous amounts of information easily accessible to an increasingly large fraction of the world population. Such information is mostly encoded in the form of running text which, in most cases, is written in a language different from the native language of the user. This state of affairs creates many situations in which the main barrier to the fulfillment of an information need is not technological but linguistic. For example, in some cases the user has some knowledge of the language in which the text containing a relevant piece of information is written, but does not have a sufficient control of this language to express his/her information needs. In other cases, documents in many different languages must be categorized in a same categorization schema, but manually categorized examples are available for only one language.

While the automatic translation of text from a natural language into another (machine translation) is one of the oldest problems on which computers have been used, a palette of other tasks has become relevant only more recently, due to the technological advances mentioned above. Most of them were originally motivated by needs of government Intelligence communities, but received a strong impulse from the diffusion of the World-Wide Web and of the Internet in general.

Tasks and Methods

A number of specific tasks fall under the term of Cross-lingual text mining (CLTM), including:

- *Cross-language information retrieval*
- *Cross-language document categorization*
- *Cross-language document clustering*
- *Cross-language question answering*

These tasks can in principle be performed using methods which do not involve any ▶ Text Mining, but as a matter of fact all of them have been successfully approached relying on the statistical analysis of multilingual document collections, especially *parallel corpora*. While CLTM tasks differ in many respect, they are all characterized by the fact that they require to reliably measure the similarity of two text spans written in different languages. There are essentially two families of approaches for doing this:

1. In *translation-based* approaches one of the two text spans is first translated into the language of the other. Similarity is then computed based on any measure used in mono-lingual cases. As a variant, both text spans can be translated in a third *pivot* language.
2. In *latent semantics* approaches, an abstract vector space is defined based on the statistical properties of a *parallel corpus* (or, more rarely, of a *comparable corpus*). Both text spans are then represented as vectors in such *latent semantic* space, where any similarity measure for vector spaces can be used.

The rest of this entry is organized as follows: first Translation-related approaches will be introduced, followed by Latent-semantic approaches. Finally, each of the specific CLTM tasks will be discussed in turn.

Translation-Based Approaches

The simplest approach consists in using a manually-written machine-readable bilingual dictionary: words from the first span are looked up and replaced with words in the second language (see e.g., Zhang and Vines 2005). Since typically dictionaries contain entries for "citation forms" only (e.g., the singular for nouns, the infinitive for verbs etc.), words in both spans are preliminarily *lemmatized*, i.e., replaced with the corresponding citation form. In all cases when the lexica and morphological analyzers required to perform lemmatization are not available, a frequently adopted crude alternative consists in *stemming* (i.e., truncating by taking away a suffix) both the words in the span to be translated and in the corresponding side in the lexicon. Some languages (e.g., Germanic languages) are characterized by a very productive *compounding*: simpler words are connected together to form complex words. Compound words are rarely in dictionaries as such: in order to find them it is first necessary to break compounds into their elements. This can be done based on additional linguistic resources or by means of heuristics, but in all cases it is a challenging operation in itself. If the method used afterward to compare the two spans in the target language can take weights into account, translations are "normalized" in such a way that the cumulative weight of all translations of a word is the same regardless of the number of alternative translations. Most often, the weight is simply distributed uniformly among all alternative translations. Sometimes, only the first translation for each word is kept, or the first two or three.

A second approach consists in extracting a bilingual lexicon from a *parallel corpus* instead of using a manually-written one. Methods for extracting probabilistic lexica look at the frequencies with which a word s in one language was translated with a word t to estimate the translation probability $p(t|s)$. In order to determine which word is the translation of which other word in the available examples, these examples are preliminarily aligned, first at the sentence level (to know what sentence is the translation of what other sentence) and then at the word level. Several methods for aligning sentences at the word level have been proposed, and this problem is a lively research topic in itself (see Brown et al. 1993 for a seminal paper).

Once a probabilistic bilingual dictionary is available, it can be used much in the same way as human-written dictionaries, with the notable difference that the estimated conditional probabilities provide a natural way to distribute weight across translations. When the example documents used for extracting the bilingual dictionaries are of the same style and domain as the text spans to be translated, this can result in a significant increase in accuracy for the final task, whatever this is.

It is often the case that a parallel corpus sufficiently similar in topic and style to the spans to be translated is unavailable, or it is too small to be used for reliably estimating translation probabilities. In such cases, it can be possible to replace or complement the parallel corpus with a "comparable" corpus. A comparable corpus is a pair of collections of documents, one in each of the languages of interest, which are known to be similar in content, although not the translation of one another. A typical case might be two sets of articles from corresponding sections of different newspapers collected during a same period of time. If some additional bilingual *seed* dictionary (human-written or extracted from a parallel corpus) is also available, then the comparable corpus can be leveraged as well: a word t is likely to be the translation of a word s if it turns out that the words often appearing near s are translations of the words often appearing near t. Using this observation it is thus possible to estimate the probability that t is a valid translation of s even though they are not contained in the original dictionary. Most approaches proceed by associating with s a *context vector*. This vector, with one component for each word in the source language, can simply be formed by summing together the count histograms of the words occurring within a fixed window centered in all occurrences of s in the corpus, but is often constructed using statistically more robust association measures, such as mutual information. After a possible normalization step, the context vector $CV(s)$ is translated using the seed dictionary into the target language. A context vector is also extracted from the corpus for all target words t. Eventually, a translation score between s and t is computed as $\langle Tr(CV(s)), CV(t)\rangle$:

$$\begin{aligned}\mathcal{S}(s,t) &= \langle CV(s), Tr(CV(t))\rangle \\ &= \sum_{(s',t')\in\mathcal{D}} a(s,s')a(t,t'),\end{aligned}$$

where a is the association score used to construct the context vector. While effective in many cases, this approach can provide inaccurate similarity values when polysemous words and synonyms appear in the corpus. To deal with this problem, Gaussier et al. (2004) propose the following extension:

$$\mathcal{S}(s,t) = \sum_{(s',t')\in\mathcal{D}} \left(\sum_{s'} a(s's'')a(s,s'')\right) \left(\sum_{t''} a(t',t'')a(t,t'')\right),$$

which is more robust in cases when the entries in the seed bilingual dictionary do not cover all senses actually present in the two sides of the comparable corpus.

Although these methods for building bilingual dictionaries can be (and often are) used in isolation, it can be more effective to combine them.

Using a bilingual dictionary directly is not the only way for translating a span from one language into another. A second alternative consists in using a *machine translation* (MT) system. While the MT system, in turn, relies on a bilingual dictionary of some sort, it is in general in the position of leveraging contextual clues to select the correct words and put them in the right order in the translation. This can be more or less useful depending on the specific task. MT systems fall, broadly speaking, into two classes: rule-based and statistical. Systems in the first class rely on sets of hand-written rules describing how words and syntactic structures should be translated. Statistical machine translation (SMT) systems learn this mapping by performing a statistical analysis of a parallel corpus. Some authors (e.g., Savoy and Berger 2005) also experimented with combining translation from multiple machine translation systems.

Latent Semantic Approaches

In CLTM, *Latent Semantic* approaches rely on some interlingua (language-independent) representation. Most of the time, this interlingua representation is obtained by linear or non-linear statistical analysis techniques and more specifically ▶ dimensionality reduction methods with ad-hoc optimization criterion and constraints. But, others adopt a more manual approach by exploiting multilingual thesauri or even multilingual ontologies in order to map textual objects towards a list – possibly weighted – of interlingua concepts.

For any textual object (typically a document or a section of document), the *interlingua* concept representation is derived from a sequence of operations that encompass:

1. Linguistic preprocessing (as explained in previous sections, this step amounts to extract the relevant, normalized "terms" of the textual objects, by tokenisation, word segmentation/decompounding, lemmatisation/stemming, part-of-speech tagging, stopword removal, corpus-based term filtering, Noun-phrase extractions, etc.).
2. Semantic enrichment and/or monolingual dimensionality reduction.
3. Interlingua semantic projection.

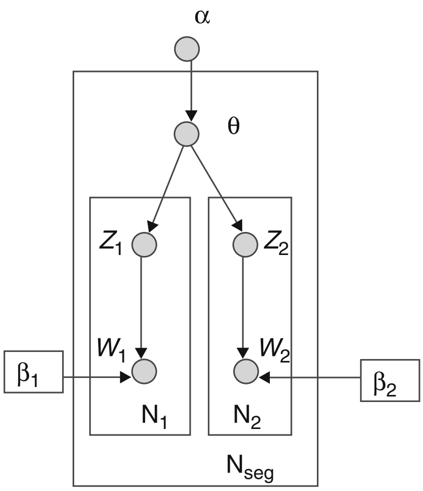
A typical semantic enrichment method is the *generalized vector space model*, that adds related terms – or neighbour terms – to each term of the textual object, neighbour terms being defined by some co-occurrence measures (for instance, mutual information). Semantic enrichment can alternatively be achieved by using (monolingual) thesaurus, exploiting relationships such as synonymy, hyperonymy and hyponymy. Monolingual dimensionality reduction consists typically in performing some *latent semantic analysis* (LSA), some form of principal component analysis on the textual object/term matrix. Dimensionality reduction techniques such as LSA or their discrete/probabilistic variants such as *probabilistic semantic analysis* (PLSA) and *latent dirichlet allocation* (LDA) offer to some extent a semantic robustness to deal with the effects of polysemy/synonymy, adopting a language-dependent concept representation in a space of dimension much smaller than the size of the vocabulary in a language.

Of course, steps (1) and (2) are highly language-dependent. Textual objects written in different languages will not follow the same linguistic processing or semantic enrichment/ dimensionality reduction. The last step (3), however, aims at projecting textual objects in the same language-independent concept space, for any source language. This is done by first extracting these common concepts, typically from a parallel corpus that offers a natural multiple-view representation of the same objects. Starting from these multiple-view observations, common factors are extracted through the use of canonical correlation analysis (CCA), cross-language latent semantic analysis, their kernelized variants (eg. Kernel-CCA) or their discrete, probabilistic extensions (cross-language latent dirichlet allocation, multinomial CCA, ...). All these methods try to discover latent factors that simultaneously explain as much as possible the "intra-language" variance and the "inter-language" correlation. They differ in the choice of the underlying distributions and how they precisely define and combine these two criteria. The following subsections will describe them in more details.

As already emphasized, CLTM mainly relies on defining appropriate similarities between textual objects expressed in different languages. Numerous categorization, clustering and retrieval algorithms focus on defining efficient and powerful measures of similarity between objects, as strengthened recently by the development of kernel methods for textual information access. We will see that the (linear) statistical algorithms used for performing steps (2) and (3) can most of the time be embedded into one valid (Mercer) kernel, so that we can very easily obtain non-linear variants of these algorithms, just by adopting some standard non-linear kernels.

Cross-Language Semantic Analysis

This amounts to concatenate the vectorial representation of each view of the objects of the parallel collection (typically, objects are aligned sentences), and then to perform standard singular value decomposition of the global object/term matrix. Equivalently, defining the kernel similarity matrix between all pairs of multi-view objects as the sum of the mono-lingual textual similarity matrices, this amounts to perform the eigenvalue decomposition of the corresponding kernel Gram matrix, if a dual formulation is adopted. The number of eigenvalues/eigenvectors that are retained to define the latent factors and the corresponding projections is typically from several hundreds of components to several thousands, still much fewer than the original sizes of the vocabulary. Note that this process does not really control the formation of *interlingua* concepts: nothing



Cross-Lingual Text Mining, Fig. 1 Latent dirichlet allocation of a parallel corpus

prevents the method from extracting factors that are linear combination of terms in one language only.

Cross-Language Latent Dirichlet Allocation

The extraction of *interlingua components* is realised by using LDA to model the set of parallel objects, by imposing the same proportion of components (topics) for all views of the same object. This is represented in Fig. 1.

LDA is performing some form of clustering, with a predefined number of components (K) and with the constraint that the two views of the same object belongs to the clusters with the same membership values. This results in $2.K$ component profiles that are then used for "folding in" (projecting) new documents by launching some form of EM to derive their posterior probabilities to belong to each of the language-independent component. The similarity between two documents written in different languages is obtained by comparing their posterior distribution over these latent classes. Note that this approach could easily integrate supervised topic information and provides a nice framework for semi-supervised *interlingua* concept extraction.

Cross-Language Canonical Correlation Analysis

The Primal Formulation

CCA is a standard statistical method to perform multi-block multivariate analysis, the goal being to find linear combinations of variables for each block (i.e., each language) that are maximally correlated. In other words, CCA is able to enforce the commonality of latent concept formations by extracting maximally correlated projections. Starting from a set of paired views of the same objects (typically, aligned sentences of a parallel corpus) in languages L1 and L2, the algebraic formulation of this optimization problem leads to a generalized eigenvalue problem of size $(n_1 + n_2)$, where n_1 and n_2 are the sizes of the vocabularies in L1 and L2 respectively. For obvious scalability reasons, the dual – or kernel – formulation (of size N, the number of paired objects in the training set) is often preferred.

Kernel Canonical Correlation Analysis

Basically, Kernel Canonical Correlation Analysis amounts to do CCA on some implicit, but more complex feature space and to express the projection coefficients as linear combination of the training paired objects. This results in the dual formulation, which is a generalized eigenvalue/vector problem of size $2N$, that involves only the monolingual kernel gram matrices K_1 and K_2 (matrices of monolingual textual similarities between all pairs of objects in the training set in language L1 and L2 respectively). Note that it is easy to show that the eigenvalues go by pairs: we always have two symmetrical eigenvalues $+\lambda$ and $-\lambda$. This kernel formulation has the advantage to include any text specific prior properties in the kernel (e.g., use of N-gram kernels, word-sequence kernels, and any semantically-smoothed kernel). After extraction of the first k generalized eigenvalues/eigenvectors, the similarity between any pair of test objects in languages L1 and L2 can be computed by using projection matrices composed of extracted eigenvector as well as the (monolingual) kernels of the test objects with the training objects.

Regularization and Partial Least Squares Solution

When the number of training examples (N) is less than n_1 and n_2 (the dimensions of the monolingual feature spaces), the eigenvalue spectrum of the KCCA problem has generally two null eigenvalues (due to data centering), $(N - 1)$ eigenvalues in $+1$ and $(N - 1)$ eigenvalues in -1, so that, as such, the KCCA problem only results in trivial solutions and is useless. When using kernel methods, the case $(N < n_1, n_2)$ is frequent, so that some regularization scheme is needed. One way of realizing this regularization is to resort to finding the directions of maximum covariance (instead of correlation): this can be considered as a partial least squares (PLS) problem, whose formulation is very similar to the CCA problem. Adopting a mixed criterion CCA/PLS (trying to maximize a combination of covariance and correlation between projections) turns out to both avoid over-fitting (or spurious solutions) and to enhance numerical stability.

Approximate Solutions

Both CCA and KCCA suffer from a lack of scalability, due to the fact the complexity of generalized eigenvalue/vector decomposition is $O(N^3)$ for KCCA or $O(\min(n_1, n_2)^3)$ for CCA. As it can be shown that performing a complete KCCA (or KPLS) analysis amounts to do first complete PCA's, and then a linear CCA (or PLS) on the resulting new projections, it is obvious that we could reduce the complexity by working on a reduced-rank approximation (incomplete KPCA) of the kernel matrices. However, the implicit projections derived from incomplete KPCA may be not optimal with respect to cross-correlation or covariance criteria. Another idea to decrease the complexity is to perform some incomplete Cholesky decomposition of the (monolingual) kernel matrices K_1 and $K \quad _2$ (that is equivalent to partial Gram-Schmit orthogonalisation in the feature space): $K_1 = G_1 . G_1^t$ and $K_2 = G_2 . G_2^t$, with G_i of rank $k \ll N$. Considering G_i as the new representation of the training data, KCCA now reduces to solving a generalized eigenvalue problem of size $2.k$.

Specific Applications

The previous sections illustrated a number of different ways of solving the core problem of cross-language text mining: quantifying the similarity between two spans of text in different languages. In this section we turn to describing some actual applications relying on these methods.

Cross-Language Information Retrieval (CLIR)

Given a collection of documents in several languages and a single query, the CLIR problem consists in producing a single ranking of all documents according to their relevance to the query. CLIR is in particular useful whenever a user has some knowledge of the languages in which documents are written, but not enough to express his/her information needs in those languages by means of a precise query. Sometimes CLIR engines are coupled with translation tools to help the user access the content of relevant documents written in languages unknown to him/her. In this case document collections in an even larger number of languages can be effectively queried.

It is probably fair to say that the vast majority of the CLIR systems use a translation-based approach. In most cases it is the query which is translated in all languages before being sent to monolingual search engines. While this limits the amount of translation work that needs be done, it requires doing it on-line at query time. Moreover, when queries are short it can be difficult to translate them correctly, since there is little context to help identifying the correct sense in which words are used. For these reasons several groups also proposed translating all documents at indexing time instead. Regardless of whether queries or documents are translated, whenever similarity scores between (possibly translated) queries and (possibly translated) documents are not directly comparable, all methods then face the problem of merging multiple monolingual rankings in a single multilingual ranking.

Research in CLIR and cross-language question answering (see below) has been significantly stimulated by at least three government-sponsored evaluation campaigns:

- The NII Test Collection for IR Systems (NTCIR) (http://research.nii.ac.jp/ntcir/), running yearly since 1999, focusing on Asian languages (Japanese, Chinese, Korean) and English.
- The Cross-Language Evaluation Forum (CLEF) (http://www.clef-campaign.org), running yearly since 2000, focusing on European languages.
- A cross-language track at the Text Retrieval Conference (TREC) (http://trec.nist.gov/), which was run until 2002, focused on querying documents in Arabic using queries in English.

The respective websites are ideal starting points for any further exploration on the subject.

Cross-Language Question Answering (CLQA)

Question answering is the task of automatically finding the answer to a specific question in a document collection. While in practice this vague description can be instantiated in many different ways, the sense in which the term is mostly understood is strongly influenced by the task specification formulated by the National Institute of Science and Technology (NIST) of the United States for its TREC evaluation conferences (see above). In this sense, the task consists in identifying a *text snippet*, i.e., a substring, of a predefined maximal length (e.g., 50 characters, or 200 characters) within a document in the collection containing the answer. Different classes of questions are considered:

- Questions around facts and events.
- Questions requiring the definition of people, things and organizations.
- Questions requiring as answer lists of people, objects or data.

Most proposals for solving the QA problem proceed by first identifying promising documents (or document segments) by using information retrieval techniques treating the question as a query, and then performing some finer-grained analysis to converge to a sufficiently short snippet. Questions are classified in a hierarchy of possible "question types." Also, documents are preliminarily indexed to identify elements (e.g., person names) that are potential answers to questions of relevant types (e.g., "Who" questions).

Cross-language question answering (CLQA) is the extension of this task to the case where the collection contains documents in a language different than the language of the question. In this task a CLIR step replaces the monolingual IR step to shortlist promising documents. The classification of the question is generally done in the source language.

Both CLEF and NTCIR (see above) organize cross-language question answering comparative evaluations on an annual basis.

Cross-Language Categorization (CLCat) and Clustering (CLCLu)

Cross-language categorization tackles the problem of categorizing documents in different languages in a same categorization scheme.

The vast majority of document categorization systems rely on machine learning techniques to automatically acquire the necessary knowledge (often referred to as a *model*) from a possibly large collection of manually categorized documents. Most often the model is based on frequency counts of words, and is thus intrinsically language-dependent. The most direct way to perform categorization in different languages would consist in manually categorizing a sufficient amount of documents in all languages of interest and then train a set of independent categorizer. In some cases, however, it is impractical to manually categorize a sufficient number of documents to ensure accurate categorization in all languages, while it can be easier to identify bilingual dictionaries or parallel (or comparable) corpora for the language pairs and in the application domain of interest. In such cases it is then preferable to obtain manually categorized documents only for a single language *A* and use them to train a monolingual categorizer. Any of the translation-based approaches described above can then be used to translate a document originally in language B – or most often its representation as a *bag of words*– into language A. Once the document is translated, it can be categorized using the monolingual A system.

As an alternative, latent-semantics approaches can be used as well. An existing parallel corpus can be used to identify an abstract vector space common to A and B. The manually categorized documents in A can then be represented in this space, and a model can be learned which operates directly on this latent-semantic representation. Whenever a document in B needs be categorized, it is first projected in the common semantic space and then categorized using the same model.

All these considerations carry unchanged to the cross-language clustering task, which consists in identifying subsets of documents in a multilingual document collection which are mutually similar to one another according to some criterion. Again, this task can be effectively solved by either translating all documents into a single language or by learning a common semantic space and performing the clustering task there.

While CLCat and Clustering are relevant tasks in many real-world situations, it is probably fair to say that less effort has been devoted to them by the research community than to CLIR and CLQA.

Cross-Validation

Definition

Cross-validation is a process for creating a distribution of pairs of training and ▸ test sets out of a single ▸ data set. In cross validation the data are partitioned into k subsets, $S_1 \ldots S_k$, each called a *fold*. The folds are usually of approximately the same size. The learning algorithm is then applied k times, for $i = 1$ to k, each time using the union of all subsets other than S_i as the ▸ training set and using S_i as the ▸ test set.

Synonyms

Continual learning; Lifelong learning; Sequential inductive transfer

Definition

Cumulative learning (CL) exploits knowledge acquired on prior tasks to improve learning performance on subsequent related tasks. Consider, for example, a CL system that is learning to play chess. Here, one might expect the system to learn from prior games concepts (e.g., favorable board positions, standard openings, end games, etc.) that can be used for future learning. This is in contrast to base learning (Vilalta and Drissi 2002) in which a fixed learning algorithm is applied to a single task and performance tends to improve only with more exemplars. So, in CL there tends to be explicit reuse of learned knowledge to constrain new learning, whereas base learning depends entirely upon new external inputs.

Relevant techniques for CL operate over multiple tasks, often at higher levels of abstraction, such as new problem space representations, task-based selection of learning algorithms, dynamic adjustment of learning parameters, and iterative analysis and modification of the learning algorithms themselves. Though actual usage of this term is varied and evolving, CL typically connotes sequential ▶ inductive transfer. It should be noted that the word "inductive" in this connotation qualifies the transfer of knowledge to new tasks, not the underlying learning algorithms.

Related Terminology

The terms "meta-learning" and "learning to learn" are sometimes used interchangeably with CL. However each of these concepts has a specific relationship to CL.

▶ Meta-learning (Brazdil et al. 2009; Vilalta and Drissi 2002) involves the application of learning algorithms to meta-data, which are abstracted representations of input data or learning system knowledge. In the case that abstractions of system knowledge are themselves learning algorithms, meta-learning involves assessing the suitability of these algorithms for previous tasks and, on that basis, selecting algorithms for new tasks (see entry on "▶ Metalearning"). In general, the sharing of abstracted knowledge across tasks in a CL system implies the use of meta-learning techniques. However, the converse is not true. Meta-learning can and does occur in learning systems that do not accumulate and transfer knowledge across tasks.

Learning to learn is a synonym for inductive transfer. Thus, learning to learn is more general than CL. Though it specifies the application of knowledge learned in one domain to another, it does not stipulate whether that knowledge is accumulated and applied sequentially or shared in a parallel learning context.

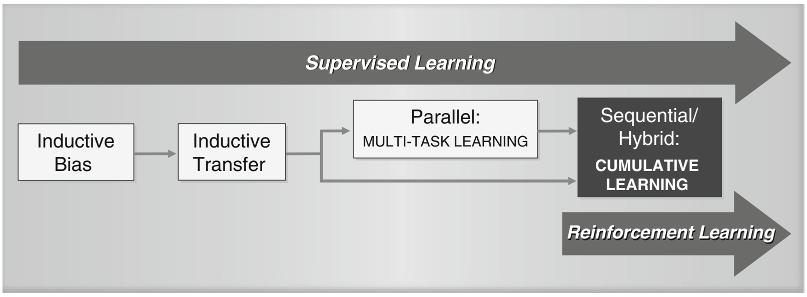
Motivation and Background

Traditional ▶ supervised learning approaches require large datasets and extensive training in order to generalize to new inputs in a single task. Furthermore, traditional (non-CL) ▶ reinforcement learning approaches require tightly constrained environments to ensure a tractable state space. In contrast, humans are able to generalize across tasks in dynamic environments from brief exposure to small datasets. The human advantage seems to derive from the ability to draw upon prior task and context knowledge to constrain hypothesis development for new tasks. Recognition of this disparity between human learning and traditional machine learning had led to the pursuit of methods that seek to emulate the accumulation and exploitation of task-based knowledge that is observed in humans. A coarse evolution of this work is depicted in Fig. 1.

History

Advancements in CL have resulted from two classes of innovation: the development of techniques for ▶ inductive transfer and the integration of those techniques into autonomous learning systems.

Alan Turing (1950) was the first to propose a cumulative learning system. His 1950 paper is best remembered for the imitation game, later known as the Turing test. However, the final sections of the paper address the question of how a machine could be made sufficiently complex to be able to pass the test. He posited that program-



Cumulative Learning, Fig. 1 Evolution of cumulative learning

ming it would be too difficult a task. Therefore, it should be instructed as one might teach a child, starting with simple concepts and working up to more complex ones.

Banerji (1964) introduced the use of predicate logic as a description language for machine learning. Thus, Banerji was one of the earliest advocates of what would later become ► ILP. His concept description language allowed the use of background knowledge and therefore was an extensible language. The first implementation of a cumulative learning system based on Banerjis ideas was Cohens CONFUCIUS (Cohen 1978; Cohen and Sammut 1982). In this work, an instructor teaches the system concepts that are stored in a long-term memory. When examples of a new concept are seen, their descriptions are matched against stored concepts, which allow the system to re-describe the examples in terms of the background knowledge. Thus, as more concepts are accumulated, the system is capable of describing complex objects more compactly than if it had not had the background knowledge. Compact representations generally allow complex concepts to be learned more efficiently. In many cases, learning would be intractable without the prior knowledge. See the entries on ► Inductive Logic Programming, which describe the use of background knowledge further.

Independent of the research in symbolic learning, much of the ► inductive transfer research that underlies CL took root in ► artificial neural network research, a traditional approach to ► supervised learning. For example, Abu-Mostafa (1990) introduced the notion of reducing the hypothesis space of a neural network by introducing "hints" either as hard-wired additions to the network or via examples designed to teach a particular invariance. The task of a neural network can be thought of as the determination of a function that maps exemplars into a classification space. So, in this context, hints constitute an articulation of some aspect of the target mapping function. For example, if a neural network is tasked with mapping numbers into primes and composites, one "hint" would be that all even numbers (besides 2) are composite. Leveraging such a priori knowledge about the mapping function may facilitate convergence on a solution. An inherent limitation to neural networks, however, is their immutable architecture, which does not lend itself to the continual accumulation of knowledge. Consequently, Ring (1991) introduced a neural network that constructs new nodes on demand in a reinforcement learning context in order to support ongoing hierarchical knowledge acquisition and transfer. In this model, nodes called "bions" correspond simultaneously to the enactment and perception of a single behavior. If two bions are activated in sequence repeatedly, a new bion is created to join the coincident pair and represent their collective functionality.

Contemporaneously, Pratt et al. (1991) investigated the hypothesis that knowledge acquired by one neural network could be used to assist another neural network learn a related task. In the speech recognition domain, they trained three separate networks, each corresponding to speech segments of a different length, such that each network was optimized to learn certain types of phonemes. They then demonstrated that a direct transfer of information encoded as network weights from these three specialized networks to a single, combined speech recognition network resulted in a tenfold reduction in training epochs for the combined network compared with the number of training epochs required when no knowledge was transferred. This was one of the first empirical results in neural network-based transfer learning. Caruana (1993) extended this work to demonstrate the performance benefits associated with the simultaneous transfer of ▶ inductive bias in a "Multitask Learning" (MTL) methodology. In this work, Caruana hypothesized that training the same neural network simultaneously on related tasks would naturally induce additional constraints on learning for each individual task. The intuition was that converging on a mapping in support of multiple tasks with shared representations might best reveal aspects of the input that are invariant across tasks, thus obviating within-task regularities, which might be less relevant to classification. Those empirical results are supported by Baxter (1995) who proved that the number of examples required by a representation learner for learning a single task is an inverse linear function of the number of simultaneous tasks being learned.

Though the innovative underpinnings of inductive transfer that critically underlie CL evolved in a supervised learning context, it was the integration of those methods with classical reinforcement learning that has led to current models of CL. Early integration of this type comes from Thrun and Mitchell (1995), who applied an extension of explanation-based learning (EBL), called explanation-based neural networks (EBNN) (Mitchell and Thrun 1993), to an agent-based "lifelong learning framework." This framework provides for the acquisition of different control policies for different environments and reward functions. Since the robot actuators, sensors, and the environment (largely) remain invariant, this framework supports the use of knowledge acquired from one control problem to be applied to another. By using EBNN to allow learning from previous control problems to constrain learning on new control problems, learning is accelerated over the lifetime of the robot.

More recently, Silver and Mercer (2002) introduced a hybrid model that involves a combination of parallel and sequential inductive transfer in an autonomous agent framework. The so-called task rehearsal method (TRM) uses MTL to combine new training inputs with relevant exemplars that are generated from prior task knowledge. Thus, inductive bias is achieved by training the neural networks on new tasks while simultaneously rehearsing learned task knowledge.

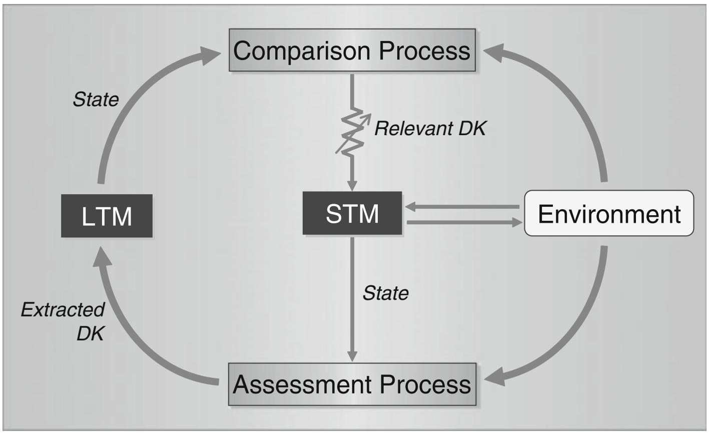
Structure of the Learning System

CL is characterized by systems that use prior knowledge to bias future learning. The canonical interpretation is that knowledge transfer occurs at the task level. Although this description encompasses a broad research space, it is not boundless. In particular, CL systems must be able to (1) retain knowledge and (2) use that knowledge to restrict the hypothesis space for new learning. Nonetheless, learning systems can vary widely across numerous orthogonal dimensions and still meet these criteria.

Toward a CL Specification

Recognizing the empirical utility of a more specific delineation of CL systems, Silver and Poirier (2005) introduced a set of functional requirements, classification criteria, and performance specifications that characterize more precisely the scope of machines capable of lifelong learning. Any system that meets these requirements is considered a machine lifelong learning (ML3) system. A general CL architecture that conforms to the ML3 standard is depicted in Fig. 2.

Two basic memory constructs are typical of CL systems. Long term memory (LTM) is required for storing domain knowledge (DK) that can be used to bias new learning. Short term memory (STM) provides a working memory for building representations and testing hypotheses associated with new task learning. Most of the ML3 requirements specify the interplay of these constructs.



Cumulative Learning, Fig. 2 Typical CL system

LTM and STM are depicted in Fig. 2, along with a comparison process, an assessment process, and the learning environment. In this model, the comparison process evaluates the training input in the context of LTM to determine the most relevant domain knowledge that can be used to constrain short term learning. The comparison process also determines the weight assigned to domain knowledge that is used to bias short term learning. Once the rate of performance improvement on the primary task falls below a threshold the assessment process compares the state of STM to the environment to determine which domain knowledge to extract and store in LTM.

Classification of CL Systems

The simplicity of the architecture shown in Fig. 2 belies the richness of the feature space for CL systems. The following classification dimensions are derived largely from the ML3 specification. This list includes both qualitative and quantitative dimensions. They are presented in three overlapping categories: architectural features, characteristics of the knowledge base, and learning capabilities.

Architecture

The following architectural dimensions for a CL system range from paradigm choices to low-level interface considerations.

Learning paradigm – The learning paradigm(s) may include supervised learning (e.g., neural network, SVM, ILP, etc.), unsupervised learning (e.g., clustering), reinforcement learning (e.g., automated agent), or some combination thereof. Figure 2 depicts a general architecture with processes that are common across these learning paradigms, and which could be elaborated to reflect the details of each.

Task order – CL systems may learn tasks sequentially (Thrun and Mitchell 1995), in parallel (e.g., Caruana 1993), or via a hybrid methodology (e.g., TRM Silver and Mercer 2002). One hybrid approach is to engage in practice (i.e., revisiting prior learned tasks). Transferring knowledge between learned tasks through practice may serve to improve generalization accuracy. Task order would be reflected in the sequence of events within and among process arrows in the Fig. 2 architecture. For example, a system may alternate between processing new exemplars and "practicing" with old, stored exemplars.

Transfer method – Knowledge transfer can also be representational or functional. Functional transfer provides implicit pressure from related training exemplars. For example, the environmental input in Fig. 2 may take the form of training exemplars drawn randomly from data representing two related tasks, such that learning to classify exemplars from one task implicitly constrains learning on the other task. Representational knowledge transfer involves the direct or indirect (Pratt et al. 1991) assignment of a hypothesis representation. A direct inductive transfer entails the assignment of an original hypothesis representation, such as a vector of trained neural network activation weights. This might take the form of a direct injection to LTM in Fig. 2. Indirect transfer implies that some level of abstraction analysis has been applied to the hypothesis representation prior to assignment.

Learning stages – A learning system may implement learning in a single stage or in a series of stages. An example of a two-stage system is one that waits to initiate the long-term storage of domain knowledge until after primary task learning in short-term memory is complete. Like task order, learning stages would be reflected in the sequence of events within and among process arrows in the Fig. 2 architecture. But in this case, ordering pertains to the manner in which learning is staged across encoding processes.

Interface cardinality – The interface cardinality can be fixed or variable. Fixing the number of inputs and outputs has the advantage of providing a consistent interface without posing restrictions on the growth of the internal representation.

Data type – The input and output data types can be fixed or variable. A type-flexible system can produce both categorical and scalar predictions.

Scalability – CL systems may or may not scale on a variety of dimensions including inputs, outputs, training examples, and tasks.

Knowledge

This category pertains to the long-term storage of learned knowledge. Thus, the following CL dimensions characterize knowledge representation, storage, and retrieval.

Knowledge representation – Stored knowledge can manifest as functional or representational. Functional knowledge retention involves the storage of specific exemplars or parameter values, which tends to be more accurate, whereas representational knowledge retention involves the storage of hypotheses derived from training on exemplars, which has the advantage of storage economy.

Retention efficacy – The efficacy of long term retention varies across CL systems. Effective retention implies that only domain knowledge with an acceptable level of accuracy is retained so that errors aren't propagated to future hypotheses. A related consideration is whether or not the consolidation of new domain knowledge degrades the accuracy of current or prior hypotheses.

Retention efficiency – The retention efficiency of long term memory can vary according to both economy of representation and computationally efficiency.

Indexing method – The input to the comparison process used to select appropriate knowledge for biasing new learning may simply be exemplars (as provided by LTM in Fig. 2) or may take a representational form (e.g., a vector of neural network weights).

Indexing efficiency – CL systems vary in terms of the speed and accuracy with which they can identify related prior knowledge that is suitable for inductive transfer during short term learning. The input to this selection process is the indexing method.

Meta-knowledge – CL systems differentially exhibit the ability to abstract, store, and utilize meta-knowledge, such as characteristics of the input space, learning system parameter values, etc.

Learning

While all of the dimensions listed herein impact learning, the following dimensions correspond to specific learning capabilities or learning performance metrics.

Agency – The agency of a learning system is the degree of sophistication exhibited by its top-level controller. For example a learning system may be on the low end of the agency continuum if it always applies one predetermined learning method to one task or on the high end if it selects among many learning methods as a function of the learning task. One might imagine, for example, two process diagrams such as the one depicted in Fig. 2, that share the same LTM, but are otherwise distinct and differentially activated by a governing controller as a function of qualitative aspects of the input.

Utility – Domain knowledge acquisition can be deliberative in the sense that the learning system decides which hypotheses to incorporate based upon their estimated utility, or reflexive, in which case all hypotheses are stored irrespective of utility considerations.

Task awareness – Task awareness characterizes the system's ability to identify the beginning and end of a new task.

Bias modulation – A CL system may have the ability to determine the extent to which short-term learning would benefit from inductive transfer and, on that basis, assign a relevant weight. The depth of this analysis can vary and might consider factors such as the estimated sample complexity, number of exemplars, the generalization accuracy of retained knowledge, and relatedness of retained knowledge.

Learning efficacy – A measure of learning efficacy is derived by comparing generalization performance in the presence and absence of an inductive bias. Learning is considered effective when the application of an inductive bias results in greater generalization performance on the primary task than when the bias is absent.

Learning efficiency – Similarly, learning efficiency is assessed by comparing the computational time needed to generate a hypothesis in the presence and absence of an inductive bias. Lower computational time in the presence of bias signifies greater learning efficiency.

The Research Space

Table 1 summarizes the classification dimensions, providing an overview of the research space, an evaluative framework for assessing and contrasting CL approaches, and a generative framework for identifying new areas of exploration. In addition, checked items in the Values column indicate ML3 guidance. Specifically, an ideal ML3 system would correspond functionally to the called-out items and performance criteria. However, Silver and Poirier (2005) allude to the fact that it would be nigh impossible to generate a strictly compliant ML3 system since some of the recommended criteria do not coexist easily. For example, effective and efficient learning are mutually incompatible because they require different forms of knowledge transfer. Nonetheless, a CL system that falls within scope of the majority of the ML3 criteria would be well-positioned to exhibit lifelong learning behavior.

Future Directions

Emergent work (Oblinger 2006; Swarup et al. 2006) in instructable computing has given rise to a new CL paradigm that is largely ML3 compliant and involves high degrees of task awareness and agency sophistication. Swarup et al. (2006) describe an approach in which domain knowledge is represented in the form of structured graphs. Short term (primary task) learning occurs via a genetic algorithm, after which domain knowledge is extracted by mining frequent subgraphs. The accumulated domain knowledge forms an ontology to which the learning system grounds symbols as a result of structured interactions with instructional agents. Subsequent interactions occur using the symbol system as a shared lexicon for communication between the instructor and the learning system. Knowledge acquired from these interactions bootstrap future learning.

The Bootstrapped Learning framework proposed by Oblinger (2006) provides for hierarchical, domain-independent learning that, like the effort described above, is also premised on a model of building concepts from structured lessons. In this case, however, there is no a priori knowledge acquisition. Instead, some "common" knowledge about the world is provided explicitly to the learning system, and then lessons are taught by a human teacher using the same natural instruction methods that would be used to teach another human. Rather than requiring a specific learning algorithm, this framework provides a context for evaluating and comparing learning algorithms. It includes a knowledge representation language that supports syntactic, logical, procedural, and functional knowledge, an interaction language for communication among the learning system, instructor, and environment, and an integration architecture that evaluates, processes, and responds to interaction language communiqués in the context of existing knowledge and through the selective utilization of available learning algorithms.

Cumulative Learning, Table 1 CL system dimensions

Category	Dimension	Values (ML3 guidance is indicated by {✓})
Architecture	Learning paradigm	Supervised learning
		Reinforcement learning
		Unsupervised learning
		{✓} Hybrid
	Task order	Sequential
		Parallel
		{✓} Revisit (practice)
		Hybrid
	Transfer method	Functional
		Representational – direct
		Representational – indirect
	Learning stages	{✓} Single (computational retention efficiency)
		Multiple
	Interface cardinality	{✓} Fixed
		Variable
	Data type	Fixed
		Variable
	Scalability	{✓} Inputs
		{✓} Outputs
		{✓} Exemplars
		{✓} Tasks
Knowledge	Representation	Functional
		Representational – disjoint
		{✓} Representational – continuous
	Retention efficacy	{✓} Improves prior task performance
		{✓} Improves new task performance
	Retention efficiency	{✓} Space (memory usage)
		{✓} Time (computational processing)
	Indexing method	{✓} Deliberative – functional
		{✓} Deliberative – representational
		Reflexive
	Indexing efficiency	{✓} Time $< \mathrm{O}(n^c), c > 1(n = \text{tasks})$

Curse of Dimensionality

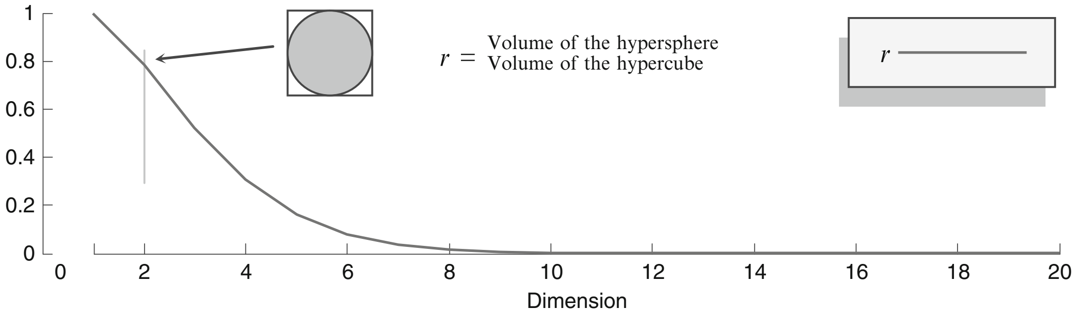
Eamonn Keogh and Abdullah Mueen
University of California-Riverside, Riverside, CA, USA

Definition

The curse of dimensionality is a term introduced by Bellman to describe the problem caused by the exponential increase in volume associated with adding extra dimensions to Euclidean space (Bellman 1957).

For example, 100 evenly-spaced sample points suffice to sample a unit interval with no more than 0.01 distance between points; an equivalent sampling of a 10-dimensional unit hypercube with a grid with a spacing of 0.01 between adjacent points would require 10^{20} sample points: thus, in some sense, the 10D hypercube can be said to be a factor of 10^{18} “larger” than the unit interval.

Informally, the phrase *curse of dimensionality* is often used to simply refer to the fact that one’s intuitions about how data structures, sim-



Curse of Dimensionality, Fig. 1 The ratio of the volume of the hypersphere enclosed by the unit hypercube. The most intuitive example, the unit square and unit circle, are shown as an *inset*. Note that the volume of the hypersphere quickly becomes irrelevant for higher dimensionality

ilarity measures, and algorithms behave in low dimensions do typically generalize well to higher dimensions.

Background

Another way to envisage the vastness of high-dimensional Euclidean space is to compare the size of the unit sphere with the unit cube as the dimension of the space increases: as the dimension increases. As we can see in Fig. 1, the unit sphere becomes an insignificant volume relative to that of the unit cube. In other words, almost all of the high-dimensional space is *far away* from the center.

In research papers, the phrase *curse of dimensionality* is often used as shorthand for one of its many implications for machine learning algorithms. Examples of these implications include:

- ▶ Nearest neighbor searches can be made significantly faster for low-dimensional data by indexing the data with an R-tree, a KD-tree, or a similar spatial access method. However, for high-dimensional data all such methods degrade to the performance of a simple linear scan across the data.
- For machine learning problems, a small increase in dimensionality generally requires a large increase in the numerosity of the data, in order to keep the same level of performance for regression, clustering, etc.
- In high-dimensional spaces, the normally intuitive concept of proximity or similarity may not be qualitatively meaningful. This is because the ratio of an object's nearest neighbor over its farthest neighbor approaches one for high-dimensional spaces (Aggarwal 2001). In other words, all objects are approximately equidistant from each other.

There are many ways to attempt to mitigate the *curse of dimensionality*, including ▶ feature selection and ▶ dimensionality reduction. However, there is no single solution to the many difficulties caused by the effect.

Abstract

Before data can be analyzed, they must be organized into an appropriate form. Data preparation is the process of manipulating and organizing data prior to analysis.

Data preparation is typically an iterative process of manipulating raw data, which is often unstructured and messy, into a more structured and useful form that is ready for further analysis. The whole preparation process consists of a series of major activities (or tasks) including data profiling, cleansing, integration, and transformation.

Synonyms

Data preprocessing; Data wrangling

Motivation and Background

Data are collected for many purposes, not necessarily with machine learning or data mining in mind. Consequently, there is often a need to identify and extract relevant data for the given analytic purpose. Every learning system has specific requirements about how data must be presented for analysis, and hence data must be transformed to fulfill those requirements. Further, the selection of the specific data to be analyzed can greatly affect the models that are learned. For these reasons, data preparation is a critical part of any machine learning exercise and is often the most time-consuming part of any nontrivial machine learning or data mining project.

In most cases, the preparation process consists of dozens of transformations and needs to be repeated several times. Despite advances in technologies for working with data, each of those transformations may involve much-handcrafted work and can consume a significant amount of time and effort. Thus, working with huge and diverse data remains a challenge. It is often agreed that data wrangling/preparation is the most tedious and time-consuming aspect of data analysis. It has become a big bottleneck or “iceberg” for performing advanced data analysis, particularly on big data. A recent article in the New York Times For Big-Data Scientists reported that the whole process of data wrangling could account up to 80 % of the time in the analysis cycle. In other words, there is only a small fraction of time for data analysts and scientists to do analysis work. According to the data science report Data science report, published by Crown in 2015, messy and disorganized data are the number one obstacle holding data scientists back. The same study reports that 70 % of a data scientist’s time is spent in cleaning data.

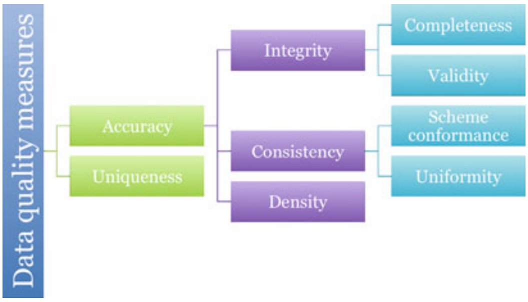
Processes and Techniques

The manner in which data are prepared varies greatly depending upon the analytic objectives for which they are required and the specific learning techniques and software by which they are to be analyzed. The following are a number of key processes and techniques.

Data Profiling: Sourcing, Selecting, and Auditing Appropriate Data

It is necessary to review the data that are already available, assess their suitability to the task at hand, and investigate the feasibility of sourcing new data collected specifically for the desired task. It is also important to assess whether there are sufficient data to realistically obtain the desired machine learning outcomes.

Data quality should also be investigated, as data sets are often of low quality. Those responsible for manual data collection may have little commitment to assuring data accuracy and may take shortcuts in data entry. For example, when default values are provided by a system, these tend to be substantially overrepresented



Data Preparation, Fig. 1 Data quality measures (Adapted from Müller and Freytag 2005)

in the collected data. Automated data collection processes might be faulty, resulting in inaccurate or incorrect data. The precision of a measuring instrument may be lower than desirable. Data may be out-of-date and no longer correct.

Assuring and improving data quality are two of the primary reasons for data preprocessing. There are common criteria to measure and evaluate the quality of data, which can be categorized into two main elements, accuracy and uniqueness (Müller and Freytag 2005), as explained in Fig. 1.

Accuracy is described as an aggregated value over the quality criteria: integrity, consistency, and density. Intuitively this describes the extent to which the data are an exact, uniform, and complete representation of the *mini-world*: the aspects of the world that the data describe. We describe each accuracy criterion as follows:

- **Integrity:** An integral data collection contains representations of all the entities in the mini-world and only of those. Integrity requires both completeness and validity.
  - **Completeness:** Complete data give a comprehensive representation of the mini-world and contain no missing values. We achieve completeness within data cleansing by correcting anomalies and not just deleting them. It is also possible that additional data are generated, representing existing entities that are currently unrepresented in the data. A problem with assessing completeness is that you do not know what you do not know. As a result, there are no known gold standard data, which can be used as a reference to measure completeness.
  - **Validity:** Data are valid when there are no constraints violated. There are numerous mechanisms to increase validity including mandatory fields, enforcing unique values, and data schema/structure.
- **Consistency:** This quality concerns syntactic anomalies as well as contradictions. The main challenge concerning data consistency is choosing which data source you trust for reliable agreement among data across different sources.
  - **Schema conformance:** This is especially true for the relational database systems where the adherence of domain formats relies on the user.
  - **Uniformity:** This is directly related to irregularities.
- **Density:** This criterion concerns the quotient of missing values in the data. There still can be nonexistent values or properties that have to be represented by null values having the exact meaning of not being known.

The above three criteria of integrity, consistency, and density collectively represent the accuracy measure.

The other major quality measure that is also crucial to measure data quality is uniqueness. Uniqueness is satisfied when the data do not contain any duplicates.

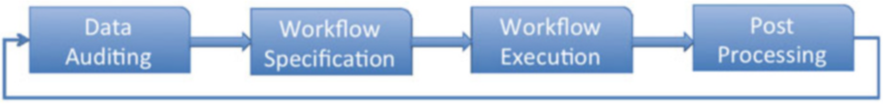
Timeliness is another criterion that also has been considered for data quality. This criterion refers to the currency of the data that keeps it up to date.

More information about data quality can be found in Dasu and Johnson (2003) and Müller and Freytag (2005).

Data Cleansing

Where the data contain noise or anomalies, it may be desirable to identify and remove outliers and other suspect data points or take other remedial action. See ▶ noise.

Data cleansing is defined as the process of detecting and correcting (or removing) corrupt or inaccurate records from a record set, table, or database. Data cleansing can also be referred to as data cleaning, data scrubbing, or data reconcilia-



Data Preparation, Fig. 2 Data cleansing process (Adapted from Müller and Freytag 2005)

tion. More precisely, the process of data cleansing could be explained as a four-stage process:

1. Define and identify errors in data such as incompleteness, incorrectness, inaccuracy, or irrelevancy.
2. Clean and rectify these errors by replacing, modifying, or deleting them.
3. Document error instances and error types.
4. Measure and verify to see whether the cleansing meets the user's specified tolerance limits in terms of cleanliness.

Data Anomalies

Data are symbolic representations of information, i.e., facts or entities from parts of the world, called a mini-world, depicted by symbolic values. Imperfections in the data set correspond to differences between an ideal (i.e., error-free) data set (DI) and the real data (DR). In this context, anomalousness is a property of data that renders an erroneous representation of the mini-world.

The term *data anomaly* describes any distortion of data resulting from the data collection process. From this perspective, anomalies include duplication, inconsistency, missing values, outliers, noisy data, or any kind of distortion that can cause data imperfections.

Anomalies can be classified at a high level into three categories:

- **Syntactic anomalies:** describe characteristics concerning the format and values used for the representation of the entities. Syntactic anomalies include lexical errors, domain format errors, syntactical errors, and irregularities.
- **Semantic anomalies:** hinder the data collection from being a comprehensive and nonredundant representation of the mini-world. These types of anomalies include integrity constraint violations, contradictions, duplicates, and invalid tuples.
- **Coverage anomalies:** decrease the number of entities and entity properties from the mini-world that is represented in the data collection. Coverage anomalies are categorized as missing values and missing tuples.

Therefore, it is clear that data anomalies can take a number of different forms, each with a different range of analytical consequences.

Data Cleansing Process

Data cleansing is an iterative process that consists of the four consecutive steps (Müller and Freytag 2005), as depicted in Fig. 2:

1. **Data auditing:** This first step mainly identifies the types of anomalies that reduce data quality. Data auditing checks the data using validation rules that are prespecified and then creates a report of the quality of the data and its problems. We often apply some statistical tests in this step for examining the data.
2. **Workflow specification:** The next step is to detect and eliminate anomalies by a sequence of operations on the data. The information collected from data auditing is then used to create a data-cleaning plan. It identifies the causes of the dirty data and plans steps to resolve them.
3. **Workflow execution:** The data-cleaning plan is executed, applying a variety of methods on the data set.
4. **Post-processing and controlling:** The post-processing or control step involves examination of the workflow results and performs exception handling for the data mishandled by the workflow.

Dealing with Missing Values

One major task in data cleansing is dealing with missing values. It is important to determine whether the data have missing values and, if so, to ensure that appropriate measures are taken to allow the learning system to handle this situation See ► missing attribute values.

Handling data that contain missing values is crucial for the data cleansing process and data wrangling in general. In real-life data, most of existing data sets contain missing values that were not introduced or were lost in the recording process for many reasons.

Handling Outliers

An outlier is another type of data anomaly that requires attention in the cleansing process. Outliers are data that do not conform to the overall data distribution.

Outliers can be seen from two different perspectives; first, they might be seen as glitches in the data. Alternatively, they might be also seen as interesting elements that could potentially represent significant elements in the data. For example, outliers in sales records for a store might reflect a successful marketing campaign. Therefore, to classify data as outliers, we must define what the normal behavior of the data is and therefore how different or significant the outlier is relative to normal behavior. There might be different normal behaviors for data and thus different classes of outliers. From the above definition, we can see that as the normality in data differs, various classes of outliers can be detected. To be able to do that, we need to formalize both the normality in the data and inconsistency of the outliers. Read more about handling outliers for data preprocessing in Han et al. (2011).

Data Enrichment/Integration

Existing data may be augmented through data enrichment. This commonly involves sourcing of additional information about the data points on which data are already held. For example, customer data might be enriched by obtaining socioeconomic data about individual customers. The imported data must be integrated with the other data for a unified view of all data sources.

Data integration is a crucial task in data preparation. Combining data from different sources is not trivial especially when dealing with large amounts of data and heterogeneous sources. Data are typically presented in different forms (structured, semi-structured, or unstructured) as well as from different sources (web, database) that could be stored locally or distributed. Moreover, structured data coming from a single source might have different schemas. The combination of these variations is not an easy task.

Integration of data brings many opportunities, yet it also comes with various challenges. We highlight the most relevant challenges below:

1. **Data are heterogeneous:** Data integration involves a combination of data coming from different sources that have been developed independently of each other and thus vary in data format. Each source will have its own schemas, definition of objects, and structure of data (tables, XML, unstructured text, etc.).
2. **The number of sources:** Data integration is already a challenge for a small number of sources, but the challenges are exacerbated when the number of sources grows (such as Web-scale data integration).
3. **Object identity and separate schemas:** Differences exist both on the level of individual objects and the schema level. Every source classifies their data according to taxonomies pertinent to a certain domain.
4. **Time synchronization:** Each source might have a different time window over which data have been captured, different granularities at which events are modeled (daily, weekly, annually), and frequency at which they are updated. Synchronization of these differences and making time-sensitive data compatible are another challenge.
5. **Dealing with legacy data:** There are still important data stored in a legacy form such as IMS, spreadsheets, and ad hoc structures. Combining legacy data with other modern data structures such as XML is a challenging task.
6. **Abstraction levels:** Different data sources might provide data at incompatible levels of abstraction. When combining data, differences in levels of specificity must be resolved.
7. **Data quality:** Data are often erroneous, and combining data often aggravates the problem. Erroneous data has a potentially devastating

impact on the overall quality of the integration process.

The integration process can be divided into two main subtasks, schema integration and data integration, where each has its own techniques and challenges. Schema integration concerns a holistic view across data sources. It focuses on formats, structures, and identification of objects and their level of abstraction. This includes semantic mapping, matching, resolving naming conflicts, and entity resolution. The contents of data add another clue to the integration process.

Even with data from different sources that have identical schemas, integration on the data level is still essential. Data integration deals with different types of problems that concern the data itself rather than the overall structure as in schema integration. Common data integration problems are duplication in data and inconsistency. Correlated or duplicated values/attributes may increase both size and complexity of the data. Resolving conflicts at the data level enhances the overall performance of the integration process.

Data Transformation

It is frequently necessary to transform data from one representation to another. There are many reasons for changing representations:

- **To generate symmetric distributions instead of the original skewed distributions**.
- **Transformation improves visualization** of data that might be tightly clustered relative to a few outliers.
- Data are transformed to achieve **better interpretability.**
- Transformations are often used to **improve the compatibility of the data with assumptions underlying a modeling process**, for example, to linearize (straighten) the relation between two variables whose relationship is nonlinear. Some of the data mining algorithms require the relationship between data to be linear.

In the following, we will discuss different types of transformation whereby each data point $\mathbf{x_i}$ is replaced with a **transformed value** $\mathbf{y_i} = \mathbf{f}(\mathbf{x_i})$, where $\mathbf{f}$ is the transformation function. Many techniques are applied for data transformation. Each technique has its own purpose and dependency on the nature of data. Some of the major transformations are discussed below.

Numeric to Numeric Transformation

Normalization and Rescaling

It is usually the case that raw data are not in a suitable form to be processed by machine learning and data mining techniques. Data normalization is the process of transforming raw data values to another form with properties that are more suitable for modeling and analysis. The normalization process focuses on scaling data in terms of range and distribution. Therefore, it consists of two main processes:

- *Min-max normalization* projects the original range of data onto a new range. Very common normalization intervals are [0,1] and [−1,1]. This normalization method is very useful when we apply a machine learning or data mining approach that utilizes distance. For example, in k-nearest neighbor methods, using un-normalized values might cause attributes whose values have greater magnitudes to dominate over other attributes. Therefore, normalization aims to standardize magnitudes across variables. A useful application for min-max scaling is image processing where pixel intensities have to be normalized to fit within a certain range (i.e., 0–255 for the RGB color range). Also, typical neural network algorithms (ANN) require data that is on a 0–1 scale. Normalization provides the same range of values for each of the inputs to the model.
- **Z-score normalization** (also referred to as standardization) is a normalization method that transforms not only the data magnitude but also the dispersion. Some data mining methods are based on the assumption that data follow a certain distribution. For example, methods such as logistic regression, SVM, and neural network when

using gradient descent/ascent optimization methods assume data follow a Gaussian distribution. Otherwise, the approaches will be ill conditioned and might not guarantee a stable convergence of weight and biases. Other approaches such as linear discriminant analysis (LDA), principal component analysis (PCA), and kernel principal component analysis require features to be on the same scale to find directions that maximize the variance (under the constraints that those directions/eigenvectors/principal components are orthogonal). Z-score normalization overcomes the problem of variables with different units as it transforms variables so that they are centered on 0 with a standard deviation of 1.

- **Decimal scaling** is another type of scaling transformation where the decimal place of a numeric value is shifted so the maximum absolute value will be always less than 1.

Linear Transformation

Linear transformations preserve linear relationships within data. A function f(.) results in a linear transformation if and only if for all values x and y in the original representation, f(x)+f(y) = f(x+y) and f(x)−f(y) = f(x−y). Examples of a linear transformation are transforming Celsius to Fahrenheit, miles to kilometers, and inches to centimeters. All linear transformations follow the standard linear regression formula to convert variables linearly.

Many other transformations are not linear. A nonlinear transformation changes (increases or decreases) linear relationships between variables and, thus, changes the correlation between variables. Examples of nonlinear transformations are square root, raising to a power, logarithm, and any of the trigonometric functions. In the following, we discuss some nonlinear transformation methods.

Power Transformation (Tukey's Ladder of Powers)

Tukey describes a way of re-expressing variables using a power transformation (Tukey 1977). The aim of this transformation is to improve the linearity between variables. When we consider two variables (x and y), transformation can be applied to one variable or both of them depending on the relationship between the two variables. This kind of transformation fits when the relationship between the two variables is monotonic and has a single bend. When the data are represented as pairs of (x,y), Tukey has expressed data transformation as

$$\boldsymbol{y^a = \beta_0 + \beta_1 + x^b}.$$

The choice of $\boldsymbol{a}$ and $\boldsymbol{b}$ decides on the transformation type in the relationship between x and y. Figure 3 shows a visual rule of thumb that has been proposed by John Tukey. The following diagram gives us an insight to understand which transformations are likely to work with different types of data.

We explain Tukey's ladder rule as follows: Suppose the data patterns follow a similar curve as the blue line in Q1; thus the data could be transformed by going up the ladder for x, y, or both. If the data pattern is shaped similar to that shown in Q2, then we should try to transform the data by going the down-ladder for x and/or up-ladder for y. Similar procedures can be applied for the other two quarters. Figure 4 explains the ladder of power for variable y. The transformation is stronger when the power value is away from 1 (the original data) in both directions (up and down).

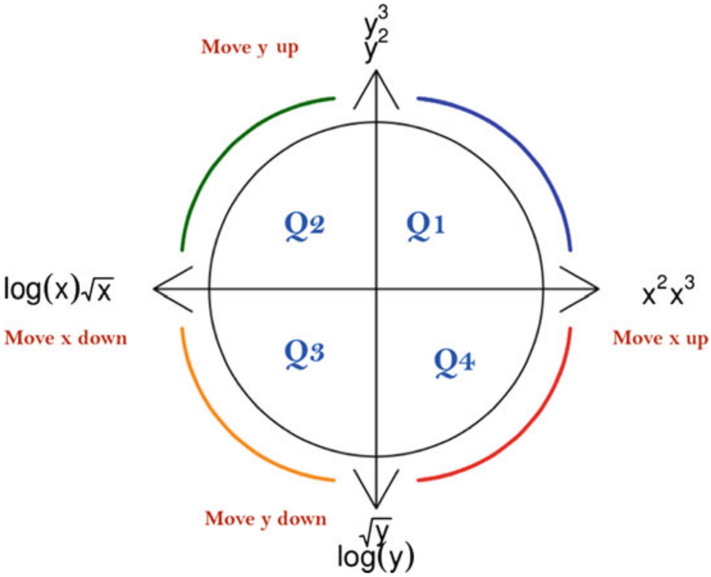
Choosing the Right Numeric Transformation

There is no definite answer to what is the best transformation method to use for a particular data set. The choice is very data dependent and requires an understanding of the domain as well as the data distribution. Trial and error for the common transformation methods may also be required. Table 1 summarizes the main transformation methods.

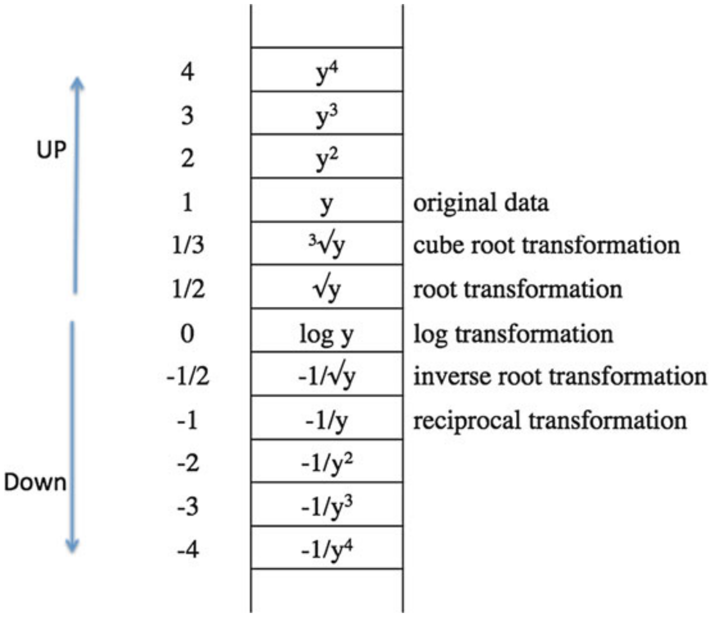
Nominal to Numeric Transformation

All the aforementioned methods transform and re-express numerical variables. However, the transformation of nominal variables is equally

Data Preparation, Fig. 3
Tukey's ladder rule



Data Preparation, Fig. 4
The ladder of power



4	y^4	
3	y^3	
2	y^2	
1	y	original data
1/3	$\sqrt[3]{y}$	cube root transformation
1/2	$\sqrt{y}$	root transformation
0	log y	log transformation
-1/2	$-1/\sqrt{y}$	inverse root transformation
-1	-1/y	reciprocal transformation
-2	$-1/y^2$	
-3	$-1/y^3$	
-4	$-1/y^4$	

important, especially for machine learning and data mining methods that only accept numerical values such as SVM and ANN. Assume that we have a nominal variable x with N different nominal values. There are two approaches to transform x into a numeric variable:

1. The first and simplest approach is to map nominal values to the integers 1 to N. Although simple, this method has two major drawbacks:
   - Integer substitution may impose an ordering that does not actually exist in the original data.
   - The integer value might be used as part of the calculation in the mining algorithm giving an incorrect meaning of weights based on the assigned values.

Data Preparation, Table 1 Summary of key transformation methods

Method	Pros	Cons
Standard linear regression	–Preserves the relationship between variables	–No actual transformation occurred
Reciprocal transformation	–Making small values bigger and big values smaller –Reducing the effect of outliers	–Not applicable for zero
Log transformation	–Good for right skewed data –$\log_{10}(x)$ is especially good at handling higher-order powers of 10 (e.g., 1000,100,000)	–Not applicable for zero and negative values (constant can be added to overcome this)
Root transformation	–Simple counts –Good for right skewed data	–Not applicable for negative values (constant can be added to overcome this)
Logit transformation	–Works with proportions and percents	–Not applicable for 0 and 1 values
Cube root transformation	–Can be applied on negative and 0 values	–Not effective in transformation as long model

2. The other main approach is to first binarize the variable (see 3.7 Binarization) and then map each of the N new binary attributes to the integer values 0 and 1. This approach is generally viewed as safer than the first and hence is more widely used.

Propositionalization

Some data sets contain information expressed in a relational format, describing relationships between objects in the world. While some learning systems can accept relations directly, most operate only on attribute-value representations. Therefore, a relational representation must be re-expressed in attribute-value form. In other words, a representation equivalent to first-order logic must be converted to a representation equivalent only to propositional logic.

Discretization

Discretization transforms continuous data into a discrete form. This is useful in many cases for better data representation, data volume reduction, better data visualization, and representing data at various levels of granularity for data analysis. Data discretization approaches are categorized as supervised, unsupervised, bottom-up, or top-down. Approaches for data discretization include binning, entropy based, nominal to numeric, 3-4-5 rule, and concept hierarchy. See ▶ Discretization.

Binarization

Some systems cannot process multivalued categorical variables. This limitation can be circumvented by binarization, a process that converts a multivalued categorical variable into multiple binary variables, one new variable to represent the presence or absence of each value of the original variable.

Conversely, multiple mutually exclusive binary variables might be converted into a single multivalued categorical variable.

Granularity

It is important to select appropriate levels of granularity for analysis. For example, when distinguishing products, should a gallon of low-fat milk be described as a dairy product, and hence not distinguished from any other type of dairy product; be described as low-fat milk, and hence not distinguished from other brands and quantities; or be uniquely distinguished from all other products?

Analysis at the lowest level of granularity makes possible identification of potentially valuable fine-detail regularities in the data but may make it more difficult to identify high-level relationships.

Dimensionality Reduction

As many learning systems have difficulty with high-dimension data, it may be desirable to project the data onto a lower-dimensional space. Popular approaches to doing so include principal component analysis and kernel methods.

Feature Engineering

It is often desirable to create derived values. For example, the available data might contain fields for purchase price, costs, and sale price. The relevant quantity for analysis might be profit, which must be computed from the raw data.

Feature engineering can be considered as means for dimensionality reduction also, by replacing the original features by a smaller number of derived features.

See ▶ Feature Selection and ▶ Feature Construction in Text Mining.

Sampling

Much of the theory on which learning systems are based assumes that the training data are randomly sampled from the population about which the user wishes to learn a model. However, much historical data contains sampling biases, for example, data that were easy to collect or were considered interesting for some other purpose. It is important to consider whether the available data are sufficiently representative of the future data to which a learned model is to be applied.

In all sampling methods, the aim is to select a sample S containing N instances from the entire data D. Each method models the relationship between a population and a sample with an underlying mathematical process. We discuss in the following some of these methods:

Random Sampling

In this method, S is selected randomly from D with a probability of $1/N$ for any instance in D to be selected. *Simple random sampling* may have very poor performance in the presence of skew in data. There are two main variants of simple random sampling, *with replacement* (SRSWR) and *without replacement* (SRSWOR). For sampling with replacement, the instance that is drawn from the population is replaced, and therefore it might be chosen again. For sampling without replacement, each instance that is drawn from D is removed, and hence S must contain N distinct instances.

Simple random sampling is usually easy to implement and to understand. However, it might cause loss of accuracy if applied to skewed data by failing to include sufficient data to accurately represent the tail of the distribution. The simple random sample might also result in substantial variance across samples.

Cluster Sampling

This method approximates the percentage of each class (or subpopulation of interest) in the overall data set; then it draws a simple random sample from each cluster. In this method, we might not have a complete list of population members (i.e., not all data available). However, a list of groups or "clusters" of this population is available and complete. That means the clusters could be incomplete, but a list of them is complete. Therefore, cluster sampling is a cost-efficient sampling method, as it does not require data to be complete. A drawback for cluster sampling is the possible poor representation of the diversity in clusters.

Stratified Sampling

If D is divided into mutually disjoint parts called strata, obtaining a simple random sample from each stratum generates a stratified sample.

Stratified sampling has a number of advantages. First, inferences can be made about specific subgroups for more efficient statistical estimates. Since each stratum is treated as an independent population, different sampling approaches can be applied to different strata. Second, this method will never result in lower efficiency than the simple random sample, provided that each stratum is proportional to the group's size in the population. Finally, it increases data readability as it represents individual preexisting strata within a population rather than the overall population.

Stratified sampling is complex to implement and estimate. It also can be sensitive to parameters such as selection criteria and minimum group size. Finally, stratified sampling techniques are generally used when the population is heterogeneous, or dissimilar, where certain homogeneous, or similar, subpopulations can be isolated (strata). Thus, this method will not be useful when there are no homogeneous subgroups. Read more about sampling techniques in García et al. (2015).

Balanced sampling is a special case of stratified sampling where the strata correspond to the classes and the sample drawn from each strata is proportional to the class's size in the population.

Decision Epoch

In a ▶ Markov decision process, *decision epochs* are sequences of times at which the decision-maker is required to make a decision. In a discrete time Markov decision process, decision epochs occur at regular, fixed intervals, whereas in a continuous time Markov decision process (or semi-Markov decision process), they may occur at randomly distributed intervals.

Decision List

Johannes Fürnkranz
Knowledge Engineering Group, TU Darmstadt, Darmstadt, Deutschland
Department of Information Technology, University of Leoben, Leoben, Austria

Synonyms

Ordered rule set

Definition

A decision list (also called an ordered rule set) is a collection of individual ▶ classification rules that collectively form a ▶ classifier. In contrast to an unordered ▶ rule set, decision lists have an inherent order, which makes classification quite straightforward. For classifying a new instance, the rules are tried in order, and the class of the first rule that covers the instance is predicted. If no induced rule fires, a *default rule* is invoked, which typically predicts the majority class.

Typically, decision lists are learned with a ▶ covering algorithm, which learns one rule at a time, appends it to the list, and removes all covered examples before learning the next one. Decision lists are popular in ▶ inductive logic programming, because PROLOG programs may be considered to be simple decision lists, where all rules predict the same concept.

A formal definition of decision lists, a comparison of their expressiveness to decision trees and rule sets in disjunctive and conjunctive normal form, as well as theoretical results on the learnability of decision lists can be found in Rivest (1987).

Decision Lists and Decision Trees

Johannes Fürnkranz
Knowledge Engineering Group, TU Darmstadt, Darmstadt, Deutschland
Department of Information Technology, University of Leoben, Leoben, Austria

Definition

▶ Decision trees and ▶ decision lists are two popular ▶ hypothesis languages, which share quite a few similarities, but also have important differences with respect to expressivity and learnability.

Discussion

The key difference between decision trees and decision lists is that the former may be viewed as unordered ▶ rule sets, where each leaf of the tree corresponds to a single rule with a condition part consisting of the conjunction of all edge labels on the path from the root to this leaf. The hierarchical structure of the tree ensures that the rules in the set are non-overlapping, i.e., each example is covered by exactly one rule. This additional constraint makes classification easier (no conflicts from multiple rules), but may result in more complex rules. For example, it has been shown that decision lists (ordered rule sets) with at most k conditions per rule are strictly *more expressive* than decision trees of depth k Rivest (1987).

This is also reflected in the learning strategies that are typically used for learning these concept classes. Decision trees are traditionally learned with a ▸ divide-and-conquer strategy, which successively divides the example space into non-overlapping regions, whereas the ▸ covering algorithm that is typically used for learning rule sets is also known as ▸ separate-and-conquer Fürnkranz (1990) because it successively removes (separates) examples covered by previously learned rule. For a comparison between the two strategies we refer to Boström (1995).

Moreover, the restriction of decision tree learning algorithms to non-overlapping rules imposes strong constraints on learnable rules. One problem resulting from this constraint is the *replicated subtree problem* Pagallo and Haussler (1990); it often happens that identical subtrees have to be learned at various places in a decision tree, because of the fragmentation of the example space imposed by the restriction to non-overlapping rules. Rule learners do not make such a restriction, and are thus less susceptible to this problem. An extreme example for this problem has been provided by Cendrowska (1987), who showed that the minimal decision tree for the concept x defined as

```
IF A = 3 AND B = 3 THEN
   Class = x
IF C = 3 AND D = 3 THEN
   Class = x
```

has 10 interior nodes and 21 leafs assuming that each attribute A ... D can be instantiated with three different values.

On the other hand, a key advantage of decision tree learning is that not only a single rule is optimized, but that conditions are selected in a way that simultaneously optimizes the example distribution in all successors of a node. Attempts to adopt this property for rule learning have given rise to several hybrid systems, the best known being PART Frank and Witten (1998), which learns a decision list that consists of a list of rules, each one being the single best rule of a separate decision tree. This rule can be efficiently found without learning the full tree, by repeated expansion of its most promising branch. Similarly, pruning algorithms can be used to convert decision trees into sets of non-overlapping rules Quinlan (1987a).

Decision Rule

A decision rule is an element (piece) of knowledge, usually in the form of a "if-then statement":

if < Condition > then < Action >

If its Condition is satisfied (i.e., matches a fact in the corresponding database of a given problem) then its Action (e.g., classification or decision making) is performed. See also ▶ Markovian Decision Rule.

Decision Stump

Johannes Fürnkranz
Knowledge Engineering Group, TU Darmstadt,
Darmstadt, Deutschland
Department of Information Technology,
University of Leoben, Leoben, Austria

Abstract

A *decision stump* is a ▶ Decision Tree, which uses only a single attribute for splitting. For discrete attributes, this typically means that the tree consists only of a single interior node (i.e., the root has only leaves as successor nodes). If the attribute is numerical, the tree may be more complex.

Discussion

Decision stumps perform surprisingly well on some commonly used benchmark datasets from the UCI repository (Holte 1993), which illustrates that learners with a high ▶ Bias and low ▶ Variance may perform well because they are less prone to ▶ Overfitting. Decision stumps are also often used as weak learners in ▶ Ensemble Methods such as boosting Freund and Schapire (1996).

Decision Threshold

The decision threshold of a binary classifier that outputs scores, such as ▶ decision trees or ▶ naive Bayes, is the value above which scores are interpreted as positive classifications. Decision thresholds can be either fixed if the classifier outputs calibrated scores on a known scale (e.g., 0.5 for a probabilistic classifier), or learned from data if the scores are uncalibrated. Decision Tree

Johannes Fürnkranz
Knowledge Engineering Group, TU Darmstadt,
Darmstadt, Deutschland
Department of Information Technology,
University of Leoben, Leoben, Austria

Abstract

The induction of decision trees is one of the oldest and most popular techniques for learning discriminatory models, which has been developed independently in the statistical (Breiman et al. 1984; Kass 1980) and machine learning (Hunt et al. 1966; Quinlan 1983, 1986) communities. A *decision tree* is a tree-structured classification model, which is easy to understand, even by non-expert users, and can be efficiently induced from data. An extensive survey of decision-tree learning can be found in Murthy (1998).

Synonyms

Classification tree

Representation

Figure 1 shows a well-known dataset, in which examples are descriptions of weather conditions (*outlook*, *humidity*, *windy*, *temperature*), and the target concept is whether these conditions are suitable for playing golf or not (Quinlan 1986). On the right, a simple decision tree that can be induced from such data is shown. Classification of a new example starts at the top node – the *root* – and the value of the attribute that corresponds to this tree is considered (*outlook* in the example). Classification then proceeds by moving down the branch that corresponds to a particular value of this attribute, arriving at a new node with a new attribute. This process is repeated until we arrive at a terminal node – a so-called *leaf* – which is not labeled with an attribute but with a value of the target attribute (*play golf?*). For all examples that arrive at the same leaf, the same target value will be predicted. Figure 1 shows leaves as rectangular boxes.

Note that some of the attributes may not occur at all in the tree. For example, the tree in Fig. 1 does not contain a test on *temperature* because the training data can be classified without making a reference to this variable. More generally, one can say that the attributes in the upper parts of the tree (near the root) tend to have a stronger influence on the value of the target variable than the nodes in the lower parts of the tree (e.g., *outlook* will always be tested, whereas *humidity* and *windy* will only be tested under certain conditions).

Learning Algorithm

Decision trees are learned in a top-down fashion, with an algorithm known as *top-down induction of decision trees (TDIDT)*, *recursive partitioning*, or *divide-and-conquer* learning. The algorithm selects the best attribute for the root of the tree, splits the set of examples into disjoint sets, and adds corresponding nodes and branches to the tree. The simplest splitting criterion is for discrete attributes, where each test has the form $t \leftarrow (A = v)$ where v is one possible value of the chosen attribute A. The corresponding set S_t contains all training examples for which the attribute A has the value t. This can be easily adapted to numerical attributes, where one typically uses binary splits of the form $t \leftarrow (A < v_t)$, which indicate whether the attribute's value is above or below a certain threshold value v_t. Alternatively, one can transform the data beforehand using a ▶ discretization algorithm (Fig. 2).

After splitting the dataset according to the selected attribute, the procedure is recursively applied to each of the resulting datasets. If a set contains only examples from the same class, or if no further splitting is possible (e.g., because all possible splits have already been exhausted or all

Outlook	*Temp*	*Humidity*	*Windy*	*Golf?*
rainy	hot	high	false	no
rainy	hot	high	true	no
overcast	hot	high	false	yes
sunny	mild	high	false	yes
sunny	cool	normal	false	yes
sunny	cool	normal	true	no
overcast	cool	normal	true	yes
rainy	mild	high	false	no

Decision Tree, Fig. 1 A data set describing weather conditions and a target variable (*Play Golf?*) and a decision tree learned for this dataset (Quinlan 1986) remaining splits will have the same outcome for all examples), the corresponding node is turned into a leaf node and labeled with the respective class. For all other sets, an interior node is added and associated with the best splitting attribute for the corresponding set as described above. Hence, the dataset is successively partitioned into non-overlapping, smaller datasets until each set only contains examples of the same class (a so-called *pure* node). Eventually, a pure node can always be found via successive partitions unless the training data contains two identical but contradictory examples, i.e., examples with the same feature values but different class values.

```
function TDIDT($S$)

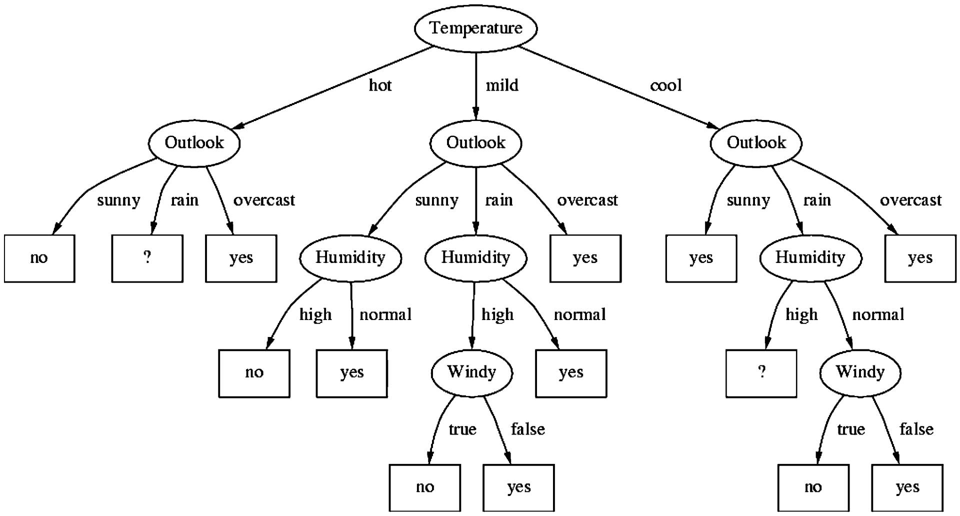
Input: $S$, a set of labeled examples.

$Tree$ = new empty node
if all examples have the same class $c$
   or no further splitting is possible
then   // new leaf
       LABEL($Tree$) = $c$
else   // new decision node
       $(A, T)$ = FINDBESTSPLIT($S$)
       for each test $t \in T$ do
              $S_t$ = all examples that satisfy $t$
              $Node_t$ = TDIDT($S_t$)
              ADDEDGE($Tree \xrightarrow{t} Node_t$)
       endfor
endif
return $Tree$
```

Decision Tree, Fig. 2 Top-down induction of decision trees

Attribute Selection

The crucial step in decision-tree induction is the choice of an adequate attribute. In the sample tree of Fig. 3, which has been generated from the same 14 training examples as the tree of Fig 1, most leaves contain only single training example, i.e., with the selected splitting criteria, the termination criterion (all examples of a node have to be of the same class) could in many cases only trivially be satisfied (only one example remained in the node). Although both trees classify the training data correctly, the former appears to be more trustworthy, and in practice, one can often observe that simpler trees are more accurate than more complex trees. A possible explanation could be that labels that are based on a higher number of training examples tend to be more reliable. However, this preference for simple models is a heuristic criterion known as ▶ Occam's Razor, which appears to work fairly well in practice. but is still the subject of ardent debates within the machine learning community.



Decision Tree, Fig. 3 A needlessly complex decision tree describing the same dataset

Typical attribute selection criteria use a function that measures the *impurity* of a node, i.e., the degree to which the node contains only examples of a single class. Two well-known impurity measures are the information-theoretic entropy (Quinlan 1986) and the Gini index (Breiman et al. 1984), which are defined as

$$Entropy(S) = -\sum_{i=1}^{c} \frac{|S_i|}{|S|} \cdot \log_2\left(\frac{|S_i|}{|S|}\right)$$

$$Gini(S) = 1 - \sum_{i=1}^{c} \left(\frac{|S_i|}{|S|}\right)^2$$

where S is a set of training examples and S_i is the set of training examples that belong to class c_i. Both functions have their maximum at the point where the classes are equally distributed (i.e., where all S_i have the same size, maximum impurity), and their minimum at the point where one S_i contains all examples ($S_i = S$) and all other S_j, $j \neq i$ are empty (minimum impurity).

A good attribute divides the dataset into subsets that are as pure as possible ideally into sets so that each one only contains examples from the same class. Thus, we want to select the attribute that provides the highest decrease in average impurity, the so-called *gain*:

$$Gain(S, A)$$

$$= Impurity(S) - \sum_{t} \frac{|S_t|}{|S|} \cdot Impurity(S_t)$$

where S_t are non-overlapping disjoint subsets $S_t \in S$ that are induced by splitting the attribute A, and *Impurity* can be any impurity measure. As the first term, *Impurity*(S), is constant for all attributes, one can also omit it and directly minimize the average impurity (which is typically done when *Gini* is used as an impurity measure).

A common problem is that attributes with many values have a higher chance of resulting in pure successor nodes and are therefore often preferred over attributes with fewer values. To counter this, the so-called *gain ratio* normalizes the gained entropy with the intrinsic entropy of the split:

$$GainRatio(S, A) = \frac{Gain(S, A)}{\sum_t \frac{|S_t|}{|S|} \cdot \log_2\left(\frac{|S_t|}{|S|}\right)}$$

A similar phenomenon can be observed for numerical attributes, where the number of possible threshold values determines the number of possible binary splits for this attribute. Numerical attributes with many possible binary splits are often preferred over numerical attributes with fewer splits because they have a higher chance that one of their possible splits fits the data. A discussion of this problem and a proposal for a solution can be found in Quinlan (1996).

Other attribute selection measures, which do not conform to the gain framework laid out above, are also possible, such as CHAID's evaluation with a χ^2 test statistic (Kass 1980). Experimental comparison of different measures can be found in Mingers (1989a) and Buntine and Niblett (1992).

Thus, the final tree is constructed by a sequence of local choices that each consider only those examples that end up at the node that is currently split. Of course, such a procedure can only find local optima for each node, but cannot guarantee convergence to a global optimum (the smallest tree). One of the key advantages of this divide-and-conquer approach is its efficiency, which results from the exponential decrease in the quantity of data to be processed at successive depths in the tree.

Overfitting Avoidance

In principle, a decision-tree model can be fit to any training set that does not contain contradictions (i.e., there are no examples with identical attributes but different class values). This may lead to ▸ Overfitting in the form of overly complex trees.

For this reason, state-of-the-art decision-tree induction techniques employ various ▸ Pruning techniques for restricting the complexity of the found trees. For example, C4.5 has a *pre-pruning* parameter m that is used to prevent further splitting unless at least two successor nodes have at least m examples. The *cost-complexity pruning* method used in CART may be viewed as a simple

▶ Regularization method, where a good choice for the regularization parameter, which trades off the fit of the data with the complexity of the tree, is determined via ▶ Cross-validation.

More typically, *post-pruning* is used for removing branches and nodes from the learned tree. More precisely, this procedure replaces some of the interior nodes of the tree with a new leaf, thereby removing the subtree that was rooted at this node. An empirical comparison of different decision-tree pruning techniques can be found in Mingers (1989b).

It is important to note that the leaf nodes of the new tree are no longer pure nodes, i.e., they no longer need to contain training examples that all belong to the same class. Typically, this is simply resolved by predicting the most frequent class at a leaf. The class distribution of the training examples within the leaf may be used as a reliability criterion for this prediction.

Well-Known Decision-Tree Learning Algorithms

The probably best-known decision-tree learning algorithm is C4.5 (Quinlan 1993), which is based upon (Quinlan 1983), which, in turn, has been derived from an earlier concept learning system (Hunt et al. 1966). ID3 realized the basic recursive partitioning algorithm for an arbitrary number of classes and for discrete attribute values. C4.5 (Quinlan 1993) incorporates several key improvements that were necessary for tackling real-world problems, including handling of numeric and missing attribute values, overfitting avoidance, and improved scalability. A C-implementation of C4.5 is freely available from its author. A re-implementation is available under the name J4.8 in the Weka data mining library. C5.0 is a commercial successor of C4.5, distributed by RuleQuest Research. CART (Breiman et al. 1984) is the best-known system in the statistical learning community. It is integrated into various statistical software packages, such as R or S.

Decision trees are also often used as components in ▶ Ensemble Methods such as random forests (Breiman 2001) or AdaBoost (Freund and Schapire 1996). They can also be modified for predicting numerical target variables, in which case they are known as ▶ regression trees. One can also put more complex prediction models into the leaves of a tree, resulting in ▶ Model Trees.

Deep Belief Nets

Geoffrey Hinton
University of Toronto, Toronto, ON, Canada

Synonyms

Deep belief networks

Definition

Deep belief nets are probabilistic generative models that are composed of multiple layers of stochastic latent variables (also called "feature detectors" or "hidden units"). The top two layers have undirected, symmetric connections between them and form an associative memory. The lower layers receive top-down, directed connections from the layer above. Deep belief nets have two important computational properties. First, there is an efficient procedure for learning the top-down, generative weights that specify how the variables in one layer determine the probabilities of variables in the layer below. This procedure learns one layer of latent variables at a time. Second, after learning multiple layers, the values of the latent variables in every layer can be inferred by a single, bottom-up pass that starts with an observed data vector in the bottom layer and uses the generative weights in the reverse direction.

Motivation and Background

The perceptual systems of humans and other animals show that high-quality pattern recognition can be achieved by using multiple layers of adaptive nonlinear features, and researchers have been trying to understand how this type of perceptual system could be learned, since the 1950s (Selfridge 1958). Perceptrons (Rosenblatt 1962) were an early attempt to learn a biologically inspired perceptual system, but they did not have an efficient learning procedure for multiple layers of features. Backpropagation (Werbos 1974; Rumelhart et al. 1986) is a supervised learning procedure that became popular in the 1980s because it provided a fairly efficient way of learning multiple layers of nonlinear features by propagating derivatives of the error in the output backward through the multilayer network. Unfortunately, backpropagation has difficulty optimizing the weights in deep networks that contain many layers of hidden units and it requires labeled training data, which is often expensive to obtain. Deep belief nets overcome the limitations of backpropagation by using *unsupervised* learning to create layers of feature detectors that model the statistical structure of the input data without using any information about the required output. High-level feature detectors that capture complicated higher-order statistical structure in the input data can then be used to predict the labels.

Structure of the Learning System

Deep belief nets are learned one layer at a time by treating the values of the latent variables in one layer, when they are being inferred from data, as the data for training the next layer. This efficient, greedy learning can be followed by, or combined with, other learning procedures that fine-tune all of the weights to improve the generative or discriminative performance of the whole network. Discriminative fine-tuning can be performed by adding a final layer of variables that represent the desired outputs and backpropagating error derivatives. When networks with many hidden layers are applied in domains that contain highly structured input vectors, backpropagation learning works much better if the feature detectors in the hidden layers are initialized by learning a deep belief net that models the structure in the input data (Hinton and Salakhutdinov 2006). Matlab code for learning and fine-tuning deep belief nets can be found at http://cs.toronto.edu/~hinton.

Composing Simple Learning Modules

Early deep belief networks could be viewed as a composition of simple learning modules, each of which is a "restricted Boltzmann machine." Restricted Boltzmann machines contain a layer of "visible units" that represent the data and a layer of "hidden units" that learn to represent features that capture higher-order correlations in the data. The two layers are connected by a matrix of symmetrically weighted connections, W, and there are no connections within a layer. Given a vector of activities $\mathbf{v}$ for the visible units, the hidden units are all conditionally independent so it is easy to sample a vector, $\mathbf{h}$, from the posterior distribution over hidden vectors, $p(\mathbf{h}|\mathbf{v}, \mathbf{W})$. It is also easy to sample from $p(\mathbf{v}|\mathbf{h}, \mathbf{W})$. By starting with an observed data vector on the visible units and alternating several times between sampling from $p(\mathbf{h}|\mathbf{v}, \mathbf{W})$ and $p(\mathbf{v}|\mathbf{h}, \mathbf{W})$, it is easy to get a learning signal which is simply the difference between the pairwise correlations of the visible and hidden units at the beginning and end of the sampling (see Chapter ▶ Boltzmann Machines for details).

The Theoretical Justification of the Learning Procedure

The key idea behind deep belief nets is that the weights, $\mathbf{W}$, learned by a restricted Boltzmann machine define both $p(\mathbf{v}|\mathbf{h}, \mathbf{W})$ and the prior distribution over hidden vectors, $p(\mathbf{h}|\mathbf{W})$, so the probability of generating a visible vector, $\mathbf{v}$, can be written as

$$p(\mathbf{v}) = \sum_{\mathbf{h}} p(\mathbf{h}|\mathbf{W})\, p(\mathbf{v}|\mathbf{h}, \mathbf{W}) \qquad (1)$$

After learning $\mathbf{W}$, we keep $p(\mathbf{v}|\mathbf{h}, \mathbf{W})$ but we replace $p(\mathbf{h}|\mathbf{W})$ by a better model of the *aggregated* posterior distribution over hidden vectors – i.e., the nonfactorial distribution produced by averaging the factorial posterior distributions produced by the individual data vectors. The better model is learned by treating the hidden activity vectors produced from the training data as the training data for the next learning module. Hinton et al. (2006) show that this replacement improves a variational lower bound on the probability of the training data under the composite model.

Deep Belief Nets with Other Types of Variable

Deep belief nets typically use the logistic function $y = 1/(1 + \exp(-x))$ of the weighted input, x, received from above or below to determine the probability that a binary latent variable has a value of 1 during top-down generation or bottom-up inference. Other types of variable within the exponential family, such as Gaussian, Poisson, or multinomial, can also be used (Welling et al. 2005; Movellan and Marks 2001) and the variational bound still applies. However, networks with multiple layers of Gaussian or Poisson units are difficult to train and can become unstable. To avoid these problems, the function $\log(1+\exp(x))$ can be used as a smooth approximation to a rectified linear unit. Units of this type often learn features that are easier to interpret than those learned by logistic units. $\log(1+\exp(x))$ is not in the exponential family, but it can be approximated very accurately as a sum of a set of logistic units that all share the same weight vector and adaptive bias term, but differ by having offsets to the shared bias of $-0.5, -1.5, -2.5, \ldots$.

Using Autoencoders as the Learning Module

A closely related approach that is also called a "deep belief net" uses the same type of greedy, layer-by-layer learning with a different kind of learning module – an "autoencoder" that simply tries to reproduce each data vector from the feature activations that it causes (Hinton 1989; Bengio et al. 2007; LeCun and Bengio 2007). However, the variational bound no longer applies, and an autoencoder module is less good at ignoring random noise in its training data (Larochelle et al. 2007).

Applications of Deep Belief Nets

Deep belief nets have been used for generating and recognizing images (Bengio et al. 2007; Hinton et al. 2006; Ranzato et al. 2007), video sequences (Sutskever and Hinton 2007), and motion-capture data (Taylor et al. 2007). If the number of units in the highest layer is small, deep belief nets perform nonlinear dimensionality reduction (Hinton and Salakhutdinov 2006), and by pretraining each layer separately, it is possible to learn very deep autoencoders that can then be fine-tuned with backpropagation (Hinton and Salakhutdinov 2006). Such networks cannot be learned in reasonable time using backpropagation alone. Deep autoencoders learn compact representations of their input vectors that are much better than those found by linear methods such as principal component analysis, and if the highest level code is forced to be binary, they allow extremely fast retrieval of documents or images (Salakhutdinov and Hinton 2007; Torralba et al. 2008).

Abstract

Deep learning artificial neural networks have won numerous contests in pattern recognition and machine learning. They are now widely used by the worlds most valuable public companies. I review the most popular algorithms for feedforward and recurrent networks and their history.

Introduction

Deep learning has revolutionized Pattern Recognition and Machine Learning. It is about credit assignment in adaptive systems with long chains of potentially causal links between actions and consequences.

The ancient term "deep learning" was first introduced to Machine Learning by Dechter (1986) and to artificial neural networks (NNs) by Aizenberg et al. (2000). Subsequently it became especially popular in the context of deep NNs, the most successful deep learners, which are much older though, dating back half a century. This article will focus on essential developments since the 1960s, addressing supervised, unsupervised, and (briefly) reinforcement learning. There is a recent, more detailed survey with 888 references (Schmidhuber 2015). LeCun et al. (2015) provide a more limited view of more recent deep learning history. The present condensed survey is based on the Scholarpedia article (Schmidhuber 2015b).

A standard NN consists of many simple, connected processors called units, each producing a sequence of real-valued activations. Input units get activated through sensors perceiving the environment, other units through connections with real-valued weights from previously active units. Some units may influence the environment by triggering actions. Learning or credit assignment is about finding weights that make the NN exhibit desired behavior, such as controlling a robot. Depending on the problem and how the units are connected, such behavior may require long causal chains of computational stages, where each stage transforms (often in a nonlinear way) the aggregate activation of the network. Deep learning in NNs is about accurately assigning credit across many such stages.

In a sense, sequence-processing recurrent NNs (RNNs) are the ultimate NNs, because they are general computers (an RNN can emulate the circuits of a microchip). In fully connected RNNs, all units have connections to all non-input units. Unlike feedforward NNs, RNNs can implement while loops, recursion, etc. The program of an RNN is its weight matrix. RNNs can learn programs that mix sequential and parallel information processing in a natural and efficient way.

To measure whether credit assignment in a given NN application is of the deep or shallow type, we consider the length of the corresponding credit assignment paths, which are chains of possibly causal connections between subsequent unit activations, e.g., from input units through hidden units to output units in feedforward NNs (FNNs) without feedback connections or through transformations over time in RNNs. FNNs with fixed topology have a problem-independent maximal problem depth bounded by the number of layers of units. RNNs, the deepest of all NNs, may learn to solve problems of potentially unlimited depth, for example, by learning to store in their activation-based "short-term memory" representations of certain important previous observations for arbitrary time intervals.

The difficulty of a problem may have little to do with its depth. Some NNs can quickly learn to solve certain deep but simple problems through random weight guessing (e.g., Hochreiter and Schmidhuber 1997b). In general, however, finding an NN that precisely models a given training set (of input patterns and corresponding labels) is an NP-complete problem and also in the case of deep NNs (e.g., Sima 1994).

First Deep Learners

Certain early NNs (McCulloch and Pitts 1943) did not learn at all. Hebb (1949) published ideas about unsupervised learning. The following decades brought shallow unsupervised NNs and supervised NNs (e.g., Rosenblatt 1958). Early supervised NNs were essentially variants of linear regressors dating back two centuries (Gauss, Legendre).

Deep learning networks originated in the 1960s when Ivakhnenko and Lapa (1965) published the first general, working learning algorithm for supervised deep feedforward multilayer perceptrons. Their units had polynomial activation functions combining additions and multiplications in Kolmogorov-Gabor polynomials. Ivakhnenko (1971) already described a deep network with eight layers trained by the "group method of data handling," still popular in the new millennium. Given a training set of input vectors with corresponding target output vectors, layers are incrementally grown and trained by regression analysis and then pruned with the help of a separate validation set, where regularization is used to weed out superfluous units. The numbers of layers and units per layer can be learned in problem-dependent fashion.

Like later deep NNs, Ivakhnenko's nets learned to create hierarchical, distributed, internal representations of incoming data. Many later nonneural methods of Artificial Intelligence and Machine Learning also learn more and more abstract, hierarchical data representations. For example, syntactic pattern recognition methods (Fu 1977) such as grammar induction discover hierarchies of formal rules to model observations.

Architectures of Convolutional NNs (CNNs)

The 1970s also saw the birth of the convolutional NN (CNN) architecture (Fukushima's Neocognitron, 1979) inspired by neurophysiological insights. Today such architectures are widely used for computer vision. Here the (typically rectangular) receptive field of a unit with given weight vector (a filter) is shifted step by step across a two-dimensional array of input values, such as the pixels of an image (usually there are several such filters). The resulting array of subsequent activation events of this unit can then provide inputs to higher-level units and so on. Due to massive weight replication, relatively few parameters may be necessary to describe the behavior of such convolutional layers, which typically feed downsampling layers consisting of units whose fixed-weight connections originate from physical neighbors in the convolutional layers below. Downsampling units use "spatial averaging" to become active if at least one of their inputs is active; their responses are insensitive to certain small image shifts. Weng (1993) later replaced spatial averaging by "max-pooling" (MP), which is widely used today. Here a two-dimensional layer or array of unit activations is partitioned into smaller rectangular arrays. Each is replaced in a downsampling layer by the activation of its maximally active unit.

Backpropagation

Ivakhnenko and Fukushima did not yet use supervised backpropagation (BP) to train the weights of their nets by gradient descent in an objective function, such as the total classification error on a given training set of input patterns and corresponding labels, although BP was also developed back then.

BP's continuous form was derived in the early 1960s (Kelley 1960; Bryson 1961; Bryson and Ho 1969). Dreyfus (1962) published the elegant derivation of BP based on the chain rule only. BP's modern efficient version for discrete sparse networks (including FORTRAN code) was published by Linnainmaa (1970). Here the complexity of computing the derivatives of the output error with respect to each weight is proportional to the number of weights. That's the method still used today. Dreyfus (1973) used BP to change weights of controllers in proportion to such gradients. By 1980, automatic differentiation could derive BP for any differentiable graph (Speelpenning 1980). Werbos (1982) published the first application of BP to NNs, extending thoughts in his 1974 thesis, which did not yet have Linnainmaa's modern, efficient form of BP. In 1980–1990, computers became 10,000 times faster than those of 1960–1970 and widely accessible in academic labs. Computational experiments then demonstrated that BP in NNs can indeed yield useful internal representations in hidden layers of NNs (Rumelhart et al. 1986). Wan (1994) produced the first BP-trained NN to win a controlled pattern recognition contest with secret test set. Amari (1998) described BP for natural gradient-based NNs. By 2003, deep BP-based standard FNNs with up to seven layers were used to successfully classify high-dimensional data (e.g., Vieira and Barradas 2003).

In the 2000s, computing hardware had again become 10,000 times faster than in the 1980s. Cheap massively parallel graphics processing units (GPUs, originally developed for video games) started to revolutionize NN research. Standard FNNs implemented on GPU were 20 times faster than on CPU (Oh and Jung 2004). A plain GPU-based FNN trained by BP with pattern distortions (Baird 1990) set a new record of 0.35 % error rate (Ciresan et al. 2010) on the MNIST handwritten digit dataset, which by then had been the perhaps most famous machine learning benchmark for decades. This seemed to suggest that advances in exploiting modern computing hardware were more important than advances in algorithms.

Backpropagation for CNNs

LeCun et al. (1989) first applied BP to Neocognitron-like CNNs, achieving good performance on MNIST. Similar CNNs were used commercially in the 1990s. Ranzato et al. (2007) first applied BP to max-pooling CNNs (MPCNNs); advantages of doing this were pointed out subsequently (Scherer et al. 2010).

Efficient parallelized GPU-based MPCNNs (Ciresan et al. 2011) further improved the MNIST record dramatically, achieving human performance (around 0.2 %) for the first time (Ciresan et al. 2012c). To detect human actions in surveillance videos, a three-dimensional CNN, combined with support vector machines, was part of a larger system using a bag of features approach to extract regions of interest. The system won three 2009 TRECVID competitions. These were possibly the first official international contests won with the help of (MP)CNNs; compare (Ji et al. 2013).

In 2011, an ensemble (Breiman 1996; Schapire 1990) of GPU-based MPCNNs also was the first system to achieve superhuman visual pattern recognition in a controlled competition, namely, the IJCNN 2011 traffic sign recognition contest in Silicon Valley (Ciresan et al. 2012c). The system was twice better than humans and three times better than the nearest nonhuman competitor. Subsequently, similar committees of GPU-MPCNNs became widely used and also won the 2012 ImageNet classification contest (Krizhevsky et al. 2012), which is popular in the computer vision community. Further progress on ImageNet was achieved through variants of such systems (e.g., Zeiler and Fergus 2013; Szegedy et al. 2014; Simonyan and Zisserman 2015).

In 2012, a GPU-MPCNN committee also was the first deep learning NN to win a contest on visual object discovery in large images (Ciresan et al. 2013), namely, the ICPR 2012 Contest on Mitosis Detection in Breast Cancer Histological Images. Here deep MPCNNs are trained on labelled patches of big images and then used as feature detectors to be shifted across unknown visual scenes, using various rotations and zoom factors. Image parts that yield highly active output units are likely to contain objects similar to those the NN was trained on. A similar GPU-MPCNN committee was the first deep learner to win a pure image segmentation contest (Ciresan et al. 2012a), namely, the ISBI 2012 segmentation of neuronal structures in EM stacks challenge. The MPCNN learned to predict for each pixel whether it belongs to the background. Fast MPCNN image scanners avoid redundant computations and speed up naive implementations by up to three orders of magnitude (Masci et al. 2013), extending earlier efficient methods for CNNs without MP (Vaillant et al. 1994).

It is fair to say that deep GPU-CNNs have revolutionized computer vision. For example, GPU-MPCNNs helped to recognize multi-digit numbers in Google Street View images (Goodfellow et al. 2014b), where part of the NN was trained to count visible digits. Other successful recent CNN applications include scene parsing (Farabet et al. 2013), shadow detection (Khan et al. 2014), and video classification (Karpathy et al. 2014), to name a few.

Fundamental Deep Learning Problem and Unsupervised Pre-training of RNNs and FNNs

There are extensions of backpropagation (BP) for supervised RNNs (e.g., Williams 1989; Robinson and Fallside 1987; Werbos 1988). During training by "BP through time" (BPTT), the RNN is "unfolded" into an FNN that has essentially as many layers as there are time steps in the observed sequence of input vectors.

The drawbacks of BP and BPTT became obvious in 1991, when the vanishing/exploding gradient problem or "Fundamental Deep Learning Problem" was identified and analyzed (Hochreiter 1991): With standard activation functions, cumulative backpropagated error signals either shrink exponentially in the number of layers (or time steps) or grow out of bounds. The problem is most apparent in RNNs, the deepest of all NNs.

To some extent, Hessian-free optimization can alleviate the problem for FNNs (Moller 1993; Pearlmutter 1994) and RNNs (Martens and Sutskever 2011).

To overcome the vanishing gradient problem, an early generative model was proposed, namely, an unsupervised stack of RNNs called the neural history compressor (Schmidhuber 1992b). A first RNN uses unsupervised learning to predict its next input. Each higher level RNN tries to learn a compressed representation of the info in the RNN below, trying to minimize the description length (or negative log probability) of the data. The top RNN may then find it easy to classify the data by supervised learning. One can also "distill" the knowledge of a higher RNN (the teacher) into a lower RNN (the student) by forcing the lower RNN to predict the hidden units of the higher one. In the early 1990s, such systems could solve previously unsolvable "very deep learning" tasks involving hundreds of subsequent computational stages.

A conceptually very similar but FNN-based system was the deep belief network (DBN, Hinton and Salakhutdinov 2006), a stack of restricted Boltzmann machines (RBMs, Smolensky 1986) with a single layer of feature-detecting units. They can be trained by the contrastive divergence algorithm (Hinton 2002). At least in theory under certain assumptions, adding more layers improves a bound on the data's negative log probability (Hinton et al. 2006), equivalent to the data's description length – just like with the RNN history compressor above. A GPU-DBN implementation (Raina et al. 2009) was orders of magnitudes faster than previous CPU-DBNs; see also Coates et al. (2013). DBNs achieved good results on phoneme recognition (Mohamed and Hinton 2010). Autoencoder stacks (Ballard 1987) became a popular alternative way of pre-training deep FNNs in unsupervised fashion, before fine-tuning them through BP (e.g., Bengio et al. 2007).

Generally speaking, unsupervised learning (UL) can help to encode input data in a form advantageous for further processing. For example, FNNs may profit from pre-training by competitive UL prior to BP-based fine-tuning

(Maclin and Shavlik 1995). Many UL methods generate distributed, sparse representations of input patterns. Ideally, given an ensemble of input patterns, redundancy reduction through a deep NN will create a factorial code (a code with statistically independent components) of the ensemble (Barlow et al. 1989). Such codes may be sparse and can be advantageous for (1) data compression, (2) speeding up subsequent BP, and (3) trivializing the task of subsequent naive yet optimal Bayes classifiers. Methods for deep UL FNNs include hierarchical self-organizing Kohonen maps (e.g., Koikkalainen and Oja 1990), hierarchical Gaussian potential function networks (Lee and Kil 1991), layer-wise UL of feature hierarchies fed into SL classifiers (Behnke 1999), the self-organizing tree algorithm (Herrero et al. 2001), and nonlinear autoencoders (AEs) with five or more layers (e.g., Kramer 1991). Predictability minimization (Schmidhuber 1992c) searches for factorial codes through nonlinear feature detectors that fight nonlinear predictors, trying to become both as informative and as unpredictable as possible. Hierarchical CNNs in a Neural Abstraction Pyramid (e.g., Behnke 2003b) can be trained to reconstruct images corrupted by structured noise, thus enforcing increasingly abstract image representations in deeper and deeper layers.

In many applications of the 2000s, however, DBNs and other unsupervised methods were largely replaced by purely supervised FNNs, especially MPCNNs (see above). Here history repeated itself, because already in the 1990s, unsupervised RNN-based history compressors (see above) were largely replaced by purely supervised LSTM RNNs (see below).

Very Deep Learning in Supervised Sequence-Processing RNNs

Supervised long short-term memory (LSTM) RNNs have been developed since the 1990s (e.g., Hochreiter and Schmidhuber 1997b; Gers and Schmidhuber 2001; Graves et al. 2009). Parts of LSTM RNNs are designed such that backpropagated errors can neither vanish nor explode but flow backward in “civilized” fashion for thousands or even more steps. Thus, LSTM variants could learn previously unlearnable very deep learning tasks (including some unlearnable by the 1992 history compressor above) that require to discover the importance of (and memorize) events that happened thousands of discrete time steps ago, while previous standard RNNs already failed in case of minimal time lags of ten steps. It is possible to evolve good problem-specific LSTM-like topologies (Bayer et al. 2009).

Recursive NNs (Goller and Küchler 1996) generalize RNNs, by operating on hierarchical structures, recursively combining child representations into parent representations. Bidirectional RNNs (BRNNs) (Schuster and Paliwal 1997) are designed for input sequences whose starts and ends are known in advance, such as spoken sentences to be labeled by their phonemes. DAG-RNNs (Baldi and Pollastri 2003) generalize BRNNs to multiple dimensions. Recursive NNs, BRNNs, and DAG-RNNs unfold their full potential when combined with LSTM (Graves et al. 2009).

Particularly successful in competitions were stacks of LSTM RNNs (Fernandez et al. 2007b) trained by connectionist temporal classification (CTC, Graves et al. 2006), a gradient-based method for finding RNN weights that maximize the probability of teacher-given label sequences, given (typically much longer and more high-dimensional) streams of real-valued input vectors. CTC performs simultaneous segmentation (alignment) and recognition. In 2009, CTC-trained LSTM became the first RNN to win controlled international contests, namely, three competitions in connected handwriting recognition. Hannun et al. (2014) used CTC-trained RNNs to break a famous speech recognition benchmark record, without using any traditional speech processing methods such as hidden Markov models (HMMs) or Gaussian mixture models.

Unlike HMMs and previous RNNs, LSTM can learn to recognize context-sensitive languages. By 2007, LSTM had started to revolutionize speech recognition, outperforming traditional

HMMs in keyword spotting tasks (Fernandez et al. 2007b). By 2013, LSTM achieved best known results on the famous TIMIT phoneme recognition benchmark (Graves et al. 2013). Hybrids of traditional methods and LSTM RNNs obtained best known performance on large-vocabulary speech recognition (Sak et al.; Google 2014a; Li and Wu 2015). LSTM also helped to improve the state of the art in numerous other fields, including image caption generation (in conjunction with CNNs) (Vinyals et al.; Google 2014a), machine translation (Sutskever et al.; Google 2014), text-to-speech synthesis (Fan et al. 2015; Zen and Sak 2015, now available for Google Android), photo-real talking heads (Fan et al.; Microsoft 2015), syntactic parsing for natural language processing (Vinyals et al.; Google, 2014b), and many other applications. In 2015, CTC-trained LSTM dramatically improved Google Voice (by 49 %) and is now available to a billion smartphone users (Sak et al. 2015).

Gradient-based LSTM is no panacea though. Other methods sometimes outperformed LSTM at least on certain tasks (e.g., Jaeger 2004; Schmidhuber et al. 2007; Martens and Sutskever 2011; Zimmermann et al. 2012; Pascanu et al. 2013b; Koutnik et al. 2014). Several alternative RNN-related methods with fast memory control have been proposed over the decades (e.g., AMAmemory 2015).

Some Tricks to Improve NNs

BP-like methods can be used to search for "simple," low-complexity NNs with high generalization capability. For example, weight decay (e.g., Hanson and Pratt 1989) encourages near-zero weights, by penalizing large weights. Related weight priors are implicit in additional penalty terms (MacKay 1992) or in methods based on validation sets (e.g., Hastie and Tibshirani 1990). Similar priors (or biases towards simplicity) are implicit in constructive and pruning algorithms, e.g., layer-by-layer sequential network construction (e.g., Ivakhnenko 1971), input pruning (Moody 1992), unit pruning (e.g., Ivakhnenko 1971; Mozer and Smolensky 1989), weight pruning (e.g., LeCun et al. 1990b), fast and short weight matrix-computing programs (Schmidhuber 1997), and flat minimum search (FMS, Hochreiter and Schmidhuber 1999). DBN training can be improved (Cho et al. 2012) through Tikhonov-type regularization (Tikhonov et al. 1977). See also sparsity-enforcing methods mentioned earlier.

Dropout (Hinton et al. 2012b) removes units from NNs during training to improve generalization. It is closely related to older, biologically plausible techniques for adding noise to neurons or synapses during training (e.g., Hanson 1990). NNs with competing units (e.g., Schmidhuber 1989b; Maass 2000; Goodfellow et al. 2013) tend to outperform those with noncompeting units and avoid catastrophic forgetting through BP when training sets change over time (Srivastava et al. 2013).

The popular activation function f of rectified linear units (ReLUs) is $f(x) = x$ for $x > 0$; $f(x) = 0$ otherwise. ReLU NNs are useful for RBMs (Nair and Hinton 2010; Maas et al. 2013), outperformed sigmoidal activation functions in deep NNs (Glorot et al. 2011), and helped to obtain best results on several benchmark problems across multiple domains (e.g., Krizhevsky et al. 2012).

Many additional tricks for improving NNs have been described (e.g., Montavon et al. 2012; Schmidhuber 2015).

Consequences for Neuroscience

Artificial NNs (ANNs) can help to better understand biological NNs (BNNs). The feature detectors learned by single-layer visual ANNs are similar to those found in early visual processing stages of BNNs. Likewise, the feature detectors learned in deep layers of visual ANNs should be highly predictive of what neuroscientists will find in deep layers of BNNs. While the visual cortex of BNNs may use quite different learning algorithms, its objective function to be minimized may be rather similar to the one of visual ANNs. In fact, results obtained with relatively deep artificial NNs (e.g., Yamins et al. 2013) seem compatible with insights about the visual pathway in the primate cerebral cortex, which has been studied for many decades.

Deep Learning with Spiking Neurons?

Current deep NNs greatly profit from GPUs, which are little ovens, much hungrier for energy than biological brains, whose neurons efficiently communicate by brief spikes (e.g., Hodgkin and Huxley 1952) and often remain quiet. Many computational models of such spiking neurons have been proposed and analyzed (e.g., Gerstner and Kistler 2002). Future energy-efficient hardware for DL in NNs may implement aspects of such models – see numerous references in the survey (Schmidhuber 2015, Sect. 5.26). In practical applications, however, current artificial networks of spiking neurons cannot yet compete with the best traditional deep NNs.

Deep Reinforcement Learning (RL)

Reinforcement learning (RL) is the most general type of learning. General RL agents must discover, without the aid of a teacher, how to interact with a dynamic, initially unknown, partially observable environment in order to maximize their expected cumulative reward signals (e.g., Kaelbling et al. 1996; Sutton and Barto 1998; Wiering and van Otterlo 2012). There may be arbitrary, a priori unknown delays between actions and perceivable consequences. The RL problem is as hard as any problem of computer science, since any task with a computable description can be formulated in the general RL framework (e.g., Hutter 2005). Deep FNNs and RNNs are useful tools for various types of RL. Many references on this since the 1980s can be found in the recent survey (Schmidhuber 2015, Sect. 6).

Outlook

Deep learning in NNs is more than a temporary fad. Physics seems to dictate that any future efficient computational hardware will have to be brain-like, with many compactly placed processors in three-dimensional space, sparsely connected by many short and few long wires, to minimize total connection cost (even if the "wires" are actually light beams). The basic architecture is essentially the one of a deep, sparsely connected, three-dimensional RNN, and deep learning methods for such RNNs are expected to become even much more important than they are today.

Density Estimation

Claude Sammut
The University of New South Wales, Sydney,
NSW, Australia

Synonyms

Kernel density estimation

Definition

Given a set of observations, $x_1, \ldots, x_N$, which is a random sample from a probability density function $f_X(x)$, density estimation attempts to approximate $f_X(x)$ by $\widehat{f}_X(x_0)$.

A simple way of estimating a probability density function is to plot a histogram from a random sample drawn from the population. Usually, the range of data values is subdivided into equally sized intervals or *bins*. How well the histogram estimates the function depends on the bin width and the placement of the boundaries of the bins. The latter can be somewhat improved by modifying the histogram so that fixed boundaries are not used for the estimate. That is, the estimate of the probability density function at a point uses that point as the centre of a neighborhood. Following Hastie et al. (2009), the estimate can be expressed as:

$$\widehat{f_X}(x_0) = \frac{\#x_i \in N(x_0)}{N\lambda} \tag{1}$$

where $x_1, \ldots, x_N$ is a random sample drawn from a probability density function $f_X(x)$ and $\widehat{f_X}(x_0)$ is the estimate of f_X at point x_0. $N(x_0)$ is a neighborhood of width λ, around x_0. That is, the estimate is the normalized count of the number of values that fall within the neighborhood of x_0.

The estimate above is still *bumpy*, like the histogram. A smoother approximation can be obtained by using a *kernel function*. Each x_i in the sample is associated with a kernel function, usually Gaussian. The count in formula (1) above is replaced by the sum of the kernel function applied to the points in the neighborhood of x_0:

$$\widehat{f_X}(x_0) = \frac{1}{N\lambda}\sum_{i=1}^{N} K_\lambda(x_0, x_i) \qquad (2)$$

where K is the kernel function associated with sample x_i near x_0. This is called the *Parzen* estimate (Parzen 1962). The *bandwidth*, λ, affects the roughness or smoothness of the kernel histogram. The kernel density estimate is said to be under-smoothed if the bandwidth is too small. The estimate is over-smoothed if the bandwidth is too large.

Density estimation is most often used in association with memory-based classification methods, which can be thought of as weighted ▸ nearest neighbor classifiers.

▸ Mixture models and ▸ Locally weighted regression are forms of kernel density estimation.

Density-Based Clustering

Joerg Sander
University of Alberta, Edmonton, AB, Canada
Statistical Machine Learning Group, NICTA,
Canberra, ACT, Australia

Abstract

The chapter gives a concise explanation of the basic principles of density-based clustering and points out important ”milestone papers” in this area.

Synonyms

Estimation of density level sets; Mode analysis; Nonparametric cluster analysis

Definition

Density-based clustering refers to unsupervised learning methods that identify distinctive groups/clusters in the data, based on the idea that a cluster in a data space is a contiguous region of high point density, separated from other such clusters by contiguous regions of low point density. The data points in the separating regions of low point density are typically considered noise/outliers.

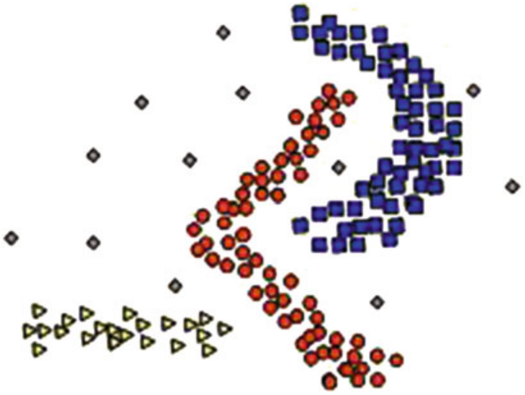
Motivation and Background

Clustering in general is an unsupervised learning task that aims at finding distinct groups in data, called “clusters.” The minimum requirements for this task are that the data is given as some set of objects O for which a dissimilarity-distance function $d: O \times O \rightarrow R^+$ is given. Often, O is a set of d-dimensional real-valued points, $O \subset R^d$, which can be viewed as a sample from some unknown probability density $p(x)$, with d as the Euclidean or some other form of distance.

There are different approaches to characterizing what establishes distinct groups in the data.

From a procedural point of view, many clustering methods try to find a partition of the data into k groups so that the within-cluster dissimilarities are minimized, while the between-cluster dissimilarities are maximized. The notions of within-cluster and between-cluster dissimilarity are defined using the given distance function d. Such methods correspond, from a statistical point of view, to a parametric approach where the unknown density $p(x)$ of the data is assumed to be a mixture of k densities $p_i(x)$, each corresponding to one of the k groups in the data; the $p_i(x)$ are assumed to come from some parametric family (e.g., Gaussian distributions) with unknown parameters, which are then estimated from the data.

In contrast, *density-based* clustering is a nonparametric approach where the groups in the data are considered to be the high-density areas of the density $p(x)$. Density-based clustering methods do not require the number of clusters as input parameters, nor do they make assumptions about the underlying density $p(x)$ or the variance within the groups that may exist in the data. Consequently, density-based clusters are not necessarily groups of points with high within-cluster similarity as measured by the distance function d but can have "arbitrary shape" in the feature space; they are sometimes also referred to as "natural clusters." This property makes density-based clustering particularly suitable for applications where clusters cannot be well described as distinct groups of low within-cluster dissimilarity, as, for instance, in spatial data where clusters of points in the space may form along natural structures such a rivers, roads, seismic faults, etc. Figure 1 illustrates density-based clusters using two-dimensional example, where the assumed dissimilarity function between the points is the Euclidean distance: there are three clusters indicated by triangles, points, and rectangles, as well as some noise points, indicated by diamond shapes. Note that the distance between some points within the clusters is much larger than the distance between some points from different clusters, yet the regions containing the clusters have clearly a higher point density than the region between them, and they can easily be separated.



Density-Based Clustering, Fig. 1 Illustration of a density-based clustering, showing three distinguishable groups

Density-based clustering is one of the prominent paradigms for clustering large data sets in the data mining community. It has been extensively studied and successfully used in many applications.

Structure of Learning System

Assuming that the data set $O \subset R^d$ is a sample from some unknown probability density $p(x)$, there are different ways of determining high-density areas of the density $p(x)$. Commonly, the notion of a high-density area is (implicitly or explicitly) based on a local density estimate at each point (typically some kernel or nearest neighbor density estimate) and a notion of connection between objects (typically points are connected if they are within a certain distance ε from each other); clusters are essentially constructed as maximal sets of objects which are directly or transitively connected to objects whose density exceeds some threshold λ. The set {x | p(x) > λ} of all high-density objects is called the *density level set* of p at λ. Objects that are not part of such clusters are called *noise* or *outliers*.

Different proposed density-based methods distinguish themselves mainly by how the density $p(x)$ is estimated, how the notion of connectivity is defined, and how the algorithm for finding connected components of the induced graph is implemented and supported by suitable data structures to achieve scalability for large data sets. Some methods include in a cluster only objects whose density exceed the threshold λ; others also include objects with lower density if they are connected to an object with density above the threshold λ.

Density-based clustering was probably introduced the first time by Wishart (1969). His algorithm for *one level mode analysis* consists of six steps: “(a) Select a distance threshold r, and a frequency (or density) threshold k. (b) Compute the triangular similarity matrix of all inter-point distances. (c) Evaluate the frequency k_i of each data point, defined as the number of points which lie within a distance r of point i (…). (d) Remove the ‘noise’ or non-dense points, those for which $k_i < k$. (e) Cluster the remaining dense points ($k_i > k$) by single linkage, forming the mode nuclei. (f) Reallocate each non-dense point to a suitable cluster according to some criterion (…).” (Wishart 1969).

Hartigan (1975) suggested a more general definition of a density-based cluster, a *density contour cluster* at level λ, as a maximally connected set of points x for which $p(x) > \lambda$, given a density $p(x)$ at each point x, a density threshold λ, and links specified for some pairs of objects. For instance, given a particular distance function, points can be defined as linked if the distance between them is no greater than some threshold r, or, if only direct links are available, one can define a “distance” for pairs of objects x and y in the following way:

$$d(x,y)=\begin{cases} -\min[p(x),p(y)] & x \text{ and } y \text{ are linked} \\ 0 & \text{otherwise} \end{cases}$$

To compute the density contour clusters, Hartigan, like Wishart, suggest a version of single-linkage clustering, which will construct the maximal connected sets of objects of density greater than the given threshold λ.

The DBSCAN algorithm (Ester et al. 1996) introduced density-based clustering independently to the Computing Science Community, also proposing the use of spatial index structures to achieve a scalable clustering algorithm. Assuming a distance threshold r, and a density threshold k, DBSCAN, like Wishart’s method, estimates the density for each point x_i as the number k_i of points that lie inside a radius r around x. *Core points* are defined as data points for which $k_i > k$. Points are considered directly connected if the distance between them is no greater than r. Density-based clusters are defined as maximally connected components of the set of points that lie within distance r from some core object (i.e., a cluster may contain points x_i with $k_i < k$, called *border objects*, if they are within distance r of a core object of that cluster). Objects not part of a cluster are considered as *noise*. The algorithm DBSCAN constructs clusters iteratively, starting a new cluster C with a non-assigned core object x and assigning all points to C that are directly or transitively connected to x. To determine directly and transitively connected points for a given point, a spatial index structure is used to perform range queries with radius r for each object that is newly added to a current cluster, resulting in an algorithm that performs well in practical situations when spatial index structures are effective (typically for low- to medium dimensional data), and has quadratic worst case runtime when index structures are not effective (e.g., for high-dimensional data).

DENCLUE (Hinneburg and Keim 1998) proposed a notion of density-based clusters using kernel density estimation. Each data point x is associated with (“attracted by”) a local maximum (“density attractor”) of the overall density function that lies in the direction of maximum increase in density from x. Density-based clusters are defined as connected components of density attractors with their associated points whose density estimate is above a given threshold λ. In this formulation, DBSCAN and Wishart's method can be seen as special cases of DENCLUE, using a uniform spherical kernel and, for Wishart's method, not including attracted points whose density is below λ. DENCLUE essentially uses a truncated Gaussian kernel for the implementation, which is based on a clever data structure to speed up local density estimation. The data space is partitioned into d-dimensional cells; nonempty cells are mapped to one-dimensional keys which are stored together with some sufficient statistics about the cell (number of points, pointers to points, and linear sum of the points belonging to the cell) in a search tree for efficient retrieval of neighboring cells and local density estimation (Hinneburg and Keim (1998) report that in an experimental comparison on 11-dimensional data sets of different sizes, DENCLUE runs up to 45 times faster than DBSCAN).

A large number of related methods and extensions have been proposed, particularly in computing science and application-oriented domains, some motivated by algorithmic considerations that could improve efficiency of the computation of density-based clusters, others motivated by special applications, proposing essentially density-based clustering algorithms using specific density measures and notions of connectivity. An algorithmic framework, called GDBSCAN, that generalizes the topological properties of density-based clusters can be found in Sander et al. (1998). GDBSCAN generalizes the notion of a density-based clustering to that of a *density-connected decomposition*, assuming only a reflexive and symmetric *neighborhood* relation for pairs of objects (direct links between some objects), and an arbitrary predicate, called "*MinWeight*," that evaluates to *true* for some neighborhood sets of objects and *false* on others, a core object can be defined as an object whose neighborhood satisfies the *MinWeight* predicate. Then, a density-connected decomposition consists of the maximally connected components of the set of objects that are in the neighborhood of some core object, and they can be computed with the same algorithmic scheme as density-based clusters by DBSCAN.

One of the principal problems of finding the density-based clusters of a density level set for a single level λ is how to determine a suitable level λ. The result of a density-based clustering method depends critically on the choice of λ, which may be difficult to determine even in situations when a meaningful level exists, depending on how well the clusters are separated in the given sample. In other situations, it may not even be possible to characterize the cluster structure appropriately using a single density threshold, when modes exist in different regions of the data space that have very different local densities or when clusters are nested within clusters. The problem of selecting suitable density threshold parameters has been already observed by Wishart (1969) who also proposed a hierarchical algorithm to represent the clusters at different density levels. Hartigan (1975) also observed that density-based clusters at different density levels have a hierarchical structure, a *density contour tree*, based on the fact that two clusters (i.e., connected components) of different density levels are either disjoint or the cluster of higher density is completely contained in the cluster of lower density. Recent proposals for hierarchical clustering methods based on a density estimate and a notion of linkage are, e.g., Ankerst et al. (1999), Stuetzle (2003), and Campello et al. (2013). These hierarchical methods are closely related and are essentially processing and rendering a minimum spanning tree of the data –with edge weights defined in different ways– and are thus also closely related to single-linkage clustering. Hierarchical methods do not, in a strict sense, compute a partition of the data but compute a representation of the overall hierarchical density structure of the data from which particular density-based clusters at different density levels or a global density threshold (a "cut level") could be determined. Recent work (Campello et al. 2013) provides an efficient hierarchical version DBSCAN, called HDBSCAN, which includes a method for automatically extracting a flat partitioning from possibly different levels of a density-based clustering hierarchy, containing only significant clusters according to a cluster stability measure.

Dimensionality Reduction

Michail Vlachos
IBM Research, Zurich, Switzerland

Abstract

Dimensionality reduction in an important data pre-processing when dealing with Big Data. We explain how it can be used for speeding up search operation and show applications for time-series datasets.

Synonyms

Feature selection; Feature projection; lossy compression

Introduction

Every data object in a computer is represented and stored as a set of features, for example, color, price, dimensions, and so on. Instead of the term *features*, one can interchangeably use the term *dimensions* because an object with n features can also be represented as a multidimensional point in an n-dimensional space. Therefore, dimensionality reduction (dR) refers to the process of mapping an n-dimensional point into a lower k-dimensional space. This operation reduces the size for representing and storing an object or a dataset in general; hence, dimensionality reduction can be seen as a method for data compression. In addition, this process promotes data visualization, particularly when objects are mapped onto two or three dimensions. Finally, in the context of classification, dimensionality reduction can be a useful tool for (a) making tractable classification schemes that are superlinear with respect to dimensionality tractable, (b) reducing the variance of classifiers that are plagued by large variance in higher dimensionalities, and (c) removing the noise that may be present, thus boosting classification accuracy.

Motivation and Background

There are many techniques for dimensionality reduction. The objective of these techniques is to appropriately select the k dimensions (and also the number k) so that the important characteristics of the original object are retained. For example, when performing dimensionality reduction on an image, e.g., using a wavelet-based technique, the desirable outcome is that the difference between the original and the final images is almost imperceptible.

When performing dimensionality reduction not on a single object, but on a dataset, an additional requirement is that the relationship between the objects in the original space be preserved. This is particularly important for reasons of classification and visualization in the new space.

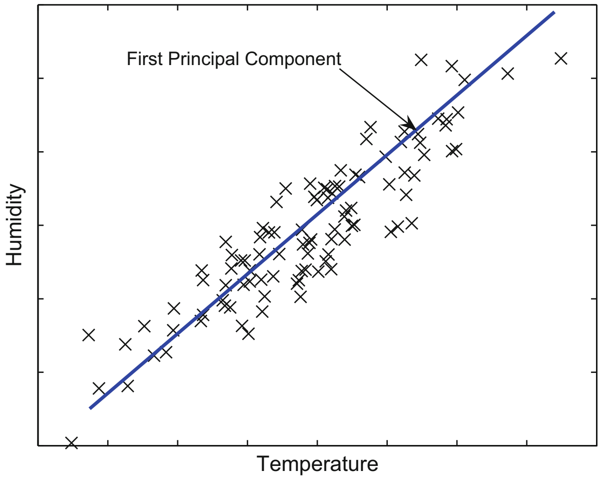
Two important categories of dimensionality reduction techniques exist:

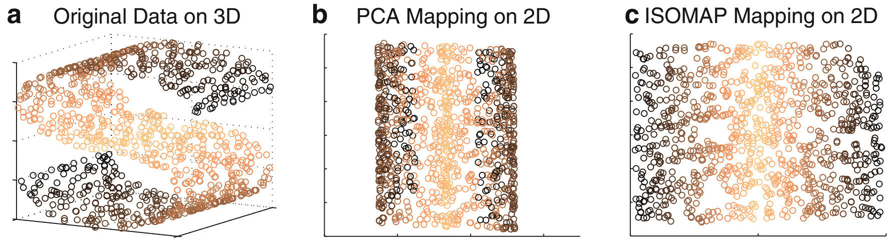
- **Feature selection** techniques, in which only the most important or descriptive features/dimensions are retained, and the rest are discarded. More details on such techniques can be found under the entry ▶ Feature Selection
- **Feature projection** methodologies, which project the existing features onto different dimensions or axes. The aim here is, again, to find those new data axes that retain the dataset structure and preserve its variance as closely as possible.

Feature projection techniques typically exploit the correlations between the various data dimensions, with the goal of creating dimensions/axes that are uncorrelated and sufficiently describe the data.

One of the most popular dimensionality reduction techniques is *principal component analysis* or PCA. It attempts to discover those axes (or

Dimensionality Reduction, Fig. 1 Principal component analysis





Dimensionality Reduction, Fig. 2 Nonlinear dimensionality reduction techniques produce a better low-dimensional data mapping than PCA if the original data lie on a high-dimensional manifold

components) onto which the data can be projected while maintaining the original correlation between the dimensions. Consider, for example, a dataset that contains records of environmental measurements over a period of time, such as humidity and temperature. The two attributes can be highly correlated, as shown in Fig. 1. By deploying PCA, this trend will be discovered, and the original two-dimensional points can be reduced to one-dimensional by projecting the original points onto the first *principal component*. In that way, the derived dataset can be stored in less space.

PCA uses the Euclidean distance as the measure of dissimilarity among objects. The first principal component (or axis) indicates the direction of maximum variance in the original dimensions. The second component shows the direction of the next highest variance (and is uncorrelated to the first component), etc.

Other dimensionality reduction techniques optimize or preserve other criteria than PCA does. Manifold-inspired methods such as ISOMAP (Tenenbaum et al. 2000) preserve the geodesic distances between objects. The notion here is to approximate the distance between objects “through” the remaining ones. The result of such dimensionality reduction techniques is that when the data lie on a manifold, the projected dimensions effectively “unfold” the underlying high-dimensional manifold. An example of this mapping is illustrated in Fig. 2, where it is also compared with the respective PCA mapping.

Other recent dimensionality reduction techniques include locally linear embedding (LLE) (Roweis and Saul 2000) and Laplacian eigenmaps (Belkin and Niyogi 2002). We also refer the interested practitioner to van der Maaten et al. (2009), for a detailed comparison of various techniques and also for Matlab implementations on a variety of dimensionality reduction algorithms.

In general, dimensionality reduction is a commonly practiced and useful operation in database and machine-learning systems because it offers the following desirable properties:

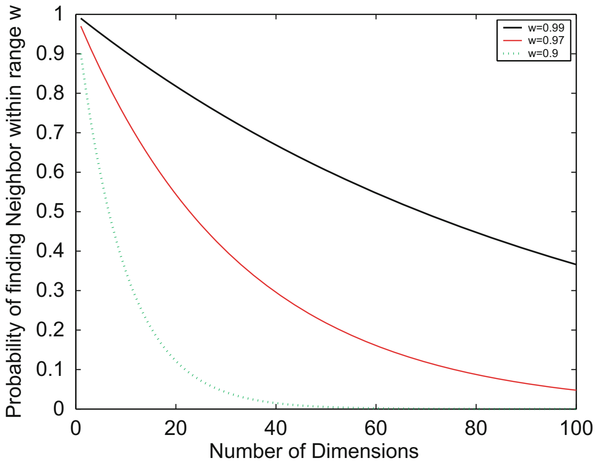
- Data compression: the dataset objects are represented in fewer dimensions, hence saving important disk storage space and offering faster loading of the compressed data from the disk.
- Better data visualization: the relationships between the original high-dimensional objects can be visualized in two- or three-dimensional projections.
- Improved classification accuracy: this can be attributed to both variance reduction and noise removal from the original high-dimensional dataset.
- More efficient data retrieval: dimensionality reduction techniques can also assist in making the retrieval of the original uncompressed data faster and more efficient, by offering very fast prefiltering with the help of the compressed data representation.
- High index performance: more effective use of indexing structures can be achieved by using the compressed data, because indexing techniques only work efficiently with lower-dimensional data (e.g., from 1 to 30 dimensions, depending on the type of the index).

The fact that indexing structures do not perform efficiently for higher-dimensional data is also known as the ▶ Curse of Dimensionality. Suppose that we are interested in performing search operations on a set of high-dimensional data. For simplicity, let us assume that the data lie in a unit hypercube $C = [0, 1]^d$, where d is the data dimensionality. Given a query point, the probability P_w that a match (neighbor) exists within radius w in the data space of dimensionality d is given by $P_w(d) = w^d$.

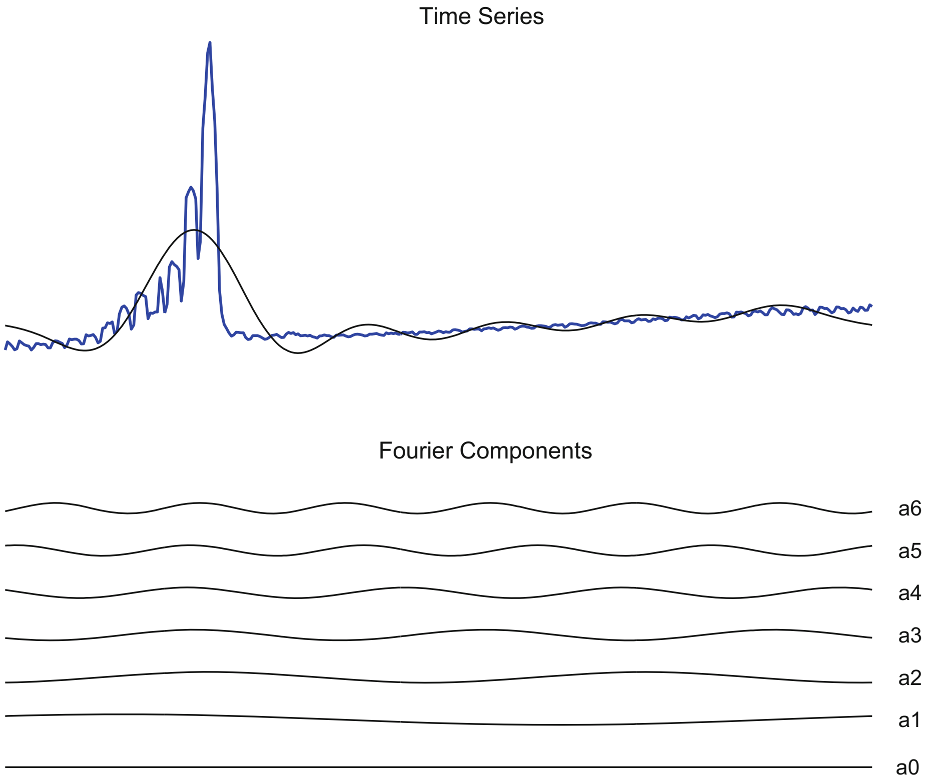
Figure 3 illustrates this probability for various values of w. Evidently, at higher dimensionalities the data becomes very sparse, and even at large radii, only a small portion of the entire space is covered. In simple terms the "curse of dimensionality" translates into the following fact: for large dimensionalities, existing indexing structures outperform a linear scan of all the data, only when the dataset size (number of objects) grows exponentially with respect to the dimensionality.

Applications: Dimensionality Reduction for Time-Series Data

In this section, we provide more detailed examples of dimensionality reduction techniques for time-series data. We chose time series to convey visually the effect of dimensionality reduction particularly for high-dimensional data such as



Dimensionality Reduction, Fig. 3 Probability $P_w(d)$ against dimensionality d. The data becomes sparse in higher dimensions



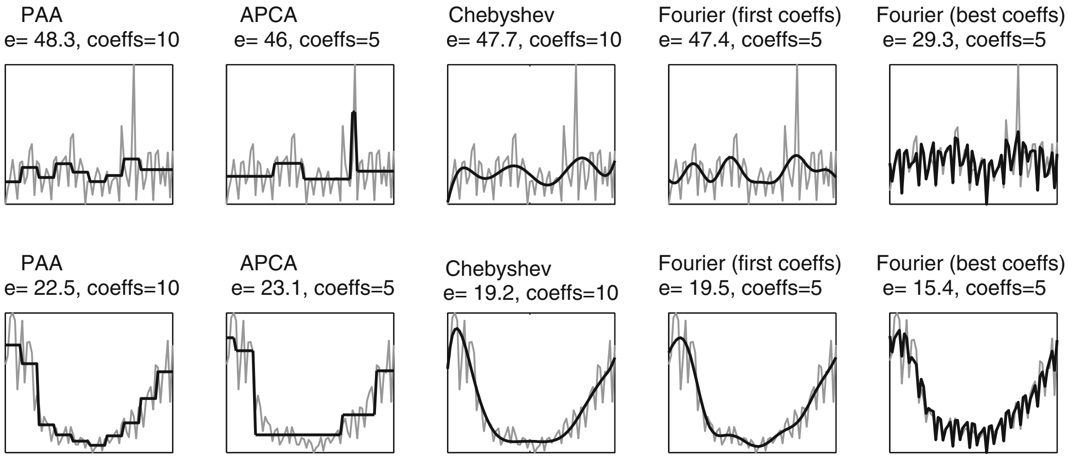
Dimensionality Reduction, Fig. 4 Decomposition of a signal into the first 7 Fourier coefficients. We can see that by using even only few of the Fourier coefficients we can achieve a good reconstruction of the original signal

time series. Later, we also show how dimensionality reduction on large datasets can help speed up search operations over the original uncompressed data.

Dimensionality reduction for one- and two-dimensional signals is commonly accomplished using Fourier decomposition. This method for data representation was first presented in the beginning of the nineteenth century by Jean Baptiste Fourier (1768–1830), in his seminal work "On the Propagation of Heat in Solid Bodies." Fourier came to the conclusion that every function could be expressed as a sum of trigonometrical series (i.e., sines and cosines). This original work was initially met with doubt (even by famous mathematicians such as Lagrange and Laplace), because of its unexpected result, and moreover, the solution was considered impractical because of the complex integration functions.

However, in the twentieth century, no one can deny the importance of Fourier's findings. With the introduction of fast ways to compute the Fourier decomposition in the 1960s (fast Fourier transform or FFT), the barrier of the high computational complexity was lifted. What the Fourier transform attempts to achieve is to represent the original signal as a linear combination of sinusoids. Therefore, each Fourier coefficient is a complex number that essentially encodes the amplitude and the phase of each of these sinusoids, after the original signal has been projected on them.

For most signals, the original sequence can be reconstructed with high accuracy using just few of the coefficients. This is where the great power of the Fourier transformation lies: by neglecting the majority of the coefficients, we can essentially compress the signal or describe it with fewer numbers. For stock market data or other



Dimensionality Reduction, Fig. 5 Comparison of various dimensionality reduction techniques for time-series data. The *darker line* indicates the approximation using the number of coefficients reported. Each figure also shows the error *e* introduced by the dimensionality reduction technique. Lower errors indicate better low-dimensional approximation of the original object

time series that follow the pattern of a random walk, the first few coefficients, which capture the low frequencies of the signal, are sufficient to describe the signal accurately (or, equivalently, to capture most of its energy). Figure 4 depicts a signal of 1024 points and its reconstruction using 7 Fourier coefficients (i.e., using $7 \times 2 = 14$ numbers).

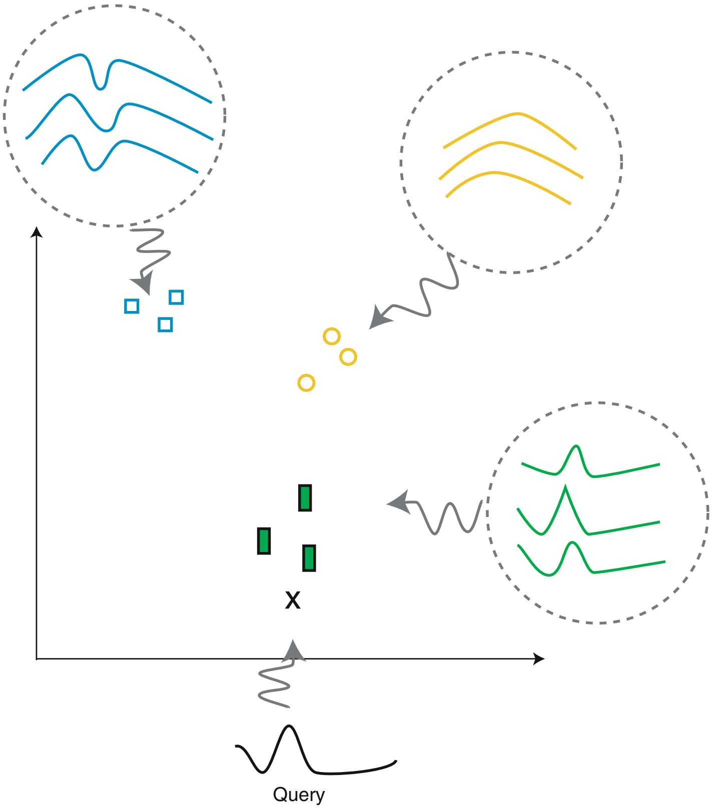
Other popular dimensionality reduction techniques for time-series data are the various wavelet transforms; piecewise linear approximations; piecewise aggregate approximation (PAA), which can be regarded as a projection in time of the wavelet coefficients adaptive piecewise constant approximation (APCA Keogh et al. 2001) and uses the highest energy wavelet coefficients; Chebyshev polynomial approximation symbolic approximation of time series (such as the SAX representation Lin et al. 2003).

No dimensionality reduction technique is universally better than all the others. Depending on the dataset characteristics, one method may provide a better approximation of a dataset than the other techniques. Therefore, the key is to carefully pick the representation that best suits the specific application or the task at hand. In Fig. 5, we demonstrate various dimensionality reduction techniques and the quality of the time-series approximation. For all methods, the same storage space is allocated for the compressed sequences. The time-series reconstruction is shown in a darker color, and the approximation error to the original sequence is also reported. In general, we notice that dimensionality reduction techniques based on selection of the highest energy coefficients consistently provide a high-quality sequence approximation.

Dimensionality Reduction and Lower Bounding

Dimensionality reduction can be a useful tool for speeding up search operations. Figure 6 illustrates dimensionality reduction for high-dimensional time-series data. After dimensionality reduction, each object is represented using fewer dimensions (attributes), so it is represented in a lower-dimensional space. Then, suppose that a user poses another high-dimensional object as query and wishes to find all the objects closest to this query.

To avoid the search on the original high-dimensional space, the query is also transformed into a point in the lower-dimensional space, and its closest matches can be discovered in the vicinity of the projected query point. However,



Dimensionality Reduction, Fig. 6 Search and dimensionality reduction. Every object (time series in this case) is transformed into a lower-dimensional point. User queries are also projected into the new space. Similarity search consists of finding the closest points to the query projection

when searching using the compressed objects, one needs to provide an estimate of the distance between the original objects. Typically, it is preferable that the distance in the new space underestimates (or lower bounds) the distance in the original high-dimensional space. The reason for this is the following.

Suppose that we are seeking the 1-Nearest-Neighbor (1-NN) a query Q in a database $\mathcal{D}$. By examining all objects (linear scan), one can guarantee that the best match will be found. Can one provide the same guarantee (i.e., that the same best match will be returned) when examining the compressed objects (after dimensionality reduction)?

The answer is positive, as long as the distance on the compressed data *underestimates* or *lower bounds* the distance on the raw data. In other words, the dimensionality reduction (dR) that is performed on the raw data must have the following property:

$$\text{Having}\quad A \subset \mathcal{D} \xrightarrow{dR} a \quad \text{and} \quad Q \xrightarrow{dR} q$$

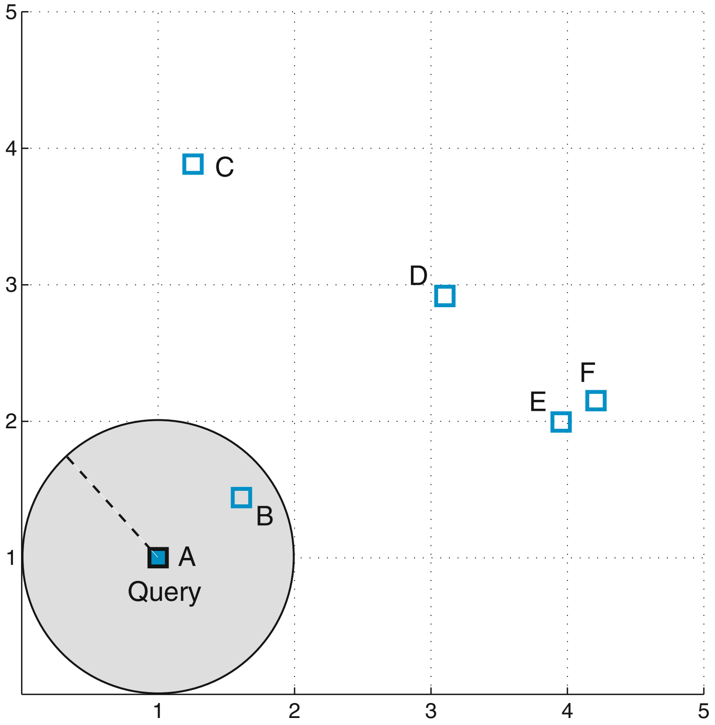
$$\text{then}$$

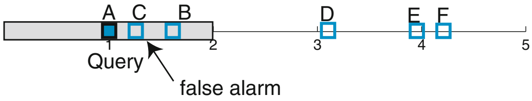
$$\Delta(q, a) \leq \Delta(Q, A)$$

As the computed distance Δ between any two compressed objects is underestimated, *false alarms* may arise. Suppose, for example, that our database consists of 6 two-dimensional points (Fig. 7). If the user query is: “Find everything that lies within a radius of 1 around A,” then B is the only result.

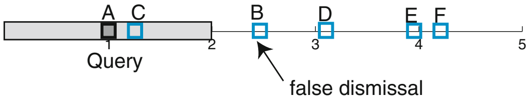
Let us assume for a minute that the dimensionality reduction performed on the data is simply a projection on the x-axis (Fig. 8). In this new space, seeking for points within a range of 1 from A would also retrieve point C, which is called a *false alarm*. However, this does not constitute a problem; in a post-processing, in a post-processing phase, the calculation of the exact

Dimensionality Reduction, Fig. 7 Range search in the original space returns only object *B*





Dimensionality Reduction, Fig. 8 Because of the dimensionality reduction, false alarms may arise



Dimensionality Reduction, Fig. 9 False dismissals may happen when the lower-bounding lemma is not obeyed

distance will remove any false alarms. Suppose now that another dimensionality reduction results in the projection of Fig. 9. Here, we have a case of a *false dismissal*, because object *B* lies outside the range of search.

This generic framework for similarity search using dimensionality reduction and lower-bounding distance functions was proposed in Agrawal et al. (1993) and is called GEMINI (**GE**neric **M**ultimedia **IN**dex**I**ng). One can show that orthonormal dimensionality reduction techniques (PCA, Fourier, wavelets) satisfy the lower-bounding lemma when the distance used is the Euclidean distance.

In conclusion, by using dimensionality reduction for search operations, one can first examine the compressed objects and eliminate many of the uncompressed objects from examination by using a lower-bounding approximation of the distance function. This initial search will return a superset of the correct answers (no false dismissals). False alarms can be filtered out by computing the original distance between the remaining uncompressed objects and the query. Therefore, a significant speedup is achieved by examining only a small subset of the original raw data.

Dirichlet Process

Yee Whye Teh
University College London, London, UK

Definition

The Dirichlet process (DP) is a stochastic process used in ▶ Bayesian nonparametric models of data, particularly in Dirichlet process mixture models (also known as infinite mixture models). It is a distribution over distributions, that is, each draw from a Dirichlet process is itself a distribution. It is called a Dirichlet process because it has Dirichlet distributed finite dimensional marginal distributions, just as the ▶ Gaussian process, another popular stochastic process used for Bayesian nonparametric regression, has Gaussian distributed finite dimensional marginal distributions. Distributions drawn from a Dirichlet process are discrete, but cannot be described using a finite number of parameters, thus the classification as a nonparametric model.

Motivation and Background

Probabilistic models are used throughout machine learning to model distributions over observed data. Traditional parametric models using a fixed and finite number of parameters can suffer from over- or under-fitting of data when there is a misfit between the complexity of the model (often expressed in terms of the number of parameters) and the amount of data available. As a result, model selection, or the choice of a model with the right complexity, is often an important issue in parametric modeling. Unfortunately, model selection is an operation that is fraught with difficulties, whether we use ▶ cross validation or marginal probabilities as the basis for selection. The Bayesian nonparametric approach is an alternative to parametric modeling and selection. By using a model with an unbounded complexity, underfitting is mitigated, while the Bayesian approach of computing or approximating the full posterior over parameters mitigates overfitting. For a general overview of Bayesian nonparametrics, see ▶ Bayesian Nonparametric Models.

Nonparametric models are also motivated philosophically by Bayesian modeling. Typically we assume that we have an underlying and unknown distribution which we wish to infer given some observed data. Say we observe $x_1, \ldots, x_n$, with $x_i \sim F$ independent and identical draws from the unknown distribution F. A Bayesian would approach this problem by placing a prior over F then computing the posterior over F given data. Traditionally, this prior over distributions is given by a parametric family. But constraining distributions to lie within parametric families limits the scope and type of inferences that can be made. The nonparametric approach instead uses a prior over distributions with wide support, typically the support being the space of all distributions. Given such a large space over which we make our inferences, it is important that posterior computations are tractable.

The Dirichlet process is currently one of the most popular Bayesian nonparametric models. It was first formalized in Ferguson (1973) for general Bayesian statistical modeling, as a prior over distributions with wide support yet tractable posteriors. (Note however that related models in population genetics date back to Ewens 1972). Unfortunately the Dirichlet process is limited by the fact that draws from it are discrete distributions, and generalizations to more general priors did not have tractable posterior inference until the development of MCMC (▶ Markov chain Monte Carlo) techniques (Escobar and West 1995; Neal 2000). Since then there has been significant developments in terms of inference algorithms, extensions, theory and applications. In the machine learning, community work on Dirichlet processes date back to Neal (1992) and Rasmussen (2000).

Theory

The Dirichlet process (DP) is a stochastic process whose sample paths are probability measures with probability one. Stochastic processes are distributions over function spaces, with sample paths being random functions drawn from the distribution. In the case of the DP, it is a distribution over probability measures, which are functions with certain special properties, which allow them to be interpreted as distributions over some probability space Θ. Thus draws from a DP can be interpreted as random distributions. For a distribution over probability measures to be a DP, its marginal distributions have to take on a specific form which we shall give below. We assume that the user is familiar with a modicum of measure theory and Dirichlet distributions.

Before we proceed to the formal definition, we will first give an intuitive explanation of the DP as an infinite dimensional generalization of Dirichlet distributions. Consider a Bayesian mixture model consisting of K components:

$$\begin{aligned} \pi|\alpha &\sim Dir\left(\tfrac{\alpha}{K}, \ldots, \tfrac{\alpha}{K}\right) & \qquad \theta_k^*|H &\sim H \\ z_i|\pi &\sim Mult(\pi) & \qquad x_i|z_i, \{\theta_k^*\} &\sim F\left(\theta_{z_i}^*\right) \end{aligned} \tag{1}$$

where π is the mixing proportion, α is the pseudocount hyperparameter of the Dirichlet prior, H is the prior distribution over component parameters θ_k^*, and $F(\theta)$ is the component distribution parametrized by θ. It can be shown that for large K, because of the particular way we parametrized the Dirichlet prior over π, the number of components typically used to model n data items becomes independent of K and is approximately $O(\alpha \log n)$. This implies that the mixture model stays well defined as $K \to \infty$, leading to what is known as an infinite mixture model (Neal 1992; Rasmussen 2000). This model was first proposed as a way to sidestep the difficult problem of determining the number of components in a mixture, and as a nonparametric alternative to finite mixtures whose size can grow naturally with the number of data items. The more modern definition of this model uses a DP and with the resulting model called a DP mixture model. The DP itself appears as the $K \to \infty$ limit of the random discrete probability measure $\sum_{k=1}^{K} \pi_k \delta_{\theta_k^*}$, where δ_θ is a point mass centered at θ. We will return to the DP mixture toward the end of this entry.

Dirichlet Process

For a random distribution G to be distributed according to a DP, its marginal distributions have to be Dirichlet distributed (Ferguson 1973). Specifically, let H be a distribution over Θ and α be a positive real number. Then for any finite measurable partition $A_1, \ldots, A_r$ of Θ the vector $(G(A_1), \ldots, G(A_r))$ is random since G is random. We say G is Dirichlet process distributed with base distribution H and concentration parameter α, written $G \sim DP(\alpha, H)$, if

$$(G(A_1), \ldots, G(A_r)) \sim Dir(\alpha H(A_1), \ldots, \alpha H(A_r)) \qquad (2)$$

for every finite measurable partition $A_1, \ldots, A_r$ of Θ.

The parameters H and α play intuitive roles in the definition of the DP. The base distribution is basically the mean of the DP: for any measurable set $A \subset \Theta$, we have $E[G(A)] = H(A)$. On the other hand, the concentration parameter can be understood as an inverse variance: $V[G(A)] = H(A)(1 - H(A))/(\alpha + 1)$. The larger α is, the smaller the variance, and the DP will concentrate more of its mass around the mean. The concentration parameter is also called the strength parameter, referring to the strength of the prior when using the DP as a nonparametric prior over distributions in a Bayesian nonparametric model, and the mass parameter, as this prior strength can be measured in units of sample size (or mass) of observations. Also, notice that α and H only appear as their product in the definition (3) of the DP. Some authors thus treat $\widetilde{H} = \alpha H$, as the single (positive measure) parameter of the DP, writing $DP(\widetilde{H})$ instead of $DP(\alpha, H)$. This parametrization can be notationally convenient, but loses the distinct roles α and H play in describing the DP.

Since α describes the concentration of mass around the mean of the DP, as $\alpha \to \infty$, we will have $G(A) \to H(A)$ for any measurable A, that is $G \to H$ weakly or pointwise. However this not equivalent to saying that $G \to H$. As we shall see later, draws from a DP will be discrete distributions with probability one, even if H is smooth. Thus G and H need not even be absolutely continuous with respect to each other. This has not stopped some authors from using the DP as a nonparametric relaxation of a parametric model given by H. However, if smoothness is a concern, it is possible to extend the DP by convolving G with kernels so that the resulting random distribution has a density.

A related issue to the above is the coverage of the DP within the class of all distributions over Θ. We already noted that samples from the DP are discrete, thus the set of distributions with positive probability under the DP is small. However it turns out that this set is also large in a different sense: if the topological support of H (the smallest closed set S in Θ with $H(S) = 1$) is all of Θ, then any distribution over Θ can be approximated arbitrarily accurately in the weak or pointwise sense by a sequence of draws from $DP(\alpha, H)$. This property has consequence in the consistency of DPs discussed later.

For all but the simplest probability spaces, the number of measurable partitions in the definition (3) of the DP can be uncountably large. The natural question to ask here is whether objects satisfying such a large number of conditions as (3) can exist. There are a number of approaches to establish existence. Ferguson (1973) noted that the conditions (3) are consistent with each other, and made use of Kolmogorov's consistency theorem to show that a distribution over functions from the measurable subsets of Θ to $[0, 1]$ exists satisfying (3) for all finite measurable partitions of Θ. However it turns out that this construction does not necessarily guarantee a distribution over probability measures. Ferguson (1973) also provided a construction of the DP by normalizing a gamma process. In a later section we will see that the predictive distributions of the DP are related to the Blackwell–MacQueen urn scheme. Blackwell and MacQueen (1973) made use of this, along with de Finetti's theorem on exchangeable sequences, to prove existence of the DP. All the above methods made use of powerful and general mathematical machinery to establish existence, and often require regularity assumptions on H and Θ to apply these machinery. In a later section, we describe a stick-breaking construction of the DP due to Sethuraman (1994), which is a direct and elegant construction of the DP, which need not impose such regularity assumptions.

Posterior Distribution

Let $G \sim DP(\alpha, H)$. Since G is a (random) distribution, we can in turn draw samples from G itself. Let $\theta_1, \ldots, \theta_n$ be a sequence of independent draws from G. Note that the θ_i's take values in Θ since G is a distribution over Θ. We are interested in the posterior distribution of G given observed values of $\theta_1, \ldots, \theta_n$. Let $A_1, \ldots, A_r$ be a finite measurable partition of Θ, and let $n_k = \#\{i : \theta_i \in A_k\}$ be the number of observed values in A_k. By (3) and the conjugacy between the Dirichlet and the multinomial distributions, we have

$$\begin{aligned}&(G(A_1), \ldots, G(A_r))|\theta_1, \ldots, \theta_n\\ &\quad \sim \text{Dir}(\alpha H(A_1) + n_1, \ldots, \alpha H(A_r) + n_r)\end{aligned} \quad (3)$$

Since the above is true for all finite measurable partitions, the posterior distribution over G must be a DP as well. A little algebra shows that the posterior DP has updated concentration parameter $\alpha + n$ and base distribution $\frac{\alpha H + \sum_{i=1}^n \delta_{\theta_i}}{\alpha + n}$, where δ_i is a point mass located at θ_i and $n_k = \sum_{i=1}^n \delta_i(A_k)$. In other words, the DP provides a conjugate family of priors over distributions that is closed under posterior updates given observations. Rewriting the posterior DP, we have

$$G|\theta_1, \ldots, \theta_n \sim DP\left(\alpha + n, \frac{\alpha}{\alpha + n} H + \frac{n}{\alpha + n} \frac{\sum_{i=1}^n \delta_{\theta_i}}{n}\right) \quad (4)$$

Notice that the posterior base distribution is a weighted average between the prior base distribution H and the empirical distribution $\frac{\sum_{i=1}^n \delta_{\theta_i}}{n}$. The weight associated with the prior base distribution is proportional to α, while the empirical distribution has weight proportional to the number of observations n. Thus we can interpret α as the strength or mass associated with the prior. In the next section we will see that the posterior base distribution is also the predictive distribution of θ_{n+1} given $\theta_1, \ldots, \theta_n$. Taking $\alpha \to 0$, the prior becomes non-informative in the sense that the predictive distribution is just given by the empirical distribution. On the other hand, as the amount of observations grows large, $n \gg \alpha$, the posterior is simply dominated by the empirical distribution, which is in turn a close approximation of the true underlying distribution. This gives a consistency property of the DP: the posterior DP approaches the true underlying distribution.

Predictive Distribution and the Blackwell–MacQueen Urn Scheme

Consider again drawing $G \sim DP(\alpha, H)$, and drawing an i.i.d. (independently and identically distributed) sequence $\theta_1, \theta_2, \ldots \sim G$. Consider the predictive distribution for θ_{n+1}, conditioned on $\theta_1, \ldots, \theta_n$ and with G marginalized out. Since $\theta_{n+1}|G, \theta_1, \ldots, \theta_n \sim G$, for a measurable $A \subset \Theta$, we have

$$\begin{aligned}P(\theta_{n+1} \in A|\theta_1, \ldots, \theta_n) &= E[G(A)|\theta_1, \ldots, \theta_n]\\ &= \frac{1}{\alpha + n}\left(\alpha H(A) + \sum_{i=1}^n \delta_{\theta_i}(A)\right)\end{aligned} \quad (5)$$

where the last step follows from the posterior base distribution of G given the first n observations. Thus with G marginalized out:

$$\theta_{n+1}|\theta_1,\ldots,\theta_n \sim \frac{1}{\alpha+n}\left(\alpha H + \sum_{i=1}^{n} +\delta_{\theta_i}\right) \tag{6}$$

Therefore the posterior base distribution given $\theta_1,\ldots,\theta_n$ is also the predictive distribution of θ_{n+1}.

The sequence of predictive distributions (6) for $\theta_1,\theta_2,\ldots$ is called the Blackwell–MacQueen urn scheme (Blackwell and MacQueen 1973). The name stems from a metaphor useful in interpreting (6). Specifically, each value in Θ is a unique color, and draws $\theta \sim G$ are balls with the drawn value being the color of the ball. In addition we have an urn containing previously seen balls. In the beginning there are no balls in the urn, and we pick a color drawn from H, that is, draw $\theta_1 \sim H$, paint a ball with that color, and drop it into the urn. In subsequent steps, say the $n+1$st, we will either, with probability $\frac{\alpha}{\alpha+n}$, pick a new color (draw $\theta_{n+1} \sim H$), paint a ball with that color and drop the ball into the urn, or, with probability $\frac{n}{\alpha+n}$, reach into the urn to pick a random ball out (draw θ_{n+1} from the empirical distribution), paint a new ball with the same color, and drop both balls back into the urn.

The Blackwell–MacQueen urn scheme has been used to show the existence of the DP (Blackwell and MacQueen 1973). Starting from (6), which are perfectly well defined conditional distributions regardless of the question of the existence of DPs, we can construct a distribution over sequences $\theta_1,\theta_2,\ldots$ by iteratively drawing each θ_i given $\theta_1,\ldots,\theta_{i-1}$. For $n \geq 1$ let

$$P(\theta_1,\ldots,\theta_n) = \prod_{i=1}^{n} P(\theta_i|\theta_1,\ldots,\theta_{i-1}) \tag{7}$$

be the joint distribution over the first n observations, where the conditional distributions are given by (6). It is straightforward to verify that this random sequence is infinitely exchangeable. That is, for every n, the probability of generating $\theta_1,\ldots,\theta_n$ using (6), in that order, is equal to the probability of drawing them in any alternative order. More precisely, given any permutation σ on $1,\ldots,n$, we have

$$P(\theta_1,\ldots,\theta_n) = P(\theta_{\sigma(1)},\ldots,\theta_{\sigma(n)}) \tag{8}$$

Now de Finetti's theorem states that for any infinitely exchangeable sequence $\theta_1,\theta_2,\ldots$ there is a random distribution G such that the sequence is composed of i.i.d. draws from it:

$$P(\theta_1,\ldots,\theta_n) = \int \prod_{i=1}^{n} G(\theta_i)dP(G) \tag{9}$$

In our setting, the prior over the random distribution $P(G)$ is precisely the Dirichlet process $DP(\alpha,H)$, thus establishing existence.

A salient property of the predictive distribution (6) is that it has point masses located at the previous draws $\theta_1,\ldots,\theta_n$. A first observation is that with positive probability draws from G will take on the same value, regardless of smoothness of H. This implies that the distribution G itself has point masses. A further observation is that for a long enough sequence of draws from G, the value of any draw will be repeated by another draw, implying that G is composed only of a weighted sum of point masses, that is, it is a discrete distribution. We will see two sections below that this is indeed the case, and give a simple construction for G called the stick-breaking construction. Before that, we shall investigate the clustering property of the DP.

Clustering, Partitions, and the Chinese Restaurant Process

In addition to the discreteness property of draws from a DP, (6) also implies a ▶ clustering property. The discreteness and clustering properties of the DP play crucial roles in the use of DPs for clustering via DP mixture models, described in the application section. For now we assume that H is smooth, so that all repeated values are due to the discreteness property of the DP and not due to H itself. (Similar conclusions can be drawn when H has atoms, there is just more bookkeeping.) Since the values of draws are repeated, let $\theta_1^*,\ldots,\theta_m^*$ be the unique values among $\theta_1,\ldots,\theta_n$, and n_k be the number of repeats of θ_k^*. The predictive distribution can be equivalently written as

$$\theta_{n+1}\big|\theta_1,\ldots,\theta_n \sim \frac{1}{\alpha+n}\left(\alpha H + \sum_{k=1}^{m} n_k \delta_{\theta_k^*}\right) \tag{10}$$

Notice that value θ_k^* will be repeated by θ_{n+1} with probability proportional to n_k, the number of times it has already been observed. The larger n_k is, the higher the probability that it will grow. This is a rich-gets-richer phenomenon, where large clusters (a set of θ_i's with identical values θ_k^* being considered a cluster) grow larger faster.

We can delve further into the clustering property of the DP by looking at partitions induced by the clustering. The unique values of $\theta_1,\ldots,\theta_n$ induce a partitioning of the set $[n] = \{1,\ldots,n\}$ into clusters such that within each cluster, say cluster k, the θ_i's take on the same value θ_k^*. Given that $\theta_1,\ldots,\theta_n$ are random, this induces a random partition of $[n]$. This random partition in fact encapsulates all the properties of the DP, and is a very well-studied mathematical object in its own right, predating even the DP itself (Aldous 1985; Ewens 1972; Pitman 2002). To see how it encapsulates the DP, we simply invert the generative process. Starting from the distribution over random partitions, we can reconstruct the joint distribution (7) over $\theta_1,\ldots,\theta_n$, by first drawing a random partition on $[n]$, then for each cluster k in the partition draw a $\theta_k^* \sim H$, and finally assign $\theta_i = \theta_k^*$ for each i in cluster k. From the joint distribution (7) we can obtain the DP by appealing to de Finetti's theorem.

The distribution over partitions is called the Chinese restaurant process (CRP) due to a different metaphor. (The name was coined by Lester Dubins and Jim Pitman in the early 1980s (Aldous 1985)) In this metaphor we have a Chinese restaurant with an infinite number of tables, each of which can seat an infinite number of customers. The first customer enters the restaurant and sits at the first table. The second customer enters and decides either to sit with the first customer, or by herself at a new table. In general, the $n+1$st customer either joins an already occupied table k with probability proportional to the number n_k of customers already sitting there, or sits at a new table with probability proportional to α. Identifying customers with integers $1, 2, \ldots$ and tables as clusters, after n customers have sat down the tables define a partition of $[n]$ with the distribution over partitions being the same as the one above. The fact that most Chinese restaurants have round tables is an important aspect of the CRP. This is because it does not just define a distribution over partitions of $[n]$, it also defines a distribution over permutations of $[n]$, with each table corresponding to a cycle of the permutation. We do not need to explore this aspect further and refer the interested reader to Aldous (1985) and Pitman (2002).

This distribution over partitions first appeared in population genetics, where it was found to be a robust distribution over alleles (clusters) among gametes (observations) under simplifying assumptions on the population, and is known under the name of Ewens sampling formula (Ewens 1972). Before moving on we shall consider just one illuminating aspect, specifically the distribution of the number of clusters among n observations. Notice that for $i \geq 1$, the observation θ_i takes on a new value (thus incrementing m by one) with probability $\frac{\alpha}{\alpha+i-1}$ independently of the number of clusters among previous θ's. Thus the number of cluster m has mean and variance:

$$\begin{aligned} E[m|n] &= \sum_{i=1}^{n} \frac{\alpha}{\alpha+i-1} = \alpha(\psi(\alpha+n) - \psi(\alpha)) \\ &\simeq \log\left(1+\frac{n}{\alpha}\right) \quad \text{for} N, \alpha \gg 0, \end{aligned} \tag{11}$$

$$\begin{aligned} V[m|n] &= \alpha(\psi(\alpha+n) - \psi(\alpha)) \\ &\quad + \alpha^2(\psi'(\alpha+n) - \psi'(\alpha)) \\ &\simeq \alpha \log\left(1+\frac{n}{\alpha}\right) \quad \text{for } n > \alpha \gg 0, \end{aligned} \tag{12}$$

where $\psi(\cdot)$ is the digamma function. Note that the number of clusters grows only logarithmically in the number of observations. This slow growth of the number of clusters makes sense because of the rich-gets-richer phenomenon: we expect there to be large clusters thus the number of clusters m has to be smaller than the number of observations n. Notice that α controls the number of clusters in a direct manner, with larger α implying a larger number of clusters a priori. This intuition will help in the application of DPs to mixture models.

Stick-Breaking Construction

We have already intuited that draws from a DP are composed of a weighted sum of point masses. Sethuraman (1994) made this precise by providing a constructive definition of the DP as such, called the stick-breaking construction. This construction is also significantly more straightforward and general than previous proofs of the existence of DPs. It is simply given as follows:

$$\begin{aligned} \beta_k &\sim Beta(1,\alpha) & \theta_k^* &\sim H \\ \pi_k &= \beta_k \prod_{l=1}^{k-1} & G &= \sum_{k=1}^{\infty} \pi_k \delta_{\theta_k^*} \end{aligned} \tag{13}$$

Then $G \sim DP(\alpha, H)$. The construction of π can be understood metaphorically as follows. Starting with a stick of length 1, we break it at β_1, assigning π_1 to be the length of stick we just broke off. Now recursively break the other portion to obtain π_2, π_3, and so forth. The stick-breaking distribution over π is sometimes written $\pi \sim GEM(\alpha)$, where the letters stand for Griffiths, Engen, and McCloskey (Pitman 2002). Because of its simplicity, the stick-breaking construction has lead to a variety of extensions as well as novel inference techniques for the Dirichlet process (Ishwaran and James 2001).

Applications

Because of its simplicity, DPs are used across a wide variety of applications of Bayesian analysis in both statistics and machine learning. The simplest and most prevalent applications include Bayesian model validation, density estimation, and clustering via mixture models. We shall briefly describe the first two classes before detailing DP mixture models.

How does one validate that a model gives a good fit to some observed data? The Bayesian approach would usually involve computing the marginal probability of the observed data under the model, and comparing this marginal probability to that for other models. If the marginal probability of the model of interest is highest we may conclude that we have a good fit. The choice of models to compare against is an issue in this approach, since it is desirable to compare against as large a class of models as possible. The Bayesian nonparametric approach gives an answer to this question: use the space of all possible distributions as our comparison class, with a prior over distributions. The DP is a popular choice for this prior, due to its simplicity, wide coverage of the class of all distributions, and recent advances in computationally efficient inference in DP models. The approach is usually to use the given parametric model as the base distribution of the DP, with the DP serving as a nonparametric relaxation around this parametric model. If the parametric model performs as well or better than the DP relaxed model, we have convincing evidence of the validity of the model.

Another application of DPs is in ▶ density estimation (Escobar and West 1995; Lo 1984; Neal 1992; Rasmussen 2000). Here we are interested in modeling the density from which a given set of observations is drawn. To avoid limiting ourselves to any parametric class, we may again use a nonparametric prior over all densities. Here again DPs are a popular. However note that distributions drawn from a DP are discrete, thus do not have densities. The solution is to smooth out draws from the DP with a kernel. Let $G \sim DP(\alpha, H)$ and let $f(x|\theta)$ be a family of densities (kernels) indexed by θ. We use the following as our nonparametric density of x:

$$p(x) = \int f(x|\theta)G(\theta)d\theta \tag{14}$$

Similarly, smoothing out DPs in this way is also useful in the nonparametric relaxation setting above. As we see below, this way of smoothing out DPs is equivalent to DP mixture models, if the data distributions $F(\theta)$ below are smooth with densities given by $f(x|\theta)$.

Dirichlet Process Mixture Models

The most common application of the Dirichlet process is in clustering data using mixture models (Escobar and West 1995; Lo 1984; Neal 1992; Rasmussen 2000). Here the nonparametric nature of the Dirichlet process translates to mixture models with a countably infinite number of components. We model a set of observations $\{x_1, \ldots, x_n\}$ using a set of latent parameters $\{\theta_1, \ldots, \theta_n\}$. Each θ_i is drawn independently and identically from G, while each x_i has distribution $F(\theta_i)$ parametrized by θ_i:

$$\begin{aligned} x_i|\theta_i &\sim F(\theta_i) \\ \theta_i|G &\sim G \\ G|\alpha, H &\sim DP(\alpha, H) \end{aligned} \tag{15}$$

Because G is discrete, multiple θ_i's can take on the same value simultaneously, and the above model can be seen as a mixture model, where x_i's with the same value of θ_i belong to the same cluster. The mixture perspective can be made more in agreement with the usual representation of mixture models using the stick-breaking construction (13). Let z_i be a cluster assignment variable, which takes on value k with probability π_k. Then (15) can be equivalently expressed as

$$\begin{array}{ll} \pi|\alpha \sim GEM(\alpha) & \theta_k^*|H \sim H \\ z_i|\pi \sim Mult(\pi) & x_i|z_i\{\theta_k^*\} \sim F(\theta_{z_i}^*) \end{array} \tag{16}$$

with $G = \sum_{k=1}^{\infty} \pi_k \delta_{\theta_k^*}$ and $\theta_i = \theta_{z_i}^*$. In mixture modeling terminology, π is the mixing proportion, θ_k^* are the cluster parameters, $F(\theta_k^*)$ is the distribution over data in cluster k, and H the prior over cluster parameters.

The DP mixture model is an *infinite* mixture model – a mixture model with a countably infinite number of clusters. However, because the π_k's decrease exponentially quickly, only a small number of clusters will be used to model the data a priori (in fact, as we saw previously, the expected number of components used a priori is logarithmic in the number of observations). This is different than a finite mixture model, which uses a fixed number of clusters to model the data. In the DP mixture model, the actual number of clusters used to model data is not fixed, and can be automatically inferred from data using the usual Bayesian posterior inference framework (see Neal (2000) for a survey of MCMC inference procedures for DP mixture models). The equivalent operation for finite mixture models would be model averaging or model selection for the appropriate number of components, an approach that is fraught with difficulties. Thus infinite mixture models as exemplified by DP mixture models provide a compelling alternative to the traditional finite mixture model paradigm.

Generalizations and Extensions

The DP is the canonical distribution over probability measures and a wide range of generalizations have been proposed in the literature. First and foremost is the *Pitman–Yor process* (Ishwaran and James 2001; Pitman and Yor 1997), which has recently seen successful applications modeling data exhibiting power-law properties (Goldwater 2006; Teh 2006). The Pitman–Yor process includes a third parameter $d \in [0, 1)$, with $d = 0$ reducing to the DP. The various representations of the DP, including the Chinese restaurant process and the stick-breaking construction, have analogues for the Pitman–Yor process. Other generalizations of the DP are obtained by generalizing one of its representations. These include Pólya trees, normalized random measure, Poisson–Kingman models, species sampling models and stick-breaking priors.

The DP has also been used in more complex models involving more than one random probability measure. For example, in nonparametric regression we might have one probability measure for each value of a covariate, and in multitask settings each task might be associated with a probability measure with dependence across tasks implemented using a hierarchical Bayesian model. In the first situation, the class of models is typically called dependent Dirichlet processes (MacEachern 1999), while in the second the appropriate model is a hierarchical Dirichlet process (Teh et al. 2006).

Future Directions

The Dirichlet process, and Bayesian nonparametrics in general, is an active area of research within both machine learning and statistics. Current research trends span a number of directions. Firstly, there is the issue of efficient inference in DP models. Reference Neal (2000) is an excellent survey of the state-of-the-art in 2000, with all algorithms based on Gibbs sampling or small-step Metropolis–Hastings MCMC sampling. Since then there has been much work, including split-and-merge and large-step auxiliary variable MCMC sampling, sequential Monte Carlo, expectation propagation, and variational methods. Secondly, there has been interest in extending the DP, both in terms of new random distributions, as well as novel classes of nonparametric objects inspired by the DP. Thirdly, theoretical issues of convergence and consistency are being explored to provide frequentist guarantees for Bayesian nonparametric models. Finally, there are applications of such models, to clustering, transfer learning, relational learning, models of cognition, sequence learning, and regression and classification among others. We believe DPs and Bayesian nonparametrics will prove to be rich and fertile grounds for research for years to come.

Discrete Attribute

A **discrete attribute** assumes values that can be counted. The attribute cannot assume all values on the number line within its value range. See ▶ Attribute and ▶ Measurement Scales.

Discretization

Ying Yang
Australian Taxation Office, Box Hill, VIC,
Australia

Synonyms

Binning

Definition

Discretization is a process that transforms a ▶ numeric attribute into a ▶ categorical attribute. Under discretization, a new categorical attribute X' is formed from and replaces an existing numeric attribute X. Each value x' of X' corresponds to an interval $(a,b]$ of X. Any original numeric value x of X that belongs to $(a,b]$ is replaced by x'. The boundary values of formed intervals are often called "cut points."

Motivation and Background

Many learning systems require categorical data, while many data are numeric. Discretization allows numeric data to be transformed into categorical form suited to processing by such systems. Further, in some cases effective discretization can improve either computational or prediction performance relative to learning from the original numeric data.

Taxonomy

The following taxonomy identifies many key dimensions along which alternative discretization techniques can be distinguished.

Supervised vs. **Unsupervised** (Dougherty et al. 1995). Supervised methods use the class information of the training instances to select discretization cut points. Methods that do not use the class information are unsupervised.

Global vs. **Local** (Dougherty et al. 1995). Global methods discretize with respect to the whole training data space. They perform discretization only once, using a single set of intervals throughout a single classification task. Local methods allow different sets of intervals to be formed for a single attribute, each set being applied in a different classification context. For example, different discretizations of a single attribute might be applied at different nodes of a decision tree (Quinlan 1993).

Eager vs. **Lazy** (Hsu et al. 2000). Eager methods perform discretization prior to classification time. Lazy methods perform discretization during the process of classification.

Disjoint vs. **Nondisjoint** (Yang and Webb 2002). Disjoint methods discretize the value range of a numeric attribute into disjoint intervals. No intervals overlap. Nondisjoint methods discretize the value range into intervals that can overlap.

Parameterized vs. **Unparameterized**. Parameterized discretization requires input from the user, such as the maximum number of discretized intervals. Unparameterized discretization uses information only from data and does not need input from the user, for instance, the entropy minimization discretization (Fayyad and Irani 1993).

Univariate vs. **Multivariate** (Bay 2000). Methods that discretize each attribute in isolation are univariate. Methods that take into consideration relationships among attributes during discretization are multivariate.

Split vs. **Merge** (Kerber 1992) vs. **Single-scan** (Yang and Webb 2001). Split discretization initially has the whole value range as an interval and then continues splitting it into subintervals until some threshold is met. Merge discretization initially puts each value into an interval and then continues merging adjacent intervals until some threshold is met. Single-scan discretization uses neither split nor merge process. Instead, it scans the ordered values only once, sequentially forming the intervals.

Discriminative Learning

Definition

Discriminative learning refers to any ▶ classification learning process that classifies by using a model or estimate of the probability $P(y|\mathbf{x})$ without reference to an explicit estimate of any of $P(\mathbf{x})$, $P(y, \mathbf{x})$, or $P(\mathbf{x}|y)$, where y is a class and $\mathbf{x}$ is a description of an object to be classified. Discriminative learning contrasts to ▶ generative learning which classifies by using an estimate of the joint probability $P(y, \mathbf{x})$ or of the prior probability P(y) and the conditional probability $P(\mathbf{x}|y)$.

It is also common to categorize as discriminative any approaches that are directly based on a decision risk function (such as ▶ Support Vector Machines, ▶ Artificial Neural Networks, and ▶ Decision Trees), where the decision risk is minimized without estimation of $P(\mathbf{x})$, $P(y, \mathbf{x})$, or $P(\mathbf{x}|y)$.

Disjunctive Normal Form

Bernhard Pfahringer
University of Waikato, Hamilton, New Zealand

Disjunctive normal form is an important normal form for propositional logic. A logic formula is in disjunctive normal form if it is a single disjunction of conjunctions of (possibly negated) literals. No more nesting and no other negations are allowed. Examples are:

$$a$$

$$\neg b$$

$$a \vee b$$

$$(a \wedge \neg b) \vee (c \wedge d)$$

$$\neg a \vee (b \wedge \neg c \wedge d) \vee (a \wedge \neg d)$$

Any arbitrary formula in propositional logic can be transformed into disjunctive normal form by application of the laws of distribution, De Morgan's laws, and by removing double negations. It is important to note that this process can lead to exponentially larger formulas which implies that the process in the worst case runs in exponential time. An example for this behavior is the following formula given in ▶ conjunctive normal form (CNF), which is linear in the number of propositional variables in this form. When transformed into disjunctive normal form (DNF), its size is exponentially larger.

$$\text{CNF: } (a_0 \vee a_1) \wedge (a_2 \vee a_3) \wedge \cdots \wedge (a_{2n} \vee a_{2n+1})$$

$$\text{DNF: } (a_0 \wedge a_2 \wedge \cdots \wedge a_{2n}) \vee (a_1 \wedge a_2 \wedge \cdots \wedge a_{2n}) \vee \cdots \vee (a_1 \wedge a_3 \wedge \cdots \wedge a_{2n+1})$$

Divide-and-Conquer Learning

Johannes Fürnkranz
Knowledge Engineering Group, TU Darmstadt, Darmstadt, Deutschland
Department of Information Technology, University of Leoben, Leoben, Austria

Synonyms

Recursive partitioning; TDIDT strategy

Definition

The *divide-and-conquer* strategy is a learning algorithm for inducing ▶ Decision Trees. Its name reflects its key idea, which is to successively partition the dataset into smaller sets (the *divide* part) and recursively call itself on each subset (the *conquer* part). It should not be confused with the *separate-and-conquer* strategy which is used in the ▶ Covering Algorithm for rule learning.

Abstract

Document Classification analogous to general classification of instances, deals with

assigning labels to documents. The documents can be written in different natural languages, can be of different length and structure, can be written by different authors using variety of writing styles. Moreover, the documents to classify can be obtained from different sources including official news, internal company documentation, as well as public Web pages and texts from social media. In document classification, in addition to the algorithm we are using for constructing a classifier, data representation is crucial. Commonly used is word vector representation, where either raw data in the form of words and phrases is used or a more abstract form is constructed. Deep learning has been shown very effective for learning text representation using various deep learning architectures.

Synonyms

Document categorization; Supervised learning on text data

Definition

Document classification refers to a process of assigning one or more ▶ labels for a document from a predefined set of labels (also referred to class values). The main issues in document classification are connected to classification of free text giving document content, for instance, classifying Web documents on the content topic as being about arts, education, science, etc., or on the page type (personal homepage, company page, etc.), classifying news articles by their topic (politics, technology, science, health, etc.), and classifying movie reviews by their opinion (positive review, negative review). In general, one can consider different properties of a document in document classification and combine them, such as document type, authors, links to other documents, content, etc. Machine ▶ learning methods applied to document classification are based on general classification methods adjusted to handle some specifics of text data.

Motivation and Background

Documents and text data provide for valuable sources of information and their growing availability in electronic form naturally led to application of different analytic methods. One of the common ways is to take a whole vocabulary of the natural language in which the text is written as a feature set, resulting in several tens of thousands of features. In a simple setting, each feature gives a count of the word occurrences in a document. In this way, text of a document is represented as a vector of numbers. The representation of a particular document contains many zeros, as most of the words from the vocabulary do not occur in a particular document. In addition to the already mentioned two common specifics of text data, having a large number of features and a sparse data representation, it was observed that frequency of words in text generally follows Zipf's law – a small subset of words occur very frequently in texts, while a large number of words occur only rarely. Document classification takes these and some other data specifics into account when developing the appropriate classification methods.

Structure of Learning System

Document classification is usually performed by representing documents as vectors of feature; usually the features are words so each document is a word vector and the representation is referred to as the "bag-of-words" or "vector space model" representation. Classifier is then built using a set of documents that have been manually classified (Cohen and Singer 1996; Mladenić and Grobelnik 2003; Sebastiani 2002; Yang 1997).

Data Representation

In the word vector representation of a document, a vector of word weights is formed taking all the words occurring in all the documents. Most researchers have used single words when representing text, but there is also research that proposes using additional information to improve classification results. For instance, the feature set might be extended with various multi-word features, e.g., n-grams (sequences of n adjacent words), loose phrases (n-grams in which word order is ignored), or phrases based on grammatical analysis (noun phrases, verb phrases, etc.). Information external to the documents might also be used if it is available, for example, when dealing with Web pages, their graph organization can be a source of additional features (e.g., features corresponding to the adjacency matrix, features based on graph vertex statistics such as degree or PageRank, or features taken from the documents that are adjacent to the current document in the Web graph).

The commonly used approach to weighting words is based on ▶ TF-IDF weights where the number of occurrences of the word in the document, referred to as term frequency (TF), is multiplied by the importance of the word with regard to the whole corpus (▶ (IDF) inverse document frequency). The IDF weight for the ith word is defined as $\text{IDF}_i = \log(N/\text{DF}_i)$, where N is total number of documents and DF_i is the document frequency of the ith word (the number of documents from the whole corpus in which the ith word appears). The IDF weight decreases the influence of common words (which are not as likely to be useful for discriminating between classes of documents) and favors the less common words. However, the least frequently occurring words are often deleted from the documents as a preprocessing step, based on the notion that if a word that does not occur often enough in the training set cannot be useful for learning and generalization and would effectively be perceived as noise by the learning ▶ algorithm. A stopword list is also often used to delete some of the most common and low-content words (such as "the," "of," "in," etc.) during preprocessing. For many purposes, the vectors used to represent documents should be normalized to unit length so that the vector reflects the contents and themes of the document but not its length (which is typically not relevant for the purposes of document categorization).

Even in a corpus of just a few thousand documents, this approach to document representation can easily lead to a feature space of thousands, possibly tens of thousands, of features. Therefore, feature selection is sometimes used to reduce the feature set before training. Such questions as whether feature selection is needed and/or beneficial, and which feature selection method should be used, depend considerably on the learning algorithm used; the number of features to be retained depends both on the learning algorithm and on the feature selection method used. For example, ▶ naive Bayes tends to benefit, indeed require, heavy feature selection, while ▶ support vector machines (SVMs) tend to benefit little or nothing from it. Similarly, odds ratio tends to value (some) rare features highly and therefore requires a lot of features to be kept, while information gain tends to score some of the more frequent features highly and thus often works better if a smaller number of features is kept (see also ▶ Feature Selection in Text Mining).

Due to the large number of features in the original data representation, some of the more computationally expensive feature selection methods from traditional machine learning cannot be used with textual data. Typically, simple feature scoring measures, such as information gain, odds ratio, and chi-squared, are used to rank the features, and the features whose score falls below a certain threshold are discarded. A better but computationally more expensive feature scoring method is to train a linear classifier on the full feature set first (e.g., using linear ▶ SVM, see below) and rank the features by the absolute value of their weights in the resulting linear model (see also ▶ Feature Construction in Text Mining).

Classification

Different ▶ classification algorithms have been adjusted and applied on text data. A few more popular are described here.

▶ Naive Bayes based on the multinomial model, where the predicted class for document d is the one that maximizes the ▶ posterior probability $P(c|d) \propto P(c)\Pi_t P(t|c)$ TF(t, d), where $P(c)$ is the ► prior probability that a document belongs to class c, $P(t|c)$ is the probability that a word chosen randomly in a document from class c equals t, and TF(t, d) is the "term frequency," or the number of occurrences of word t in a document d. Where there are only two classes, say c_+ and c_-, maximizing $P(c|d)$ is equivalent to taking the sign of ln $P(c_+|d)/P(c_-|d)$, which is a linear combination of TF(w, d). Thus, the naive Bayes classifier can be seen as a linear classifier as well. The training consists simply of estimating the probabilities $P(t|c)$ and $P(c)$ from the training documents.

► Perceptron trains a linear classifier in an incremental way as a neural unit using an additive update rule. The prediction for a document represented by the vector $\mathbf{x}$ is sgn($\mathbf{w}^T$ $\mathbf{x}$), where $\mathbf{w}$ is a vector of weights obtained during training. Computation starts with $\mathbf{w} = 0$ and then considers each training example $\mathbf{x}_i$ in turn. If the present $\mathbf{w}$ classifies document $\mathbf{x}_i$ correctly, it is left unchanged; otherwise, it is updated according to the additive rule: $\mathbf{w} \leftarrow \mathbf{w} + y_i\ \mathbf{x}_i$, where y_i is the correct class label of the document $\mathbf{x}_i$, namely, $y_i = +1$ for a positive document and $y_i = 1$ for a negative one.

► SVM trains a linear classifier of the form sgn ($\mathbf{w}^T$ $\mathbf{x}$ $+b$). Learning is posed as an optimization problem with the goal of maximizing the *margin*, i.e., the distance between the separating hyperplane $\mathbf{w}^T\ \mathbf{x} + b = 0$ and the nearest training vectors. An extension of this formulation, known as the *soft margin*, also allows for a wider margin at the cost of misclassifying some of the ► training examples. The dual form of this optimization task is a quadratic programming problem and can be solved numerically.

Results of numerous experiments reported in research papers suggest that among the classification algorithms that have been adjusted to text data SVM, ► naive Bayes and k-nearest neighbor are among the best performing (Lewis et al. 1996). Moreover, experimental evaluation on some standard Reuters news datasets shows that SVM tends to outperform other classifiers including naive Bayes and perceptron (Mladenic et al. 2004).

In many applications, a document may belong to multiple classes, e.g., because it includes discussion relevant to several topics. The classifiers described above can naturally provide multi-label predictions in a multi-class learning problem simply by treating each class as a two-class problem separately from the other classes. However, there are also methods that try to model the multi-class nature of individual documents directly. For example, recently there has been an increase of interest in using artificial neural networks for text classification, with a multiunit output layer that can generate predictions for all classes at once (Zhang and Zhou 2006; Nam et al. 2014).

Evaluation Measures

A ► characteristic property of machine learning problems arising in document classification is a very unbalanced class distribution. In a typical dataset, there may be tens (or sometimes hundreds or thousands) of categories, most of which are very small. When we train a binary (two-class) classification model for a particular category, documents belonging to that category are treated as the positive class, while all other documents are treated as the negative class. Thus, the negative class is typically vastly larger as the positive one. These circumstances are not well suited to some traditional machine learning ► evaluation measures, such as ► accuracy (if almost all documents are negative, then a useless classifier that always predicts the negative class will have very high accuracy). Instead, evaluation measures from information retrieval are more commonly used, such as ► precision, ► recall, the F_1-measure, the ► breakeven point (BEP), and the area under the ► receiver operating characteristic (ROC) curve (see also ► ROC Analysis).

The evaluation of a binary classifier for a given category c on a given ► test set can be conveniently summarized in a contingency table. We can divide documents into four groups depending on whether they belong to c and whether our classifier predicted them as positive (i.e., supposedly belonging to c) or not:

Given the number of documents in each of the four groups (TP, FP, TN, and FN), we can compute various evaluation measures as follows:

- Precision = TP/(TP + FP)
- Recall = TP_{rate} = TP/(TP + FN)
- FP_{rate} = FP/(TN + FP)
- $F_1 = 2 \bullet precision \bullet recall/(precision + recall)$

	Belongs to *c*	Not in *c*
Predicted positive	TP (true positives)	FP (false positives)
Predicted negative	FN (false negatives)	TN (true negatives)

Thus, precision is the proportion of documents predicted positive that are really positive, while recall is the proportion of positive documents that have been correctly predicted as positive. The F_1 is the ▶ harmonic mean of precision and recall; thus, it lies between ▶ precision and recall but is closer to the lower of these two values. This means that a classifier with high F_1 has both good precision and good recall. In practice, there is usually a tradeoff between precision and recall; by making the classifier more liberal (i.e., more likely to predict positive), we can increase recall at the expense of precision, while by making it more conservative (less likely to predict positive), we can usually increase precision at the expense of recall. Often the classification model involves a threshold which can be varied at will to obtain various $\langle precision, recall\rangle$ pairs. These can be plotted on a chart, resulting in the *precision-recall curve*. As we decrease the threshold (thus making the classifier more liberal), precision decreases and recall increases until at some point precision and recall are equal; this value is known as the (*precision-recall*) *BEP* (Lewis 1991). Instead of $\langle precision, recall\rangle$ pairs, one can measure $\langle \text{TP}_{\text{rate}}, \text{FP}_{\text{rate}}\rangle$ pairs, resulting in an ▶ ROC curve (see ▶ ROC analysis). The ▶ area under the ROC curve is another valuable measure of the classifier quality.

Document classification problems are typically multi-class, multi-label problems, which are treated by regarding each category as a separate two-class classification problem. After training a two-class classifier for each category and evaluating it, the question arises how to combine these evaluation measures into an overall evaluation measure. One way is *macroaveraging*, which means that the values of precision, recall, F_1, or whatever other measure we are interested in are simply averaged over all the categories. Since small categories tend to be much more numerous than large ones, macroaveraging tends to emphasize the performance of our learning algorithm on small categories. An alternative approach is *microaveraging*, in which the contingency tables for individual two-class classifiers are summed up and measures such as precision, recall, and F_1 computed from the resulting aggregated table. This approach emphasizes the performance of our learning algorithm on larger categories.

Dynamic Programming

Martin L. Puterman[1] and Jonathan Patrick[2]
[1]University of British Columbia, Vancouver, BC, Canada
[2]University of Ottawa, Ottawa, ON, Canada

Definition

Dynamic programming is a method for modeling a sequential decision process in which past decisions impact future possibilities. Decisions can be made at fixed discrete time intervals or at random time intervals triggered by some change in the system. The decision process can last for a finite period of time or run indefinitely – depending on the application. Each time a decision needs to be made, the decision-maker (referred to as "he" in this entry with no sexist connotation intended) views the current ▶ state of the system and chooses from a known set of possible ▶ actions. As a result of the state of the system and the action chosen, the decision-maker receives a reward (or pays a ▶ cost) and the system evolves to a new state based on known probabilities. The challenge faced by the decision-maker is to choose a sequence of actions that will lead to the greatest reward over the length of the decision-making horizon. To do this, he needs to consider not only the current reward (or cost) for taking a given action but the impact such an action might have on future rewards. A policy is a complete sequence of decisions that dictates what action to take in any given state and at any given time. Dynamic programming finds the optimal policy by developing mathematical recursions that decompose the multi-decision problem into a series of single-decision problems that are analytically or computationally more tractable.

Background and Motivation

The earliest concepts that later developed into dynamic programming can be traced back to the calculus of variation problems in the seventeenth century. However, the modern investigation of stochastic sequential decision problems arguably dates back to the work by Wald in 1947 on sequential statistical analysis. At much the same time, Pierre Masse was analyzing similar problems applied to water resource management in France. However, the major name associated with dynamic programming is that of Richard Bellman who established the optimality equations that form the basis of dynamic programming.

It is not hard to demonstrate the potential scope of dynamic programming. Table 1 gives a sense of the breadth of application as well as highlighting the stochastic nature of most instances.

Structure of the Learning System

A dynamic program is a general representation of a sequential decision problem under uncertainty about the future and is one of the main methods for solving Markov decision problems (see ▸ Markov Decision Processes). Like a decision tree, it models a process where the decision we make "today" impacts where we end up tomorrow and therefore what decisions are available to us tomorrow. It has distinct advantages over a decision tree in that:

- It is a more compact representation of a decision process
- It enables efficient calculation
- It allows exploration of the structural properties of optimal decisions
- It can analyze and solve problems with infinite or indefinite time horizons

The Finite-Horizon Setting

A finite-horizon MDP is a decision process with a known end date. Thus, the decision-maker is faced with the task of making a finite sequence of decisions at fixed intervals. The MDP model is based on five elements:

- ▸ Decision epochs: Sequences of decision times $n = 1, \ldots, N$ (in the infinite horizon, we set $N = \infty$). In a discrete-time MDP, these decision times happen at regular, fixed intervals while in a continuous-time model, they occur at random times triggered by a change in the system. The time between decision epochs is called a period.
- ▸ State space: States represent the possible system configurations facing the decision-maker at each decision epoch. They contain all information available to the decision-maker at each decision epoch. The state space, S, is the set of all such states (often assumed to be finite). In choosing the state space, it is important to include all the information that may be relevant in determining a decision and that may change from decision epoch to decision epoch.
- ▸ Actions: Actions are the available choices for the decision-maker at any given decision epoch, in any given state. $A(s)$ is the set of all actions available in state s (usually assumed to be finite for all s). No action is taken in the final decision epoch N.
- ▸ Transition probabilities: The probability of being in state s' at time $t+1$, given you take action a from state s at time t, is written as $p_t(s'|s,a)$. It clearly makes sense to allow the transition probabilities to be conditional upon the current state and the action taken.
- ▸ Rewards/costs: In most MDP applications, the decision-maker receives a reward each period. This reward can depend on the current state, the action taken, and the next state and is denoted by $r_t(s,a,s')$. Since a decision must be made before knowing the next state, s', the MDP formulation deals with the expected reward:

$$r_t(s,a) = \sum_{s' \in S} r_t(s,a,s') p_t(s'|s,a).$$

We also define the terminal rewards as $r_N(s)$ for being in state s at the final decision epoch.

Dynamic Programming, Table 1 Dynamic programming applications

Application	System state	Actions	Rewards	Stochastic aspect
Capacity	Size of plant	Maintain or add capacity	Costs of expansion and production at current capacity	Demand for a product
Cash mgt	Cash available	Borrow or invest	Transaction costs and less interest	External demand for cash
Catalog mailing	Customer purchase record	Type of catalog to send, if any	Purchases in current period less mailing costs	Customer purchase amount
Clinical trials	Number of successes with each treatment	Stop or continue the trial	Costs of treatment and incorrect decisions	Response of a subject to treatment
Economic growth	State of the economy	Investment or consumption	Utility of consumption	Effect of investment
Fisheries mgt	Fish stock in each age class	Number of fish to harvest	Value of the catch	Population size
Forest mgt	Size and condition of stand	Harvesting and reforestation activities	Revenues and less harvesting costs	Stand growth and price fluctuation
Gambling	Current wealth	Stop or continue playing	Cost of playing	Outcome of the game
Inventory control	Stock on hand	Order additional stock	Revenue per item sold and less ordering, holding, and penalty costs	Demand for items
Project selection	Status of each project	Project to invest in at present	Return from investing in project	Change in project status
Queueing control	Number in the queue	Accept/reject new customers or control service rate	Revenue from serving customers and less delay costs	Interarrival times and service times
Reliability	Age or status of equipment	Inspect and repair or replace if necessary	Inspection, repair, and failure costs	Failure and deterioration
Reservations	Number of confirmed reservations	Accept, wait-list, or reject new reservation	Profit from satisfied reservations and less overbooking penalties	Number of arrivals and the demand for reservations
Scheduling	Activities completed	Next activity to schedule	Cost of activity	Length of time to complete activity
Selling an asset	Current offer	Accept or reject the offer	The offer is less than the cost of holding the asset for one period	Size of the offer
Water resource management	Level of water in each reservoir	Quantity of water to release	Value of power generated	Rainfall and runoff

These are independent of the action since no action is taken at that point.

The objective in the finite-horizon model is to maximize total expected reward:

$$\max\left\{E\left[\sum_{t=1}^{N} r_t(s_t,a_t,s_{t+1})+r_N(s_N)|s_1=s\right]\right\}. \tag{1}$$

At any given time t, the decision-maker has observed the history up to time t, represented by $h_t = (s_1, a_1, s_2, a_2, \ldots, a_{t-1}, s_t)$, and needs to choose a_t in such a way as to maximize (1). A ▶ decision rule, d_t, determines what action to take, based on the history to date at a given decision epoch and for any possible state. It is deterministic if it selects a single member of $A(s)$ with probability 1 for each $s \in S$ and for a given h_t, and it is ▶ randomized (▶ randomized decision rule) if it selects a member of $A(s)$ at random with probability $q_{d_t(h_t)}(a)$. It is Markovian (▶ Markovian decision rule) if it depends on h_t only through s_t. That is, $d_t(h_t) = d_t(s_t)$.

A policy, $\pi = (d_1, \ldots, d_{N-1})$, denotes a complete sequence of decision rules over the whole horizon. It can be viewed as a "contingency plan" that determines the action for each possible state at each decision epoch. One of the major results in MDP theory is that, under reasonable conditions, it is possible to prove that there exists a Markovian, deterministic policy that attains the maximum total expected reward. Thus, for the purposes of this entry, we will concentrate on this subset of all policies.

If we define $v_t(s)$ as the expected total reward from time t to the end of the planning horizon, given that at time t the system occupies state s, then a recursion formula can be built that represents v_t in terms of v_{t+1}. Specifically,

$$v_t(s) = \max_{a \in A(s)} \left\{ r_t(s,a) + \sum_{s' \in S} p(s'|s,a) v_{t+1}(s') \right\} \tag{2}$$

This is often referred to as the ▶ Bellman equation, named after Richard Bellman who was responsible for the seminal work in this area. It breaks the total reward at time t into the immediate reward $r_t(s,a)$ and the total future expected reward, $\sum_{s' \in S} p(s'|s,a) v_{t+1}(s')$. Define $A^*_{s,t}$ as the set of actions that attain the maximum in (2) for a given state s and decision epoch t. Then the finite-horizon discrete-time MDP can be solved through the following backward induction algorithm.

Backward Induction Algorithm

- Set $t = N$ and $v_t(s) = r_N(s) \quad \forall s \in S$ (since there is no decision at epoch N and no future epochs, it follows that the optimal reward-to-go function is just the terminal reward).
- Let $t = t - 1$ and compute for each $s \in S_t$

$$v_t(s) = \max_{a \in A(s)} \left\{ r_t(s,a) + \sum_{s' \in S} p(s'|s,a) v_{t+1}(s') \right\} .$$

- For each $s \in S_t$, compute $A^*_{s,t}$ by solving

$$\text{argmax}_{a \in A(s)} \left\{ r_t(s,a) + \sum_{s' \in S} p(s'|s,a) v_{t+1}(s') \right\} .$$

- If $t = 1$ then stop else return to step 2.

The function $v_1(s)$ is the maximum expected reward over the entire planning horizon given the system starts in state s. The optimal policy is constructed by choosing a member of $A^*_{s,t}$ for each $s \in S$ and $t \in \{1, \ldots, N\}$. In essence, the algorithm solves a complex N-period decision problem by solving N simple 1-period decision problems.

Example – inventory control: Periodically (daily, weekly, or monthly), an inventory manager must determine how much of a product to stock in order to satisfy random external demand for the product. If too little is in stock, potential sales are lost. Conversely, if too much is on hand, a cost for carrying inventory is incurred. The objective is to choose an ordering rule that maximizes expected total profit (sales minus holding and ordering costs) over the planning horizon. To formulate an MDP model of this system requires precise assumptions such as:

- The decision regarding the quantity to order is made at the beginning of each period and delivery occurs instantaneously.

- Demand for the product arrives throughout the period, but all orders are filled on the last day of the period.
- If demand exceeds the stock on hand, potential sales are lost.
- The revenues, costs, and demand distribution are the same each period.
- The product can only be sold in whole units.
- The warehouse has a capacity for M units.

(These assumptions are not strictly necessary but removing them leads to a different formulation.) Decisions epochs correspond to the start of a period. The state, $s_t \in \{0, \ldots, M\}$, represents the inventory on hand at the start of period t and the action, $a_t \in \{0, 1, 2, \ldots, M - s\}$, is the number of units to order that period; the action 0 corresponds to not placing an order. Let D_t represent the random demand throughout period t and assume that the distribution of demand is given by $p_t(d) = P(D_t = d), d = 0, 1, 2, \ldots$. The cost of ordering u units is $O(u) = K + c(u)$ (a fixed cost plus variable cost) and the cost of storing u units is $h(u)$, where $c(u)$ and $h(u)$ are increasing functions in u. We will assume that leftover inventory at the end of the planning horizon has value $g(u)$ and that the sale of u units yields a revenue of $f(u)$. Thus, if there are u units on hand at decision epoch t, the expected revenue is

$$F_t(u) = \sum_{j=0}^{u-1} f(j)p_t(j) + f(u)P(D_t \geq u).$$

The expected reward is therefore

$$r_t(s, a) = F(s + a) - O(a) - h(s + a)$$

and the terminal rewards are $r_N(s, a) = g(s)$. Finally, the transition probabilities depend on whether or not there is enough stock on hand, $s + a$, to meet the demand for that month, D_t. Specifically,

$$p_t(j|s, a) = \begin{cases} 0 & \text{if } j > s + a, \\ p_t(j) & \text{if } j = s + a - D_t, s + a \leq M, \\ & \quad s + a > D_t, \\ \sum_{d=s+a}^{\infty} p_t(d) & \text{if } j = 0, s + a \leq M, s + a \leq D_t. \end{cases}$$

Solving the finite-horizon version of this problem through backward induction reveals a simple form to the optimal policy referred to as an (s, S) policy. Specifically, if at time t, the inventory is below some number s^t, then it is optimal to order a quantity that raises the inventory level to S^t. It has been shown that a structured policy of this type is optimal for several variants of the inventory management problem with a fixed ordering cost. Many variants of this problem have been studied; these models underlie the field of supply chain management.

The Infinite-Horizon Setting

In the infinite (or indefinite)-horizon setting, the backward induction algorithm described above no longer suffices as there are no terminal rewards with which to begin the process.

In most finite-horizon problems, the optimal policy begins to look the same at each decision epoch as the horizon is pushed further and further into the future. For instance, in the inventory example above, $s^t = s^{t+1}$ and $S^t = S^{t+1}$ if t is sufficiently removed from the end of the horizon. The form of the optimal policy only changes as the end of the time horizon approaches. Thus, if there is no fixed time horizon, we should expect the optimal policy to be *stationary* in most cases. We call a policy *stationary* if the same decision rule is applied at each decision epoch (i.e., $d_t = d \; \forall \, t$). One necessary assumption for this to be true is that the rewards and transition probabilities are independent of time (i.e., $r_t(s, a) = r(s, a)$ and $p_t(s'|s, a) = p(s'|s, a) \, \forall \, s,' s \in S$ and $a \in A(s)$). For the infinite-horizon MDP, the theory again proves that under mild assumptions, there exists an optimal policy that is *stationary, deterministic*, and *Markovian*. This fact greatly simplifies the process of finding the optimal policy as we can concentrate on a small subset of all potential policies.

The setup for the infinite-horizon MDP is entirely analogous to the finite-horizon setting with the same ▶ decision epochs, ▶ states, ▶ actions, ▶ rewards, and ▶ transition probabilities (with the last two assumed to be independent of time).

The most obvious objective is to extend the finite-horizon objective to infinity and seek to find the policy, π, that maximizes the total expected reward:

$$v^{\pi}(s) = \lim_{N\to\infty}\left\{E_s^{\pi}\left[\sum_{t=1}^{N} r(s_t, a_t)\right]\right\} . \qquad (3)$$

This, however, is problematic since

1. The sum may be infinite for some or all policies
2. The sum may not even exist, or
3. Even if the sum exists, there may be no maximizing policy

In the first case, just because all (or a subset of all) policies lead to infinite reward in the long run does not mean that they are all equally beneficial. For instance, one may give a reward of $100 each epoch and the other $1 per epoch. Alternatively, one may give large rewards earlier on while another gives large rewards only much later. Generally speaking, the first is more appealing but the above objective function will not differentiate between them. Secondly, the limit may not exist if, for instance, the reward each decision epoch oscillates between 1 and -1. Thirdly, there may be no maximizing policy simply because there is an infinite number of policies and thus there may be an infinite sequence of policies that converges to a maximum limit but never reaches it. Thus, instead we look to maximize either the *total expected discounted reward* or the *expected long-run average reward* depending on the application.

Let $\lambda \in (0,1)$ be a discount factor. Assuming the rewards are bounded (i.e., there exists an M such that $|r(s,a)| < M \quad \forall (s,a) \in S \times A(s)$), the *total expected discounted reward* for a given policy π is defined as

$$\begin{aligned} v_{\lambda}^{\pi}(s) &= \lim_{N\to\infty} E_s^{\pi}\left\{\sum_{t=1}^{N} \lambda^{t-1} r(s_t, d_t(s_t))\right\} \\ &= E_s^{\pi}\left\{\sum_{t=1}^{\infty} \lambda^{t-1} r(s_t, d_t(s_t))\right\} . \end{aligned}$$

Since $\lambda < 1$ and the rewards are bounded, this limit always exists. The second objective is the *expected average reward* which, for a given policy π, is defined as

$$g^{\pi}(s) = \lim_{N\to\infty} \frac{1}{N} E_s^{\pi}\left\{\sum_{t=1}^{N} r(s_t, d_t(s_t))\right\} .$$

Once again, we are dealing with a limit that may or may not exist. As we will see later, whether the above limit exists depends on the structure of the Markov chain induced by the policy.

Let us, at this point, formalize what we mean by an optimal policy. Clearly, that will depend on which objective function we choose to use. We say that

- π^* is *total reward optimal* if $v^{\pi^*}(s) \geq v^{\pi}(s)$ $\forall s \in S$and $\forall \pi$.
- π^* is *discount optimal* if $v_{\lambda}^{\pi^*}(s) \geq v_{\lambda}^{\pi}(s)$ $\forall s \in S$and $\forall \pi$.
- π^* is *average optimal* if $g^{\pi^*}(s) \geq g^{\pi}(s)$ $\forall s \in S$ and $\forall \pi$.

For simplicity, we introduce matrix and vector notation. Let $r_d(s) = r(s, d(s))$ and $p_d(j|s) = p(j|s, d(s))$. Thus r_d is the vector of rewards for each state under decision rule d, and P_d is the transition matrix of states under decision rule d. We will now take a more in-depth look at the infinite-horizon model with the total expected discounted reward as the optimality criterion.

Solving the Discounted Infinite-Horizon MDP

Given a Markovian, deterministic policy $\pi = (d_1, d_2, d_3, \ldots)$ and defining $\pi_k = (d_k, d_{k+1}, \ldots)$, we can compute

$$
\begin{aligned}
v_\lambda^\pi(s) &= E_s^{\pi_1}\left[\sum_{t=1}^{\infty} \lambda^{t-1} r(s_t, d_t(s_t))\right] \\
&= E_s^{\pi_1}\left[r(s, d_1(s)) + \lambda \sum_{t=2}^{\infty} \lambda^{t-2} r(s_t, d_t(s_t))\right] \\
&= r(s, d_1(s)) + \lambda \sum_{j\in S} p_{d_1}(j|s) E_j^{\pi_2}\left[\sum_{t=1}^{\infty} \lambda^{t-1} r(s_t, d_t(s_t))\right] \\
&= r(s, d_1(s)) + \lambda \sum_{j\in S} p_{d_1}(j|s) v_\lambda^{\pi_2}(j).
\end{aligned}
$$

In matrix notation,

$$v_\lambda^{\pi_1} = r_{d_1} + \lambda P_{d_1} v_\lambda^{\pi_2}.$$

If we follow our supposition that we need to only consider *stationary* policies (so that the same decision rule is applied to every decision epoch), $\pi = d^\infty = (d, d, \ldots)$, then this results in

$$v_\lambda^{d^\infty} = r_d + \lambda P_d v_\lambda^{d^\infty}.$$

This implies that the value function generated by a stationary policy satisfies the equation:

$$
\begin{aligned}
v &= r_d + \lambda P_d v \\
\Rightarrow v &= (I - \lambda P_d)^{-1} r_d.
\end{aligned}
$$

The inverse above always exists since P_d is a probability matrix (so that its spectral radius is less than or equal to 1) and $\lambda \in (0, 1)$. Moving to the maximization problem of finding the optimal policy, we get the recursion formula

$$v(s) = \max_{a\in A(s)} \left\{ r(s,a) + \lambda \sum_{j\in S} p(s|s,a) v(j) \right\}. \tag{4}$$

Note that the right-hand side can be viewed as a function of a vector v (given r, p, λ). We define a vector-valued function

$$Lv = \max_{d\in D^{MD}} \left\{ r_d + \lambda P_d v \right\},$$

where D^{MD} is the set of all Markovian, ▶ deterministic decision rules. There are three methods for solving the above optimization problem in order to determine the optimal policy. The first method, called *value iteration*, creates a sequence of approximations to the value function that eventually converges to the value function associated with the optimal policy.

Value Iteration

1. Start with an arbitrary $|S|$-vector v^0. Let $n = 0$ and choose $\epsilon > 0$ to be small.
2. For every $s \in S$, compute $v^{n+1}(s)$ as

$$
\begin{aligned}
&v^{n+1}(s) \\
&= \max_{a\in A(s)} \left\{ r(s,a) + \sum_{j\in S} \lambda p(j|s,a) v^n(j) \right\}.
\end{aligned}
$$

3. If $\max_{s\in S} |v^{n+1}(s) - v^n(s)| \geq \epsilon(1-\lambda)/2\lambda$ let $n \to n+1$ and return to step 2.
4. For each $s \in S$, choose

$$d_\epsilon(s) \in \text{argmax}_{a\in A(s)} \left\{ r(s,a) + \sum_{j\in S} \lambda p(j|s,a) v^{n+1}(j) \right\}.$$

It has been shown that value iteration identifies a policy with expected total discounted reward within ϵ of optimality in a finite number of iterations. Many variants of value iteration are available such as using different stopping criteria to accelerate convergence or combining value iteration with the policy iteration algorithm described below.

A second algorithm, called *policy iteration*, iterates through a sequence of policies eventually converging to the optimal policy.

Policy Iteration

1. Set $d_0 \in D$ to be an arbitrary policy. Let $n = 0$.
2. (Policy evaluation) Obtain v^n by solving
$$v^n = (I - \lambda P_{d_n})^{-1} r_{d_n}.$$
3. (Policy improvement) Choose d_{n+1} to satisfy
$$d_{n+1} \in \text{argmax}_{d \in D}\{r_d + \lambda P_d v^n\}$$
componentwise. If d_n is in this set, then choose $d_{n+1} = d_n$.
4. If $d_{n+1} = d_n$, set $d^* = d_n$ and stop. Otherwise, let $n \to n+1$ and return to (2).

Note that value iteration and policy iteration have different conceptual underpinnings. Value iteration seeks a *fixed point* of the operator L using successive approximations, while policy iteration can be viewed as using Newton's method to solve $Lv - v = 0$.

Finally, a third method for solving the discounted infinite-horizon MDP takes advantage of the fact that, because L is monotone, if $Lv \leq v$, then $L^2 v \leq Lv$ and more generally, $L^k v \leq v$. Thus, induction implies that the value function of the optimal policy, v^*_λ, is less than or equal to v for any v, where $Lv \leq v$. We define the set $U := \{v \in V | Lv \leq v\}$. Then, not only is v^*_λ in the set U, it is also the smallest element of U. Therefore, we can solve for v^*_λ by solving the following linear program:

$$\min_v \sum_{s \in S} \alpha(s) v(s)$$

subject to

$$v(s) \geq r(s,a) + \lambda \sum_{j \in S} p(j|s,a) v(j) \quad \forall s \in S, \;\; a \in A_s.$$

(Note that the above set of constraints is equivalent to $Lv \leq v$.) We call this the primal LP. The coefficients $\alpha(s)$ are arbitrarily chosen. The surprising fact is that the solution to the above LP will be v^*_λ for any strictly positive α.

We can construct the dual to the above primal to get

$$\max_X \sum_{s \in S} \sum_{a \in A_s} r(s,a) X(s,a)$$

subject to

$$\sum_{a \in A_j} X(j,a) - \sum_{s \in S} \sum_{a \in A_s} \lambda p(j|s,a) X(s,a) = \alpha(j) \quad \forall j \in S$$

$$X(s,a) \geq 0 \quad \forall s \in S, \;\; a \in A_s.$$

Let $(X(s,a) : s \in S, a \in A_s)$ be a feasible solution for the dual (i.e., satisfies the constraints but not necessarily optimal). Every such feasible solution corresponds to a randomized Markov policy d^∞ and vice versa. Furthermore, for a given feasible solution, X, and the corresponding policy d^∞, $X(s,a)$ represents the expected total number of times you will be in state s and take action a following policy d^∞ before stopping in the indefinite-horizon problem. Thus, the objective in the dual can be interpreted as the total expected reward over the length of the indefinite horizon. The strong law of duality states that at the optimal solution, the objective functions in the primal and dual will be equal. But we already know that at the optimal, the primal objective will correspond to a weighted sum of $v^*_\lambda(s), s \in S$, which is the total expected discounted reward over the infinite (or indefinite) horizon given you start in state s. Thus our interpretations for the primal and dual variables coincide.

Solving the Infinite-Horizon Average-Reward MDP

Recall that in the average-reward model, the objective is to find the policy that has the maximum average reward, often called the *gain*. The gain of a policy can be written as

$$\begin{aligned} g^{\pi}(s) &= \lim_{n\to\infty} \frac{1}{N} v^{\pi}_{N+1} \\ &= \lim_{n\to\infty} \frac{1}{N} \sum_{n=1}^{N} [P_{\pi}^{n-1} r_{d_s}](s). \end{aligned} \quad (5)$$

As mentioned earlier, the major drawback is that for a given policy π, the gain may not even exist. An important result, however, states that if we confine ourselves to stationary policies, we can in fact be assured that the gain is well defined. Our ability to solve a given infinite- horizon average-reward problem depends on the form of the Markov chains induced by the deterministic, stationary policies available in the problem. Thus, we divide the set of average-reward MDPs according to the structure of the underlying Markov chains. We say that an MDP is

- *Unichain* if the transition matrix corresponding to *every* deterministic stationary policy is unichain, that is, it consists of a single recurrent class plus a possibly empty set of transient states, or
- *Multichain* if the transition matrix corresponding to *at least one* stationary policy contains two or more closed irreducible recurrent classes

If an MDP is unichain, then the gain for any given stationary, deterministic policy can be defined by a single number (independent of starting state). This makes intuitive sense since if we assume that it is possible to visit every state from every other one (possibly minus some set of transient states that may be visited initially but will eventually be abandoned), then it would seem reasonable to assume that over the infinite horizon, the initial starting state would not impact the average reward. However, if the initial state impacts what set of states can be visited in the future (i.e., the MDP is multichain), then clearly it is likely that the expected average reward will be dependent on the initial state.

If the average-reward MDP is unichain, then the *gain* can be uniquely determined by solving

$$v(s) = \max_{a\in A(s)} \left\{ r(s,a) - g + \sum_{s'\in S} p(s'|s,a) v(s') \right\}. \quad (6)$$

Notice that the above equation has $|S| + 1$ unknowns but only $|S|$ equations. Thus, v is not uniquely determined. To specify v uniquely, it is sufficient to set $v(s') = 0$ for some $s' \in S$. If this is done, then $v(s)$ is called the relative value function and $v(j) - v(k)$ is the difference in expected total reward obtained in using an optimal policy and starting in state j as opposed to state k. It is also often represented by the letter h and called the *bias*.

As in the discounted infinite-horizon MDP, there are three potential methods for solving the average-reward case. We present only policy iteration here and refer the reader to the recommended readings for value iteration and linear programming.

Policy Iteration

1. Set $n = 0$, and choose an arbitrary decision d_n.
2. (Policy evaluation) Solve for g_n, v_n:

$$0 = r_{d_n} - ge + (P_{d_n} - I)v.$$

3. Choose d_{n+1} to satisfy

$$d_{n+1} \in \text{argmax}_{d\in D}\{r_d + P_d v_n\}.$$

Setting $d_{n+1} = d_n$ if possible.

4. If $d_{n+1} = d_n$, stop, set $d^* = d_n$. Else, increment *n* by 1 and return to step 2.

As mentioned earlier, the equation in step 2 fails to provide a unique v_n since we have $|S| + 1$ unknowns and only $|S|$ equations. We therefore need an additional equation. Any one of the following three will suffice:

1. Set $v_n(s_0) = 0$ for some fixed $s_0 \in S$.
2. Choose v_n to satisfy $P^*_{d_n} v_n = 0$.
3. Choose v_n to satisfy $-v_n + (P_d - I)w = 0$ for some $w \in V$.

Continuous-Time Models

So far, we have assumed that decision epochs occur at regular intervals but clearly in many applications this is not the case. Consider, for instance, a queueing control model where the service rate can be adjusted in response to the size of the queue. It is reasonable to assume, however, that changing the service rate is only possible following the completion of a service. Thus, if the service time is random, then the decision epochs will occur at random time intervals. We will therefore turn our attention now to systems in which the state changes and decision epochs occur at random times. At the most general level, decisions can be made at any point in time, but we will focus on the subset of models for which decision epochs only occur at state transitions. It turns out that this is usually sufficient as the added benefit of being able to change decisions apart from state changes does not generally improve performance. Thus, the models we study generalize the discrete-time MDP models by:

1. Allowing, or requiring, the decision-maker to choose actions whenever the system changes state
2. Modeling the evolution of the system in continuous time, and
3. Allowing the time spent in a particular state to follow an arbitrary probability distribution

Semi-Markov decision processes (SMDP) are continuous-time models where decisions are made at some but not necessarily all state transitions. The most common subset of these, called exponential SMDPs, are SMDPs where the intertransition times are exponentially distributed.

We distinguish between two processes:

1. The natural process that monitors the state of the system as if it were observed continually through time and
2. The embedded Markov chain that monitors the evolution of the system at the decision epochs only

For instance, in a queueing control model, one may decide only to change the rate of service every time there is an arrival. Then the embedded Markov chain would only keep track of the system at each arrival while the natural process would keep track of all state changes – including both arrivals and departures.

While the actions are generally only going to depend on the state of the system at each decision epoch, it is possible that the rewards/costs to the system may depend on the natural process. Certainly, in the queueing control model, the cost to the system would go down as soon as a departure occurs. In discrete models, it was sufficient to let the reward depend on the current state s and the current action a and possibly the next state s'. However, in an SMDP, the natural process may change between now and the next decision epoch, and moreover, the time the process stays in a given state is no longer fixed. Thus we need to consider two types of rewards/costs. First, a lump-sum reward, $k(s, a)$, for taking action a when in state s. Second, a reward *rate*, $c(j, s, a)$, paid out for each time unit that the natural process spends in state j until the next decision epoch when the state at the last decision epoch was s and the action taken was a. Note that if we insist that every state transition triggers a decision epoch, we can reduce this to $c(s, a)$ since the system remains in s until the next decision epoch.

Before we can state our objective, we need to determine what we mean by discounting. Again, because we are dealing with continuous time so that decision epochs are not evenly spaced, it is not sufficient to have a fixed discount factor λ. Instead, we will discount future rewards at rate $e^{-\alpha t}$, for some $\alpha > 0$. If we let $\lambda = e^{-\alpha}$ (the discount rate for one time unit) then $\alpha = 0.11$ corresponds to $\lambda = 0.9$. Thus an α around 0.1 is commonly used.

We can now state our objective. We look to find a policy that maximizes the total expected discounted reward over the infinite horizon. There is an average-reward model for continuous-time models as well but we will not discuss that here. Given a policy π, we can write its total expected discounted reward as

$$v_\alpha^\pi(s) = E_s^\pi\left[\sum_{n=0}^{\infty} \mathrm{e}^{-\alpha\sigma_n}\left(K(X_n, Y_n) + \int_{\sigma_n}^{\sigma_{n+1}} \mathrm{e}^{-\alpha(t-\sigma_n)} c(W_t, X_n, Y_n)\, \mathrm{d}t\right)\right], \tag{7}$$

where X_n and Y_n are the random variables that represent the state and action at time n, respectively, W_t is the random variable that represents the state of the natural process at time t, and σ_n is the random time of the nth decision epoch. Again, if we assume that each state transition triggers a decision epoch, $X_n = W_t$ for all $t \in [\sigma_n, \sigma_{n+1})$. We seek to find a policy π such that

$$v_\alpha^\pi(s) = v_\alpha^*(s) = \max_{\pi \in \Pi^{HR}} v_\alpha^\pi(s) \tag{8}$$

for all $s \in S$. Perhaps surprisingly, (7) can be reduced to one that has the same form as in the discrete-time case for any SMDP. As a consequence, all the theory and the algorithms that worked in the discrete version can be transferred to the continuous model! Again, we refer the reader to the recommended readings for the details.

Extensions

Partially Observed MDPs

In some instances, the state of the system may not be directly observable, but instead, the decision-maker receives a signal from the system that provides information about the state. For example, in medical decision-making, the health-care provider will not know the patient's true health status but will have on hand some diagnostic information that may be related to the patient's true health. These problems are modeled from a Bayesian perspective. The decision-maker uses the signal to update his estimate of the probability distribution of the system state. He then bases his decision on this probability distribution. The computational methods for solving partially observed MDPs are significantly more complex than in the fully observable case and only small problems have been solved numerically.

Parameter-Adaptive Dynamic Programming

Often the transition probabilities in an MDP are derived from a system model, which is determined by a few parameters. Examples include demand distributions in inventory control and arrival and/or service distributions in queueing systems. In these cases, the forms of the distributions are known (e.g., Poisson for demand models and exponential for arrival or service models) but their parameter values are not. Herein, the decision-maker seeks a policy that combines *learning* with *control*. A Bayesian approach is used. The parameter is related to the system state through a likelihood function, and after observing the system state, the probability distribution on the parameter is updated. This updated probability distribution provides the basis for choosing a policy.

Approximate Dynamic Programming

Arguably the greatest challenge to implementing MDP theory in practice is "the curse of dimensionality." As the complexity of a problem grows, the amount of information that needs to be stored in the state space quickly reaches a point where the MDP is no longer computationally tractable. There now exist several methods for dealing with this problem, all of which are grouped under the title of approximate dynamic programming or neuro-dynamic programming. These potential methods begin by restricting the value function to a certain class of functions and then seeking to find the optimal value function within this class. A typical approximation scheme is based on the linear architecture:

$$v^*(s) \approx \tilde{v}(s,r) = \sum_{i=1}^{k} r_i \phi_i(s),$$

where $\phi_i(s), i = 1, \ldots, k$ are predefined basis functions that attempt to characterize the state space and r is a set of weights applied to the basis functions. This reduces the problem from one with $|S|$-dimensions to one with $|k|$-dimensions. The questions are (1) how do you determine what class of functions (determined by ϕ) to choose and (2) how to find the best approximate value function within the chosen class (i.e., the best values for r). The first question is still very much wide open.

Answers to the second question fall into two main camps. On the one hand, there are a number of methods that seek to iteratively improve the approximation through the simulation of sample paths of the decision process. The second method uses linear programming but restricts the value function to the approximate form. This reduces the number of variables in the primal to a reasonable number (equal to the number of basis functions chosen). One can then determine the optimal set of weights, r, through column generation. One of the major challenges facing approximate dynamic programming is that it is difficult to determine how close the approximate value function is to its true value. In other words, how much more reward might have been accumulated had the original MDP been solved directly? Though there are some attempts in the literature to answer this question, it remains a significant challenge.

Synonyms

PAC-MDP learning

Definition

An agent acting in a world makes observations, takes actions, and receives rewards for the actions taken. Given a history of such interactions, the agent must make the next choice of action so as to maximize the long-term sum of rewards. To do this well, an agent may take suboptimal actions which allow it to gather the information necessary to later take optimal or near-optimal actions with respect to maximizing the long-term sum of rewards. These information gathering actions are generally considered exploration actions.

Motivation

Since gathering information about the world generally involves taking suboptimal actions compared with a later learned policy, minimizing the number of information gathering actions helps optimize the standard goal in reinforcement learning. In addition, understanding exploration well is key to understanding reinforcement learning well, since exploration is a key aspect of reinforcement learning which is missing from standard supervised learning settings (Fig. 1).

Efficient Exploration in Markov Decision Processes

One simplification of reinforcement learning is the ► Markov decision process setting. In this

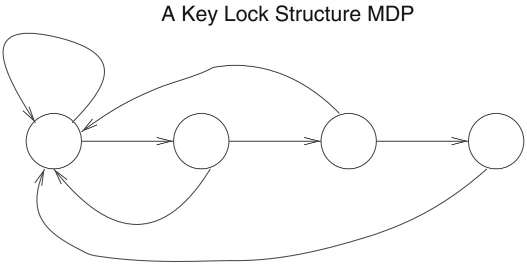
DOI 10.1007/978-1-4899-7687-1



Efficient Exploration in Reinforcement Learning, Fig. 1 An example of a keylock MDP. The state are arranged in a chain. In each state, one of the two actions leads to the next state while the other leads back to the beginning. The only reward is in the transition to the last state in the chain. Keylock MDPs defeat simple greedy strategies, because the probability of randomly reaching the last transition is exponentially small in the length of the chain

setting, an agent repeatedly takes an action a, resulting in a transition to a state according to a conditional probability transition matrix $P(s'|s,a)$, and a (possibly probabilistic) reward $R(s',a,s) \in [0,1]$. The goal is to efficiently output a policy π which is ε-optimal over T timesteps. The value of policy π in a start state s is defined as

$$\eta(\pi, s) = E_{(a,s,r)^T \sim (\pi,P,R)^T} \sum_{t=1}^{T} r_t,$$

which should be read as the expectation over T-length sequences drawn from the interaction of the policy π with the world as represented by P and R. An ε-optimal policy π therefore satisfies:

$$\max_{\pi'} \eta(\pi', s) - \eta(\pi, s) \leq \varepsilon.$$

There are several notable results in this setting, typically expressed in terms of the dependence on the number of actions A, and the number of states S. The first is for the β-greedy strategy commonly applied when using ▶ Q-learning (Watkins and Dayan 1992) which explores randomly with probability β.

Theorem 1 *There exists MDPs such that with probability at least* $1/2$, *β-greedy requires* $\Theta(A^S)$ *explorations to find an ε-optimal policy.*

This is essentially a negative result, saying that a greedy exploration strategy cannot quickly discover a good policy in some settings. The proof uses an MDP with a key-lock like structure where for each state all actions but one take the agent back to the beginning state, and the reward is at the end of a chain of states.

It turns out that there exists algorithms capable of finding a near-optimal policy in an MDP with only a polynomial number of exploratory transitions.

Theorem 2 *For all MDPs, for any* $\delta > 0$, with probability $1-\delta$, the algorithm Explicit-Explore-or-Exploit finds an *ε-optimal policy after* $\tilde{O}(S^2A)$ *explorations.*

In other words, E^3 (Kearns and Singh 1998) requires exploration steps at most proportional to the size of the probability table driving the dynamics of the agent's world. The algorithm works in precisely the manner which might be expected: it builds a model of the world based on its observations and solves the model to determine whether to explore or exploit. The basic approach was generalized to stochastic games and reformulated as an "optimistic initialization" style algorithm named R-MAX (Brafman and Tennenholtz 2002).

It turns out that an even better dependence is possible using the delayed Q-learning (Strehl et al. 2006) algorithm.

Theorem 3 *For all MDPs, for any* $\delta > 0$, with probability $1-\delta$, the algorithm delayed Q-learning finds an *ε-optimal policy after* $\tilde{O}(SA)$ *explorations.*

The delayed Q-learning algorithm requires explorations proportional to the size of the solution policy rather than proportional to the size of world dynamics. At a high level, delayed Q-learning operates by keeping values for exploration and exploitation of observed state-actions, uses these values to decide between exploration and exploitation, and carefully updates these values. Delayed Q-learning does not obsolete E^3, because the (nonvisible) dependence on ε and T are worse (Strehl 2007).

This is a best possible result in terms of the dependence on S and A (up to log factors), as the following theorem (Kakade 2003) states:

Theorem 4 *For all algorithms, there exists an MDP such that with $\Omega(SA)$ explorations are required to find an ε optimal policy with probability at least $\frac{1}{2}$.*

Since even representing a policy requires a lookup table of size SA, this algorithm-independent lower bound is relatively unsurprising.

Variations on MDP Learning

There are several minor variations in the setting and goal definitions which do not qualitatively impact the set of provable results. For example, if rewards are in a bounded range, they can be offset and rescaled to the interval [0, 1].

It's also common to use a soft horizon (or discounting) where the policy evaluation is changed to:

$$\eta_\gamma(\pi, s) = E_{(a,s,r)^\infty \sim (\pi,P,R)^\infty} \sum_{t=1}^{\infty} \gamma^t r_t$$

for some value $\gamma < 1$. This setting is not precisely equivalent to the hard horizon, but since

$$sum^{\infty}_{t=(1n(1/\epsilon)+1n(1/1-\gamma))/1-\gamma} \gamma^t r_t \leq \varepsilon$$

similar results are provable with $1/(1-\gamma)$ taking the role of T and slightly altered algorithms.

One last variation changes the goal. Instead of outputting an ε-optimal policy for the next T timesteps, we could have an algorithm to handle both the exploration and exploitation, then retrospectively go back over a trace of experience and mark a subset of the actions as "exploration actions," with a guarantee that the remainder of the actions are according to an ε-optimal policy (Kakade 2003). Again, minor alterations to known algorithms in the above setting appear to work here.

Alternative Settings

There are several known analyzed variants of the basic setting formed by making additional assumptions about the world. This includes Factored MDPs (Kearns and Koller 1999), Metric MDPs (Kakade et al. 2003), Continuous MDPs (Brunskill et al. 2008), MDPs with a Bayesian prior (Poupart et al. 2006), and apprenticeship learning where there is access to a teacher for an MDP (Abbeel and Ng 2005). The structure of these results are all similar at a high level: with some additional information, it is possible to greatly ease the difficulty of exploration allowing tractable application to much larger problems.

Emerging Patterns

Definition

Emerging pattern mining is an area of ▸ supervised descriptive rule induction. Emerging patterns are defined as itemsets whose support increases significantly from one data set to another (Dong 1999). Emerging patterns are said to capture emerging trends in time-stamped databases, or to capture differentiating characteristics between classes of data.

Empirical Risk Minimization

Xinhua Zhang
NICTA, Australian National University, Canberra, ACT, Australia
School of Computer Science, Australian National University, Canberra, ACT, Australia
NICTA London Circuit, Canberra, ACT, Australia

Definition

The goal of learning is usually to find a model which delivers good generalization performance over an underlying distribution of the data. Consider an input space $\mathcal{X}$ and output space $\mathcal{Y}$. Assume the pairs $(X \times Y) \in \mathcal{X} \times \mathcal{Y}$ are random variables whose (unknown) joint distribution is P_{XY}. It is our goal to find a predictor $f : \mathcal{X} \mapsto \mathcal{Y}$ which minimizes the expected risk:

$$P(f(X) \neq Y) = \mathsf{E}_{(X,Y)\sim P_{XY}} \left[\delta(f(X) \neq Y)\right],$$

where $\delta(z) = 1$ if z is true, and 0 otherwise.

However, in practice we only have n pairs of training examples (X_i, Y_i) drawn identically and independently from P_{XY}. Since P_{XY} is unknown, we often use the risk on the training set (called empirical risk) as a surrogate of the expected risk on the underlying distribution:

$$\frac{1}{n}\sum_{i=1}^{n} \delta(f(X_i) \neq Y_i).$$

Empirical Risk Minimization (ERM) refers to the idea of choosing a function f by minimizing the empirical risk. Although it is often effective and efficient, ERM is subject to ▶ overfitting, i.e. finding a model which fits the training data well but predicts poorly on unseen data. Therefore, ▶ regularization is often required.

More details about ERM can be found in Vapnik (1998).

Ensemble Learning

Gavin Brown
The University of Manchester, Manchester, UK

Synonyms

Committee machines; Multiple classifier systems

Definition

Ensemble learning refers to the procedures employed to train multiple learning machines and combine their outputs, treating them as a "committee" of decision makers. The principle is that the decision of the committee, with individual predictions combined appropriately, should have better overall ▶ accuracy, on average, than any individual committee member. Numerous empirical and theoretical studies have demonstrated that ensemble models very often attain higher accuracy than single models.

The members of the ensemble might be predicting real-valued numbers, class labels, posterior probabilities, rankings, clusterings, or any other quantity. Therefore, their decisions can be combined by many methods, including averaging, voting, and probabilistic methods. The majority of ensemble learning methods are generic, applicable across broad classes of model types and learning tasks.

Motivation and Background

If we could build the "perfect" machine learning device, one which would give us the best possible answer every time, there would be no need for *ensemble learning* methods – indeed, there would be no need for this encyclopedia either. The underlying principle of ensemble learning is a recognition that in real-world situations, every model has limitations and will make errors. Given that each model has these "limitations," the aim of ensemble learning is to manage their strengths and weaknesses, leading to the best possible decision being taken overall. Several theoretical and empirical results have shown that the accuracy of an ensemble can significantly exceed that of a single model.

The principle of combining predictions has been of interest to several fields over many years. Over 200 years ago, a controversial question had arisen, on how best to estimate the mean of a probability distribution given a small number of sample observations. Laplace (1818) demonstrated that the sample mean was not always optimal: under a simple condition, the sample median was a better combined predictor of the population mean. The financial forecasting community has analyzed model combination for several decades, in the context of stock portfolios. The contribution of the machine learning (ML) community emerged in the 1990s – automatic construction (from data) of both the models and the method to combine them. While the majority of the ML literature on this topic is from 1990 onward, the principle has been explored briefly by several independent authors since the 1960s. See Kuncheva (2004b) for historical accounts.

The study of ensemble methods, with model outputs considered for their abstract properties rather than the specifics of the algorithm which produced them, allows for a wide impact across many fields of study. If we can understand precisely why, when, and how particular ensemble methods can be applied successfully, we would have made progress toward a powerful new tool for Machine Learning: *the ability to automatically exploit the strengths and weaknesses of different learning systems.*

Methods and Algorithms

An ensemble consists of a set of models and a method to combine them. We begin this section by assuming that we have a set of models, generated by any of the learning algorithms in this encyclopedia; we explore popular methods of combining their outputs, for classification and regression problems. Following this, we review some of the most popular ensemble algorithms, for *learning* a set of models given the knowledge that they will be combined, including extensive pointers for further reading. Finally, we take a theoretical perspective, and review the concept of ensemble *diversity*, the fundamental property which governs how well an ensemble can perform.

Methods for Combining a Set of Models

There exist numerous methods for model combination, far too many to fully detail here. The *linear* combiner, the *product* combiner, and the *voting* combiner are by far the most commonly used in practice. Though a combiner could be specifically chosen to optimize performance in a particular application, these three rules have shown consistently good behavior across many problems, and are simple enough that they are amenable to theoretical analysis.

The linear combiner is used for models that output real-valued numbers, so is applicable for ▸ regression ensembles, or for ▸ classification ensembles producing class probability estimates. Here, notation for the latter case is only shown. We have a model $f_t(y|\mathbf{x})$, an estimate of the probability of class y given input $\mathbf{x}$. For a set of these, $t = \{1, \ldots, \mathrm{T}\}$, the ensemble probability estimate is,

$$\bar{f}(y|\mathbf{x}) = \sum_{t=1}^{T} w_t f_t(y|\mathbf{x}). \tag{1}$$

If the weights $w_t = 1/T, \forall t$, this is a simple uniform averaging of the probability estimates. The notation clearly allows for the possibility of a nonuniformly weighted average. If the classifiers have different accuracies on the data, a nonuniform combination could *in theory* give a lower error than a uniform combination. However, in practice, the difficulty of estimating the $\mathbf{w}$ parameters without overfitting, and the relatively small gain that is available (see Kuncheva 2004b, p. 282), have meant that in practice the uniformly weighted average is by far the most commonly used. A notable exception, to be discussed later in this article, is the *mixture of experts* paradigm – in MoE, weights are nonuniform, but are learnt and dependent on the input value $\mathbf{x}$. An alternative combiner is the *product rule*:

$$\bar{f}(y|\mathbf{x}) = \frac{1}{Z} \prod_{t=1}^{T} f_t(y|\mathbf{x})^{wt}, \tag{2}$$

where Z is a normalization factor to ensure $\bar{f}$ is a valid distribution. Note that Z is not *required* to make a valid decision, as the order of posterior estimates remain unchanged before/after normalization. Under the assumption that the class-conditional probability estimates are independent, this is the theoretically optimal combination strategy. However, this assumption is highly unlikely to hold in practice, and again the weights $\mathbf{w}$ are difficult to reliably determine. Interestingly, the linear and product combiners are in fact special cases of the *generalized mean* (Kuncheva 2004b) allowing for a continuum of possible combining strategies.

The linear and product combiners are applicable when our models output real-valued numbers. When the models instead output class labels, a majority (or plurality) vote can be used. Here, each classifier votes for a particular class, and the class with the most votes is chosen as the ensemble output. For a two-class problem the models produce labels, $h_t(\mathbf{x}) \in \{-1, +1\}$. In this case, the ensemble output for the *voting* combiner can be written as

$$H(\mathbf{x}) = sign\left(\sum_{t=1}^{T} w_t h_t(x)\right). \tag{3}$$

The weights $\mathbf{w}$ can be uniform for a simple majority vote, or nonuniform for a weighted vote.

We have discussed only a small fraction of the possible combiner rules. Numerous other rules exist, including methods for combining rankings of classes, and unsupervised methods to combine clustering results. For details of the wider literature, see Kuncheva (2004b) or Polikar (2006).

Algorithms for Learning a Set of Models

If we had a committee of *people* taking decisions, it is self-evident that we would not want them all to make the same bad judgments *at the same time*. With a committee of learning models, the same intuition applies: we will have no gain from combining a set of identical models. We wish the models to exhibit a certain element of "diversity" in their group behavior, though still retaining good performance individually.

We therefore make a distinction between two types of ensemble learning algorithms, those which encourage diversity *implicitly*, and those which encourage it *explicitly*. The vast majority of ensemble methods are *implicit*, in that they provide different *random subsets* of the training data to each learner. Diversity is encouraged "implicitly" by *random* sampling of the data space: at no point is a *measurement* taken to ensure diversity will emerge. The random differences between the datasets might be in the selection of examples (the ▶ Bagging algorithm), the selection of features (▶ Random Subspace Method, Ho (1998) or ▶ Rotation Forests, Rodriguez et al. 2006), or combinations of the two (the Random Forests algorithm, Breiman 2001). Many other "randomization" schemes are of course possible.

An alternative is to *explicitly* encourage diversity, constructing each ensemble member with some measurement ensuring that it is substantially different from the other members. ▶ Boosting algorithms achieve this by altering the distribution of training examples for each learner such that it is encouraged to make more accurate predictions where previous predictors have made errors. The DECORATE algorithm (Melville and Mooney 2005) explicitly alters the distribution of class labels, such that successive models are forced to learn different answers to the same problem. ▶ Negative correlation learning (see Brown 2004; Brown et al. 2005), includes a penalty term when learning each ensemble member, explicitly *managing* the accuracy-diversity trade-off.

In general, ensemble methods constitute a large class of algorithms – some based on heuristics, and some on sound learning-theoretic principles. The three algorithms that have received the most attention in the literature are reviewed here. It should be noted that we present only the most basic form of each; numerous modifications have been proposed for a variety of learning scenarios. As further study the reader is referred to the many comprehensive surveys of the field (Brown et al. 2005; Kuncheva 2004b; Polikar 2006).

Bagging

In the Bagging algorithm (Breiman 1996) each member of the ensemble is constructed from a different training dataset, and the predictions combined either by uniform averaging or voting over class labels. Each dataset is generated by sampling from the total N data examples, choosing N items uniformly at random *with replacement*. Each sample is known as a *bootstrap*; the name Bagging is an acronym derived from *B*ootstrap *AGG*regat*ING*. Since a bootstrap samples N items uniformly at random with replacement, the probability of any individual data item *not* being selected is $p = (1 - 1/N)^N$. Therefore with large N, a single bootstrap is expected to contain approximately 63. 2 % of the original set, while 36. 8 % of the originals are not selected.

Like many ensemble methods, Bagging works best with *unstable* models, that is those that produce differing generalization behavior with small changes to the training data. These are also known as *high variance* models, examples of which are ▶ decision trees and ▶ neural networks. Bagging therefore tends not to work well with very simple models. In effect, Bagging samples randomly from the space of possible models to make up the ensemble – with very simple models the sampling produces almost identical (low diversity) predictions.

Despite its apparent capability for variance reduction, situations have been demonstrated where

Algorithm 1 Bagging

```
Input: Required ensemble size $T$
Input: Training set $S = \{(x_1, y_1), (x_2, y_2), \ldots (x_N, y_N)\}$
for $t = 1$ to $T$ do
    Build a dataset $S_t$, by sampling $N$ items, randomly with replacement from $S$.
    Train a model $h_t$ using $S_t$, and add it to the ensemble
end for
For a new testing point $(x', y')$,
If model outputs are continuous, combine them by voting.
```

Algorithm 2 Adaboost

```
Input: Required ensemble size $T$
Input: Training set $S = \{(x_1, y_1), (x_2, y_2), \ldots, (x_N, y_N)\}$, where $y_j \in \{-1, +1\}$
Define a uniform distribution $D_1(i)$ over elements of $S$.
for $t = 1$ to $T$ do
    Train a model $h_t$ using distribution $D_t$.
    Calculate $e_t = P_{D_t}(h_t(x) \neq y)$
    If $\epsilon_t \geq 0.5$ break
    Set $\alpha_t = \frac{1}{2} \ln \left( \frac{1-\epsilon_t}{\epsilon_t} \right)$
    Update $D_{t+1}(i) = \frac{D_t(i) \exp(-\alpha_t y_i h_t(x_i))}{Z_t}$
where $Z_t$ is a normalization factor so that $D_{t+1}$ is a valid distribution.
end for
For a new testing point $(x', y')$ ,
$H(x') = \text{sign}(\Sigma_{t=1}^{T} \alpha_t h_t(x'))$
```

Bagging can converge *without* affecting variance (see Brown et al. 2005). Several other explanations have been proposed for Bagging's success, including links to Bayesian model averaging. In summary, it seems that several years from its introduction, despite its apparent simplicity, Bagging is still not fully understood.

Adaboost

Adaboost (Freund and Schapire 1996) is the most well known of the *Boosting* family of algorithms (Schapire 2003). The algorithm trains models sequentially, with a new model trained at each round. At the end of each round, mis-classified examples are identified and have their emphasis increased in a new training set which is then fed back into the start of the next round, and a new model is trained. The idea is that subsequent models should be able to compensate for errors made by earlier models.

Adaboost occupies somewhat of a special place in the history of ensemble methods. Though the procedure seems heuristic, the algorithm is in fact grounded in a rich learning-theoretic body of literature. (Schapire 1990) addressed a question posed by Kearns and Valiant (1988) on the nature of two complexity classes of learning problems. The two classes are *strongly learnable* and *weakly learnable* problems. Schapire showed that these classes were equivalent; this had the corollary that a weak model, performing only slightly better than random guessing, could be "boosted" into an arbitrarily accurate *strong* model. The original Boosting algorithm was a proof by construction of this equivalence, though had a number of impractical assumptions built-in. The Adaboost algorithm (Freund and Schapire 1996) was the first practical Boosting method. The authoritative historical account of the development can be found in Schapire (1999), including discussion of numerous variants and interpretations of the algorithm. The procedure is shown in Algorithm 2. Some similarities with Bagging are evident; a key differences is that at each round t, Bagging has a uniform distribution D_t, while Adaboost adapts a nonuniform distribution.

The ensemble is constructed by iteratively adding models. Each time a model is learnt, it is checked to ensure it has at least $\varepsilon_t < 0.5$, that is, it has performance *better than random guessing* on the data it was supplied with. If it does not, either an alternative model is constructed, or the loop is terminated.

After each round, the distribution D_t is updated to emphasize incorrectly classified examples. The update causes half the distribution mass of D_{t+1} to be over the examples incorrectly classified by the previous model. More precisely, $\sum_{h_t(x_1) \neq y_i} D_{t+1}(i) = 0.5$. Thus, if h_t has an error rate of 10 %, then examples from that small 10 % will be allocated 50 % of the next model's training "effort," while the remaining examples (those correctly classified) are underemphasized. An equivalent (and simpler) writing of the distribution update scheme is to multiply $D_t(i)$ by $1/2(1 - \varepsilon_t)$ if $h_t(x_i)$ is correct, and by $1/2\varepsilon_t$ otherwise.

The updates cause the models to sequentially minimize an exponential bound on the error rate. The training error rate on a data sample $\mathcal{S}$ drawn from the true distribution $\mathcal{D}$ obeys the bound,

$$P_{x,y\sim\mathcal{S}}(yH(x) < 0) \le \prod_{t=1}^{T} 2\sqrt{\varepsilon_t(1-\varepsilon_t)}. \quad (4)$$

This *upper bound* on the training error (though not the *actual* training error) is guaranteed to decrease monotonically with T, given $\varepsilon_t < 0.5$.

In an attempt to further explain the performance of Boosting algorithms, Schapire also developed bounds on the *generalization* error of voting systems, in terms of the voting margin, the definition of which was given in (10). Note that, this is not the same as the *geometric margin*, optimized by ▸ support vector machines. The difference is that the voting margin is defined using the one-norm $||\mathbf{w}||_1$ in the denominator, while the geometric margin uses the *two*-norm $||\mathbf{w}||_2$. While this is a subtle difference, it is an important one, forming links between SVMs and Boosting algorithms – see Rätsch et al. (2002) for details. The following bound holds with probability $1-\delta$,

$$Px, y \sim \mathcal{D}(H(x) \neq y)$$
$$\le P_{x,y\sim\mathcal{S}}(yH(x) < \theta) + \tilde{O}\left(\sqrt{\frac{d}{N\theta^2} - ln\delta}\right), \quad (5)$$

where the $\tilde{O}$ notation hides constants and logarithmic terms, and d is the ▸ VC-dimension of the model used. Roughly, this states that the generalization error is less than or equal to the training error plus a term dependent on the voting margin. The larger the minimum margin in the training data, the lower the testing error. The original bounds have since been significantly improved, see Koltchinskii and Panchenko (2005) as a comprehensive recent work. We note that this bound holds generally for *any* voting system, and is not specific to the Boosting framework.

The margin-based theory is only one explanation of the success of Boosting algorithms. Mease and Wyner (2008) present a discussion of several questions on why and how Adaboost succeeds. The subsequent 70 pages of discussion demonstrate that the story is by no means simple. The conclusion is, while no single theory can fully explain Boosting, each provides a different part of the still unfolding story.

Mixtures of Experts

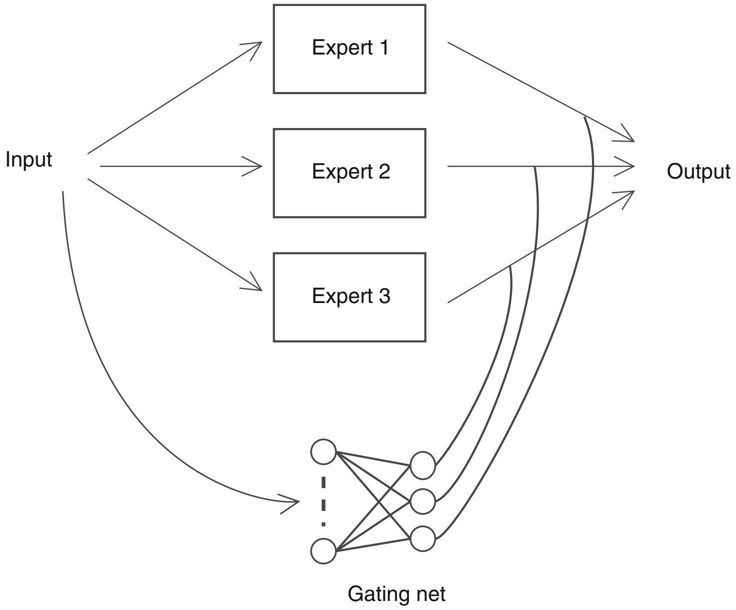
The mixtures of experts architecture is a widely investigated paradigm for creating a combination of models (Jacobs et al. 1991). The principle underlying the architecture is that certain models will be able to "specialize" to particular parts of the input space. It is commonly implemented with a neural network as the base model, or some other model capable of estimating probabilities. A *Gating network* receives the same inputs as the component models, but its outputs are used as the weights for a linear combiner. The Gating network is responsible for learning the appropriate weighted combination of the specialized models ("experts") for any given input. Thus, the input space is "carved-up" between the experts, increasing and decreasing their weights for particular examples. In effect, a mixture of experts explicitly learns how to create expert ensemble members in different portions of the input space, and select the most appropriate subset for a new testing example (Fig. 1).

The architecture has received wide attention, and has a strong following in the probabilistic modeling community, where it may go under the pseudonym of a "mixture model." A common training method is the ▸ expectation-maximization algorithm.

Theoretical Perspectives: Ensemble Diversity

We have seen that all ensemble algorithms in some way attempt to encourage "diversity." In

Ensemble Learning, Fig. 1 The mixtures of experts architecture



this section, we take a more formalized perspective, to understand what is meant by this term.

What Is Diversity?

The optimal "diversity" is fundamentally a *credit assignment* problem. If the committee as a whole makes an erroneous prediction, how much of this error should be attributed to each member? More precisely, how much of the committee prediction is due to the accuracies of the individual models, and how much is due to their interactions when they were combined? We would ideally like to reexpress the ensemble error as two distinct components: a term for the accuracies of the individual models, plus a term for their interactions, i.e., their *diversity*.

It turns out that this so-called *accuracy-diversity* breakdown of the ensemble error is not always possible, depending on the type of error function, and choice of combiner rule. It should be noted that when "diversity" is referred to in the literature, it is most often meant to indicate classification with a majority vote combiner, but for completeness we address the general case here. In the following sections, the existing work to understand diversity in three distinct cases is described: for regression tasks (a linear combiner), and classification tasks, with either a linear combiner or a voting combiner.

Regression Error with a Linear Combination Rule

In a regression problem, it is common to use the squared error criterion. The accuracy-diversity breakdown for this case (using a linear combiner) is called the *ambiguity decomposition* (Krogh and Vedelsby 1995). The result states that the squared error of the linearly combined ensemble, $\bar{f}(\mathbf{x})$, can be broken into a sum of two components:

$$(\bar{f}(\mathbf{x}) - d)^2 = \frac{1}{T}\sum_{t=1}^{T}(f_t(\mathbf{x}) - d)^2 - \frac{1}{T}\sum_{t=1}^{T}(f_t(\mathbf{x}) - \bar{f}(\mathbf{x}))^2. \quad (6)$$

The first term on the right hand side is the average squared error of the individual models, while the second term quantifies the interactions *between* the predictions. Note that this second term, the "ambiguity," is always positive. This guarantees that, for an arbitrary data point, the ensemble squared error is always less than or equal to the average of the individual squared errors.

The intuition here can be understood as follows. Imagine five friends, playing "guess the weight of the cake" (an old English fairground game): if a player's guess is close enough to the true weight, they win the cake. Just as they are about to play, the fairground manager states that they can only submit *one* guess. The dilemma seems to be in whose guess they should submit – however, the ambiguity decomposition shows us that taking the average of their guesses, and submitting that, will *always* be closer (on average) than choosing a person at random and submitting their guess. Note that this is qualified with "on average" – it may well be that one of the predictions will in fact be closer than the average prediction, but we presume that we have no way of identifying *which* prediction to choose, other than random. It can be seen that greater diversity in the predictions (i.e., a larger ambiguity term) results in a larger gain over the average individual performance. However, it is also clear that there is a trade-off to be had: too much diversity and the average error is extremely large.

The idea of a trade-off between these two terms is reminiscent of the ▸ bias-variance decomposition (Geman et al. 1992); in fact, there is a deep connection between these results. Taking the expected value of (6) over all possible training sets gives us the ensemble analogy to the bias-variance decomposition, called the ▸ bias-variance-covariance decomposition (Ueda and Nakano 1996). This shows that the expected squared error of an ensemble $\bar{f}(\mathbf{x})$ from a target d is:

$$\mathcal{E}_{\mathcal{D}}\{(\bar{f}(\mathbf{x})-d)^2\} = \overline{\text{bias}}^2 + \frac{1}{T}\overline{\text{var}} + \left(1-\frac{1}{T}\right)\overline{\text{covar}}, \qquad (7)$$

where the expectation is with respect to all possible training datasets $\mathcal{D}$. While the bias and variance terms are constrained to be positive, the covariance between models can become negative – thus the definition of diversity emerges as an extra degree of freedom in the bias-variance dilemma. This extra degree of freedom allows an ensemble to approximate functions that are difficult (if not impossible) to find with a single model. See Brown et al. (2005) for extensive further discussion of this concept.

Classification Error with a Linear Combination Rule

In a classification problem, our error criterion is the misclassification rate, also known as the *zero-one* loss function. For this type of loss, it is well known there is no unique definition of bias-variance; instead there exist multiple decompositions each with advantages and disadvantages (see Kuncheva 2004b, p. 224). This gives us a clue as to the situation with an ensemble – there is also no simple accuracy-diversity separation of the ensemble classification error. Classification problems can of course be addressed either by a model producing class probabilities (where we linearly combine), or directly producing class labels (where we use majority vote). Partial theory has been developed for each case.

For linear combiners, there exist theoretical results that relate the correlation of the probability estimates to the ensemble classification error. Tumer and Ghosh (1996) showed that the reducible classification error (i.e., above the Bayes rate) of a simple averaging ensemble, e_{ave}, can be written as

$$e_{\text{ave}} = e_{\text{add}}\left(\frac{1+\delta(T-1)}{T}\right), \qquad (8)$$

where e_{add} is the classification error of an individual model. The δ is a correlation coefficient between the model outputs. When the individual models are identical, the correlation is $\delta = 1$. In this case, the ensemble error is equal to the individual error, $e_{\text{ave}} = e_{\text{add}}$. When the models are statistically independent, $\delta = 0$, and the ensemble error is a fraction $1/T$ of the individual error, $e_{\text{ave}} = 1/T \times \text{e}_{\text{add}}$. When δ is negative, the models are negatively correlated, and the ensemble error is lower than the average individual error. However, (8) is derived under quite strict assumptions, holding only for a local area around the decision boundary, and ultimately resting on the bias-variance-covariance theory from regression problems. Further details, including recent work to lift some of the assumptions (Kuncheva 2004b).

Classification Error with a Voting Combination Rule

The case of a classification problem with a majority vote combiner is the most challenging of all. In general, there is no known breakdown of the ensemble classification error into neat accuracy and diversity components. The simplest intuition to show that correlation between models does affect performance is given by the Binomial theorem. If we have T models each with identical error probability $p = P(h_t(\mathbf{x}) \neq y)$, assuming they make statistically *independent* errors, the following error probability of the majority voting committee holds,

$$P(H(x) \neq y) = \sum_{k>T/2}^{T} \binom{T}{k} p^k (1-p)^{T-k}. \tag{9}$$

For example, in the case of $T = 21$ ensemble members, each with error $p = 0.3$, the majority voting error will be $0.\,026$, an order of magnitude improvement over the individual error. However, this *only* holds for statistically independent errors. The correlated case is an open problem. Instead, various authors have proposed their own heuristic definitions of diversity in majority voting ensembles. Kuncheva (2004b) conducted extensive studies of several suggested diversity measures; the conclusion was that "*no measure consistently correlates well with the majority vote accuracy.*" In spite of this, some were found useful as an approximate guide to characterize performance of ensemble methods, though should not be relied upon as the "final word" on diversity. Kuncheva's recommendation in this case is the *Q-statistic* (Kuncheva 2004b, p. 299), due to its simplicity and ease of computation.

Breiman (2001) took an alternative approach, deriving not a *separation* of error components, but a *bound* on the generalization error of a voting ensemble, expressed in terms of the correlations of the models. To understand this, we must introduce concept of *voting margin*. The voting margin for a two-class problem, with $y \in \{-1, +1\}$, is defined,

$$m = \frac{y_t \sum_{t=1}^{T} w_t h_t(\mathbf{x})}{\sum_{t=1}^{T} |w_t|} = yH(\mathbf{x}). \tag{10}$$

If the margin is positive, the example is correctly classified, if it is negative, the example is incorrectly classified. The expected margin $s = \mathcal{E}_{\mathcal{D}}\{m\}$ measures the extent to which the average number of votes for the correct class exceeds the average vote for any other class, with respect to the data distribution $\mathcal{D}$. The larger the voting margin, the more confidence in the classification. Breiman's bound shows,

$$P_{\mathcal{D}}(H(\mathbf{x}) \neq y) = P_{\mathcal{D}}(yH(\mathbf{x}) < 0) \neq \frac{\bar{\rho}(1-s^2)}{s^2}. \tag{11}$$

Here $\bar{\rho}$ is the average pairwise correlation between the errors of the individual models. Thus, the generalization error is minimized by a small $\bar{\rho}$, and an s as close to 1 as possible. The balance between a high accuracy (large s) and a high diversity (low $\bar{\rho}$) constitutes the tradeoff in this case, although the bound is quite loose.

Summary

In summary, the definition of diversity depends on the problem. In a regression problem, the optimal diversity is the trade-off between the bias, variance and covariance components of the squared error. In a classification problem, with a linear combiner, there exists partial theory to relate the classifier correlations to the ensemble error rate. In a classification problem with a voting combiner, there is no single theoretical framework or definition of diversity. However, the lack of an agreed definition of diversity has not discouraged researchers from trying to achieve it, nor has it stalled the progress of effective algorithms in the field.

Conclusions and Current Directions in the Field

Ensemble methods constitute some of the most robust and accurate learning algorithms of the past decade (Caruana and Niculescu-Mizil 2006). A multitude of heuristics have been developed for randomizing the ensemble parameters, to generate diverse models. It is arguable that this line of investigation is nowadays rather oversubscribed, and the more interesting research is now in methods for nonstandard data. ▶ Cluster ensembles (Strehl and Ghosh 2003) are ensemble techniques applied to unsupervised learning problems. Problems with *nonstationary* data, also known as *concept drift*, are receiving much recent attention (Kuncheva 2004a). The most up to date innovations are to be found in the biennial *International Workshop on Multiple Classifier Systems* (Roli et al. 2000).

Entailment

Synonyms

Implication; Logical consequence

Definition

The term entailment is used in the context of logical reasoning. Formally, a logical formula T entails a formula c if and only if all models of T are also a model of c. This is usually denoted as $T \models c$ and means that c is a logical consequence of T or that c is implied by T.

Let us elaborate this definition for propositional clausal logic, where the formulae T could be the following expression:

```
flies :- bird, normal.
bird :- blackbird.
bird :- ostrich.
```

Here, the first clause or rule can be read as flies *if* normal *and* bird, that is, normal birds fly, the second and third one as stating that blackbirds, resp. ostriches, are birds. An interpretation is then an assignment of truth-values to the propositional variables. For instance, for the above domain

```
{ostrich, bird}
{blackbird, bird, normal}
```

are interpretations, specified through the set of propositional variables that are true. This means that in the first interpretation, the only true propositions are `ostrich` and `bird`. An interpretation specifies a kind of possible world. An interpretation I is then a model for a clause $h : -b_1, \dots b_n$ if and only if $\{b_1, \dots, b_n\} \subseteq I \rightarrow h \in I$ and it is model for a clausal theory if and only if it is a model for all clauses in the theory. Therefore, the first interpretation above is a model for the theory, but the second one is not because the interpretation is not a model for the first clause (as $\{$`bird, normal`$\} \subseteq I$ but `flies` $\notin I$). Using these notions, it can now be verified that the clausal theory T above logically entails the clause

```
flies :- ostrich, normal.
```

because all models of the theory are also a model for this clause.

In machine learning, the notion of entailment is used as a covers relation in ▸ inductive logic programming, where hypotheses are clausal theories, instances are clauses, and an example is covered by the hypothesis when it is entailed by the hypothesis.

Entity Resolution

Indrajit Bhattacharya[1] and Lise Getoor[2]
[1]IBM India Research Laboratory, New Delhi, India
[2]University of Maryland, College Park, MD, USA

Abstract

References to real-world entities are often ambiguous, more commonly across data sources but frequently within a single data source as well. Ambiguities occur due to multiple reasons, such as incorrect data entry, or multiple possible representations of the entities. Given such a collection of ambiguous entity references, the goal of entity resolution

is to discover the unique set of underlying entities, and map each reference to its corresponding entity. Resolving such entity ambiguities is necessary for removing redundancy and also for accurate entity-level analysis. This is a common problem that comes up in many different applications and has been studied in different branches of computer science. As evidences for entity resolution, traditional approaches consider pair-wise similarity between references, and many sophisticated similarity measures have been proposed to compare attributes of references. The simplest solution classifies reference pairs with similarity above a threshold as referring to the same entity. More sophisticated solutions use a probabilistic framework for reasoning with the pair-wise probabilities. Recently proposed relational approaches for entity resolution make use of relationships between references when available as additional evidences. Instead of reasoning independently for each pair of references, these approaches reason collectively over related pair-wise decisions over references. One line of work within the relational family uses supervised or unsupervised probabilistic learning using probabilistic graphical models, while another uses more scalable greedy techniques for merging references in a hyper-graph. Beyond improving entity resolution accuracy, such relational approaches yield additional knowledge in the form of relationships between the underlying entities.

Synonyms

Co-reference resolution; Deduplication; Duplicate detection; Identity uncertainty; Merge-purge; Object consolidation; Record linkage; Reference reconciliation

Definition

A fundamental problem in data cleaning and integration (see ▶ Data Preparation) is dealing with uncertain and imprecise references to real-world entities. The goal of entity resolution is to take a collection of uncertain entity references (or references, in short) from a single data source or multiple data sources, discover the unique set of underlying entities, and map each reference to its corresponding entity. This typically involves two subproblems – identification of references with different attributes to the same entity and disambiguation of references with identical attributes by assigning them to different entities.

Motivation and Background

Entity resolution is a common problem that comes up in different guises (and is given different names) in many computer science domains. Examples include computer vision, where we need to figure out when regions in two different images refer to the same underlying object (the correspondence problem), natural language processing when we would like to determine which noun phrases refer to the same underlying entity (co-reference resolution), and databases, where, when merging two databases or cleaning a database, we would like to determine when two tuple records are referring to the same real-world object (deduplication and data integration). Deduplication is important for removing redundancy and for accurate analysis. In information integration, determining approximate joins is important for consolidating information from multiple sources; most often there will not be a unique key that can be used to join tables across databases.

Such ambiguities in entity references can occur due to multiple reasons. Often times, data may have data entry errors, such as typographical errors. Multiple representations, such as abbreviations, are also possible. Different databases typically have different keys – one person database may use social security numbers, while another uses name and address.

Traditional entity resolution approaches focus on matching attributes of different references for resolving entities. However, many data sources have explicit or implicit relationships present among the entity references. These relations are indicative of relationships between the underlying entities themselves. For example, person records in census data are linked by family relationships such as sibling, parent, and spouse. Researchers collaborate mostly within their organization, or their research community, as a result of which references to related researchers tend to occur closely together. Recent entity resolution approaches in statistical relational learning make use of relationships between references to improve entity resolution accuracy and additionally to discover relationships between the underlying entities.

Theory/Solution

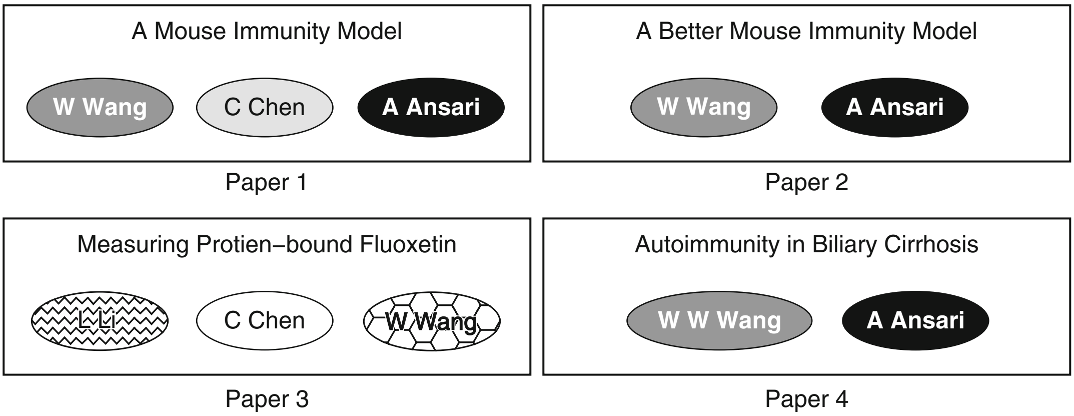
As an illustration of the entity resolution problem, consider the task of resolving the author references in a database of academic publications similar to DBLP, CiteSeer, or PubMed. Let us take as an example the following set of four papers:

1. W. Wang, C. Chen, and A. Ansari, "A mouse immunity model"
2. W. Wang and A. Ansari, "A better mouse immunity model"
3. L. Li, C. Chen, and W. Wang, "Measuring protein-bound fluoxetin"
4. W. W. Wang and A. Ansari, "Autoimmunity in biliary cirrhosis"

Now imagine that we would like to find out, given these four papers, which of these author names refer to the same author entities. This process involves determining whether paper 1 and paper 2 are written by the same author named Wang, or whether they are different authors. We need to answer similar questions about all such similar author names in the database.

In this example, it turns out there are six underlying author entities, which we will call *Wang*1 and *Wang*2, *Chen*1 and *Chen*2, *Ansari*, and *Li*. The three references with the name "A. Ansari" correspond to author $Ansari$ and the reference with name "L. Li" to author *Li*. However, the two references with name "C. Chen" map to two different authors *Chen*1 and *Chen*2. Similarly, the four references with name "W. Wang" or "W. W. Wang" map to two different authors. The "Wang" references from the first, second, and fourth papers correspond to author *Wang*1, while that from the third paper maps to a different author *Wang*2. This inference illustrates the twin problems of *identifying* "W. Wang" and "W. W. Wang" as the same author and *disambiguating* two references with name "W. Wang" as different authors. This is shown pictorially in Fig. 1, where references that correspond to the same authors are shaded identically. In the entity resolution process, all those and only those author references that are shaded identically should be resolved as corresponding to the same underlying entity.

Formally, in the entity resolution problem, we are given a set of references $\mathcal{R} = \{r_i\}$, where each reference r has attributes $r.A_1, r.A_2, \ldots, r.A_k$, such as observed names and affiliations for author references, as in our example above. The references correspond to some set of unknown entities $\mathcal{E} = \{e_i\}$. We introduce the notation $r.E$ to refer to the entity to which reference r corresponds. The goal is to recover the hidden set of entities $\mathcal{E} = \{e_i\}$ and the entity labels $r.E$ for individual references given the observed attributes of the references. In addition to the attributes, in some data sources we have information in the form of relationships between the references, such as coauthor relationships between author references in publication databases. We can capture the relationships with a set of hyper-edges $\mathcal{H} = \{h_i\}$. Each hyper-edge h may have attributes as well to capture the attributes of relationships, which we denote $h.A_1, h.A_2, \ldots, h.A_l$, and we use $h.R$ to denote the set of references that it connects. In our example, each rectangle denotes one hyper-edge corresponding to one paper in the database. The first hyper-edge corresponding to $Paper1$ has as its attribute the title "A mouse immunity model" and connects the three references having name attributes "W. Wang," "C. Chen," and "A. Ansari." A reference r can belong to zero or more hyper-edges, and we use $r.H$ to denote the set of hyper-edges in which r participates. For example, if we have paper, author, and venue references,



Entity Resolution, Fig. 1 The references in different papers in the bibliographic example. References to the same entity are identically shaded

then a paper reference may be connected to multiple author references and also to a venue reference. In general, the underlying references can refer to entities of different types, as in a publication database or in newspaper articles, which contain references to people, places, organizations, etc. When the type information is known for each reference, resolution decisions are restricted within references of the same type. Otherwise, the types may need to be discovered as well as part of the entity resolution process.

Traditional entity resolution approaches pose entity resolution as a pairwise decision problem over references based on their attribute similarity. It can also be posed as a ▶ graph clustering problem, where references are clustered together based on their attribute similarities and each cluster is taken to represent one underlying entity. Entity resolution approaches differ in how the similarities between references are defined and computed and how the resolution decisions are made based on these similarities. Traditionally, each pairwise decision is made independently of the others. For example, the decision to resolve the two *Wang* references from papers 1 and 3 would be made independently of the decision to resolve the two *Chen* references from the same papers.

The first improvement is to account for the similarity of the coauthor names when such relationships are available. However, this still does not consider the "entities" of the related references. For the two "Wang" references in the earlier example, the two "C. Chen" coauthors match regardless of whether they refer to *Chen1* or *Chen2*. The correct evidence to use here is that the "Chens" are not co-referent. In such a setting, in order to resolve the "W. Wang" references, it is necessary to *resolve* the "C Chen" references as well and not just consider their name similarity. In the collective relational entity resolution approach, resolutions are not made independently, but instead one resolution decision affects other resolutions via hyper-edges.

Below, we discuss the different entity resolution approaches in greater detail.

Attribute-Based Entity Resolution

As discussed earlier, exact matching of attributes does not suffice for entity resolution. Several sophisticated similarity measures have been developed for textual strings (Cohen et al. 2003; Chaudhuri et al. 2003) that may be used for unsupervised entity resolution. Finally, a weighted combination of the similarities over the different attributes for each reference is used to compute the attribute similarity between two references. An alternative is to use adaptive supervised algorithms that learn string ▶ similarity metrics from labeled data (Bilenko and Mooney 2003). In the traditional entity resolution approach (Fellegi and Sunter 1969; Cohen et al. 2003), similarity is computed for each pair of references r_i, r_j based on their attributes, and only those pairs that have similarity above some threshold are considered co-referent.

Efficiency

Even the attribute-only approach to entity resolution is known to be a hard problem computationally, since it is infeasible to compare all pairs of references using expensive similarity measures. Therefore, efficiency issues have long been a focus for data cleaning, the goal being the development of inexpensive algorithms for finding approximate solutions. The key mechanisms for doing this involve computing the matches efficiently and employing techniques commonly called "blocking" to quickly find potential duplicates (Hernández and Stolfo 1995; Monge and Elkan 1997), using cheap and index-based similarity computations to rule out non-duplicate pairs. Sampling approaches can quickly compute cosine similarity between tuples for fast text-joins within an SQL framework (Gravano et al. 2003). Error-tolerant indexes can also be used in data warehousing applications to efficiently look up a small but "probabilistically safe" set of reference tuples as candidates for matching for an incoming tuple (Chaudhuri et al. 2003). Generic entity resolution frameworks also exist for resolving and merging duplicates as a database operator and minimize the number of record-level and feature-level operations (Menestrina et al. 2006).

Probabilistic Models for Pairwise Resolution

The groundwork for posing entity resolution as a probabilistic ▸ classification problem was done by Fellegi and Sunter (1969), who studied the problem of labeling pairs of records from two different files to be merged as "match" (M) or "non-match" (U) on the basis of agreement γ among their different fields or attributes. Given an agreement pattern γ, the conditional probabilities $P(\gamma|M)$ and $P(\gamma|U)$ of γ given matches and non-matches are computed and compared to decide whether the two references are duplicates or not. Fellegi and Sunter showed that the probabilities $P(\gamma|M)$ and $P(\gamma|U)$ of field agreements can be estimated without requiring labeled training data if the different field agreements are assumed to be independent. Winkler (2002) used the EM algorithm to estimate the probabilities without making the independence assumption.

Probabilistic Models for Relational Entity Resolution

Probabilistic models that take into account interaction between different entity resolution decisions through hyper-edges have been proposed for named-entity recognition in natural language processing and for citation matching (McCallum and Wellner 2004; Singla and Domingos 2004). Such ▸ relational learning approaches introduce a decision variable y_{ij} for every pair of references r_i and r_j, but instead of inferring the y_{ij}'s independently, use conditional random fields for joint reasoning. For example, the decision variables for the "Wang" references and the "Chen" references in papers 1 and 3 would be connected to each other; features and functions would be defined to ensure that they are more likely to take up identical values.

Such relational models are supervised and require labeled data to train the parameters. One of the difficulties in using a supervised method for resolution is constructing a good training set that includes a representative collection of positive and negative examples. Accordingly, unsupervised relational models have also been developed (Li et al. 2005; Pasula et al. 2003; Bhattacharya and Getoor 2006). Instead of introducing pairwise decision variables, this category of approaches uses generative models for references using latent entity labels. Note that, here, the number of entities is unknown and needs to be discovered automatically from the available references. Relationships between the references, such as co-mentions or co-occurrences, are captured using joint distributions over the entity labels.

All of these probabilistic models have been shown to perform well in practice and have the advantage that the match/non-match decisions do not depend on any user-specified similarity measures and thresholds but are learned directly from data. However, this benefit comes at a price. Inference in relational probabilistic models is an expensive process. Exact inference is mostly intractable and approximate strategies such as loopy belief propagation and Monte Carlo sampling strategies are employed. Even these approximate strategies take several iterations to converge, and extending such approaches to large datasets is still an open problem.

Other Approaches for Relational Entity Resolution

Alternative approaches (Bhattacharya and Getoor 2007; Kalashnikov et al. 2005; Dong et al. 2005) consider relational structure of the entities for data integration but avoid the complexity of probabilistic inference. By avoiding a formal probabilistic model, these approaches can handle complex and longer-range relationships between different entity references, and the resolution process is significantly faster as well. Such approaches also create pairwise decision nodes between references and create a dependency graph over them to capture the relationships in the data. But instead of performing probabilistic inference, they keep updating the value associated with each decision node by propagating relational evidence from one decision node to another over the dependency graph.

When the relationships between the references and the entities can be captured in a single graph, the matching entity for a specific reference may be identified using path-based similarities between their corresponding nodes in the graph. The connection strength associated with each edge in the graph can be determined in the unsupervised fashion given all the references, their candidate entity choices, and the relationships between them, by solving a set of nonlinear equations (Kalashnikov et al. 2005). This approach is useful for incremental data cleaning when the set of entities currently in the database is known and an incoming reference needs to be matched with one of these entities.

An alternative approach to performing collective entity resolution using relational evidence is to perform collective relational clustering (Bhattacharya and Getoor 2007). The goal here is to cluster the references into entities by taking into account the relationships between the references. This is achieved by defining a similarity measure between two clusters of references that take into account not only the attribute similarity of the references in the two clusters but also the neighboring clusters of each cluster. The neighboring clusters of any reference cluster c are defined by considering the references r' connected to references r belonging to c via hyper-edges and the clusters to which these related references belong. If the $r.C$ represents the current cluster for reference c, then $N(c) = \bigcup r'.C$, where $r.H = r'.H$ and $r.C = c$. For instance, the neighboring clusters for a $Wang$ cluster in our example containing the $Wang$ references from papers 1, 2, and 4 are the $Ansari$ cluster and the $Chen$ clusters containing the other references from the same papers. The relational similarity between two clusters is then computed by comparing their neighborhoods. This relational similarity complements attribute similarity in the combined similarity between two clusters. Intuitively, two entities are likely to be the same if they are similar in attributes and are additionally connected to the same other entities. Collective relational clustering can be efficiently implemented by maintaining a priority queue for merge-able cluster pairs and updating the "neighboring" queue elements with every merge operation.

Applications

Data cleaning and reference disambiguation approaches have been applied and evaluated in a number of domains. The earliest applications were on medical data. Census data is an area where detection of duplicates poses a significant challenge and Winkler (2002) has successfully applied his research and other baselines to this domain. A great deal of work has been done making use of bibliographic data (Pasula et al. 2003; Singla and Domingos 2004; Bhattacharya and Getoor 2007). Almost without exception, the focus has been on the matching of citations. Work in co-reference resolution and disambiguating entity mentions in natural language processing (McCallum and Wellner 2004) has been applied to text corpora and newswire articles like the TREC corpus. There have also been significant applications in information integration in data warehouses (Chaudhuri et al. 2003).

▸ Expectation Propagation

Epsilon Cover

Thomas Zeugmann
Hokkaido University, Sapparo, Japan

Motivation and Background

Epsilon covers were introduced in calculus. So we provide here a very general definition.

Definition

Let (M, ϱ) be a metric space, let $S \subseteq M$, and let $\varepsilon > 0$. A set $E \subseteq M$ is an *ε-cover* for S, if for every $s \in S$ there is an $e \in E$ such that $\varrho(s, e) \leq \varepsilon$.

An *ε-cover* E is said to be *proper*, if $E \subseteq S$.

Application

The notion of an ε-cover is frequently used in kernel-based learning methods.

For further information, we refer the reader to Herbrich (2002).

Epsilon Nets

Thomas Zeugmann
Hokkaido University, Sapparo, Japan

Motivation and Background

Epsilon nets were introduced by Haussler and Welz (1987), and their usefulness for computational learning theory has been discovered by Blumer et al. (1989).

Let $X \neq \emptyset$ be any learning domain and let $\mathcal{C} \subseteq \wp(X)$ be any nonempty concept class. For the sake of simplicity, we also use $\mathcal{C}$ here as hypothesis space. In order to guarantee that all probabilities considered below do exist, we restrict ourselves to *well-behaved* concept classes (see ▸ PAC Learning).

Furthermore, let D be any arbitrarily fixed probability distribution over the learning domain X and let $c \in \mathcal{C}$ be any fixed concept.

A hypothesis $h \in \mathcal{C}$ is said to be *bad* for c iff

$$d(c, h) = \sum_{x \in c \triangle h} D(x) > \varepsilon.$$

Furthermore, we use

$$\Delta(c) =_{df} \{h \triangle c \mid h \in \mathcal{C}\}$$

to denote the set of all possible *error regions* of c with respect to $\mathcal{C}$ and D. Moreover, let

$$\Delta_\varepsilon(c) =_{df} \{h \triangle c \mid h \in \mathcal{C},\ d(c, h) > \varepsilon\}$$

denote the set of all *bad error regions* of c with respect to $\mathcal{C}$ and D.

Now we are ready to formally define the notion of an ε-net.

Definition

Let $\varepsilon \in (0, 1)$, and let $S \subseteq X$. The set S is said to be an *ε-net for* $\Delta(c)$ iff $S \cap r \neq \emptyset$ for all $r \in \Delta_\varepsilon(c)$.

Remarks

Conceptually, a set S constitutes an ε-net for $\Delta(c)$ iff every bad error region is hit by at least one point in S.

Example

Consider the one-dimensional Euclidean space $\mathbb{E}$, and let $X = [0, 1] \subseteq \mathbb{E}$. Furthermore, let $\mathcal{C}$ be the set of all closed intervals $[a, b] \subseteq [0, 1]$. Consider any fixed $c \in \mathcal{C}$, and let D be the uniform distribution, i.e., $D([a, b]) = 1/(b - a)$ for all $[a, b] \in \mathcal{C}$. Furthermore, let $h \in \mathcal{C}$; then we may write $c \triangle h = I_1 \cup I_2$, where $I_1, I_2 \in \mathcal{C}$. Let $\varepsilon \in (0, 1)$ be arbitrarily fixed, and let

$$S = \{k\varepsilon/2 \mid 0 \le k \le \lceil 2/\varepsilon \rceil,\ k \in \mathbb{N}\}\,.$$

Then, S forms an ε-net for $\Delta(c)$. This can be seen as follows. Assume $r \in \Delta_\varepsilon(c)$. Then, $D(I_1) > \varepsilon/2$ or $D(I_2) > \varepsilon/2$. Now, by the definition of S, it is obvious that $D(I_i) > \varepsilon/2$ implies $I_i \cap S \ne \emptyset$, $i = 1, 2$.

Application

Recall that in ▸ PAC Learning, the general strategy to design a learner has been to draw a sufficiently large finite sample and then to find a hypothesis that is consistent with it. For showing that this strategy is always successful, the notion of an ε-net plays an important role. This can be expressed by the following observation.

Observation. Let $S = \{x_1, \ldots, x_m\}$ be an ε-net for $\Delta(c)$, and let $h \in \mathcal{C}$ be any hypothesis such that $h(x_i) = c(x_i)$ for all $1 \le i \le m$, i.e., h is consistent. Then we have $d(c, h) \le \varepsilon$.

It then remains to show that the ▸ VC Dimension of $\mathcal{C}$ and of $\Delta(c)$ are the same and to apply Sauer's lemma to complete the proof.

Equation Discovery

Ljupčo Todorovski
University of Ljubljana, Ljubljana, Slovenia

Synonyms

Computational discovery of quantitative laws; Symbolic regression

Definition

Equation discovery is a machine learning task that deals with the problem of learning quantitative laws and models, expressed in the form of equations, in collections of measured numeric data. Equation discovery methods take at input a ▸ data set consisting of measured values of a set of numeric variables of an observed system or phenomenon. At output, equation discovery methods provide a set of equations, such that, when used to calculate the values of system variables, the calculated values closely match the measured ones.

Motivation and Background

Equation discovery methods can be used to solve complex modeling tasks, i.e., establishing a mathematical model of an observed system. Modeling tasks are omnipresent in many scientific and engineering domains.

Equation discovery is strongly related to *system identification*, another approach to mathematical modeling. System identification methods work under the assumption that the structure of the model (the form of the model equations) is known or comes from a well-defined class of model structures, such as polynomials or neural networks. Therefore, they are mainly concerned with the parameter estimation task, that is, the task of determining the values of the model parameters that minimize the discrepancy between measured data and data obtained by simulating the model. Equation discovery methods, on the other hand, aim at identifying both, an adequate structure of the model equations and appropriate values of the model parameters.

▶ Regression also deals with building predictive models from numeric data. The focus of regression methods is on building descriptive black-box models that can reconstruct the training data with high accuracy. In contrast, equation discovery methods focus on establishing explanatory models that, beside accurate predictions, provide explanations of the mechanisms that govern the behavior of the modeled system.

Early equation discovery methods dealt with rediscovering empirical laws from the history of science (this is where the synonym "computational discovery of quantitative laws" comes from). Through the years, the focus of the equation discovery methods has shifted from discovering quantitative laws to modeling real-world systems.

Structure of the Learning System

The task of equation discovery can be decomposed into two closely coupled subtasks of structural identification and parameter estimation. The first task of structural identification deals with the problem of finding the optimal structure of an equation. The second task of parameter estimation deals with the problem of finding the optimal values of the constant parameters in the equation. General approaches to and specific methods for equation discovery use different techniques to solve these two subtasks.

Approaches and Methods

There are two general and fundamentally different approaches to equation discovery. The first approach relies on a definition of a space of candidate equation structures. Following this definition, a generate-and-test (or ▶ learning as search) approach is used to generate different equation structures, solve the parameter estimation task for each of them, and report those equations that most closely approximate the data. The second approach relies on heuristics, used by scientists and engineers in the discovery or modeling processes, to establish an appropriate equation structure.

The first equation discovery system, Bacon (Langley 1981), follows the second approach described above. It incorporates a set of data-driven heuristics for detecting regularities (constancies and trends) in measured data and for formulating hypotheses based on them. An example heuristic would, when faced with a situation where the values of two observed variables increase/decrease simultaneously, introduce a new equation term by multiplying them. Furthermore, Bacon builds equation structure at different levels of description. At each level of description, all but two variables are held constant and hypotheses connecting the two changing variables are considered. Using a relatively small set of data-driven heuristics, Bacon is able to rediscover a number of physical laws including the ideal gas law, the law of gravitation, the law of refraction, and Black's specific heat law.

An alternative set of heuristics for equation discovery can be derived from dimensional analysis that is routinely used to check the plausibility of equations by using rules that specify the proper ways to combine variables and terms with different *measurements units*, different measurement scales, or types thereof. Following these rules, equation discovery method Coper (Kokar 1986) considers only equation structures that properly combine variables and constants, given the knowledge about their exact measurement units. Equation discovery method SDS (Takashi and Hiroshi 1998) extends Coper to cases, where the exact measurement units of the variables and constants involved in the equation are not known, but only knowledge about the types of the ▶ measurement scales is available.

Finally, the heuristics and design of the equation discovery method E* (Schaffer 1993) is based on a systematic survey of more than a hundred laws and models published in the Physical Review journal. The review shows that many of the published laws and models follow one of five different equation structures. By including only these five structures as its main heuristic for solving the structure identification task (implementing it as a ▶ language bias), E* was able to reconstruct the correct laws and models in about a third of the test cases collected from the same journal.

Abacus (Falkenhainer and Michalski 1990) was the first equation discovery method that followed the generate-and-test (or ▸ learning as search) approach, mentioned above. Abacus experimented with different search strategies within a fixed space of candidate equation structures. Other methods that follow the generate-and-test approach differ in the ways they define the space of candidate equation structures and solve the parameter estimation task.

Equation discovery methods EF (Zembowitz and Zytkow 1992) and Lagrange (Džeroski and Todorovski 1995) explore the space of polynomial equation structures that are linear in the constant parameters, so they apply ▸ linear regression to estimate parameters. The user can shape the space of candidate structures by specifying parameters, such as, the maximal polynomial degree, the maximal number of multiplicative terms included in a polynomial, and a set of functions that can be used to transform the original variables before combining them into multiplicative terms.

While all of the above methods assume a fixed predefined ▸ language bias (via specification of the class of candidate equation structures or via heuristics for establishing appropriate structure), equation discovery method Lagramge (Todorovski and Džeroski 1997) employs dynamic declarative ▸ language bias, that is, let the user of the equation discovery method choose or specify the space of candidate equation structures. In its first version, Lagramge uses the formalism of context-free grammars for specifying the space of equation structures. The formalism has been shown to be general enough to allow users to build their specification upon many different types of modeling knowledge, from measurement units to very specific knowledge about building models in a particular domain of interest (Todorovski and Džeroski 2007). For solving the structure identification task, Lagramge defines a refinement operator that orders the search space of candidate equation structures, defined by the user-specified grammar, from the simplest ones to more complex. Exhaustive and ▸ beam search strategies are then being employed to the search space and for each structure considered during the search, Lagramge uses gradient-descent methods for nonlinear optimization to solve the parameter estimation task. The heuristic function that guides the search is based on the ▸ mean squared error that measures the discrepancy between the measured and simulated values of the observed system variables. Alternatively, Lagramge can use heuristic function that takes into account the complexity of the equation and is based on the ▸ minimum description length principle.

Successors of Lagramge, equation discovery methods, Lagramge 2 (Todorovski and Džeroski 2007), IPM (Bridewell et al. 2008), and HIPM (Todorovski et al. 2005), primarily focus on the improvement of the knowledge representation formalism used to formalize the modeling knowledge and transform it to ▸ language bias for equation discovery. All of them follow the paradigm of ▸ inductive process modeling.

Types of Equations

At first, equation discovery methods dealt with the problem of learning algebraic equations from data. Equation discovery method Lagrange (Džeroski and Todorovski 1995) extended the scope of equation discovery to modeling dynamics from ▸ time series data with ordinary differential equations. It took a naïve approach based on transforming the task of discovering ordinary differential equations to the simpler task of discovering algebraic equations, by extending the set of observed system variables with numerically calculated time derivatives thereof. By doing so, any of the existing equation discovery methods could be, in principle, used to discover differential equations. However, the naïve approach has a major drawback of introducing large numerical errors, due to instability of methods for numerical differentiation. Equation discovery method GoldHorn (Križman et al. 1995) replaced the instable numerical differentiation with the stable numerical methods for the inverse problem of integration. Goldhorn also upgrades Lagrange with filtering methods to cope with measurement errors and noisy data.

While ordinary differential equations can model systems that change their state along a single dimension, time, partial differential equations can be used to model systems that change along many (temporal and spatial) dimensions. The naïve approach of introducing numerically calculated partial derivatives has been used in the Paddles (Todorovski et al. 2000) method for discovery of partial differential equations. The method first slices the measurement data into narrow spatial subsets, induces ordinary differential equations in each of them, and uses most frequently obtained equation structures to extend them with partial derivatives and to obtain a relatively small class of partial differential equation structures to explore. All the equation discovery tasks in Paddles are solved using Lagramge (Todorovski and Džeroski 1997).

Applications

Equation discovery methods have been applied to various tasks of discovering equation-based laws and models from measured and/or simulation data. Application domains range from physics (mechanical and electrical engineering, fluid dynamics) (Takashi and Hiroshi 1998; Todorovski and Džeroski 1997, 2007), through ecology (population dynamics) (Todorovski and Džeroski 2007; Todorovski et al. 2005) to biochemistry (chemical kinetics) (Džeroski and Todorovski 2008; Langley et al. 2006).

Error

▶ Error Rate

Error Correcting Output Codes

Synonyms

▶ ECOC

Definition

Error correcting output codes are an ▶ ensemble learning technique. It is applied to a problem with multiple classes, decomposing it into several binary problems. Each class is first encoded as a binary string of length T, assuming we have T models in the ensemble. Each model then tries to separate a subset of the original classes from all the others. For example, one model might learn to distinguish "class A" from "not class A." After the predictions, with T models we have a binary string of length T. The class encoding that is closest to this binary string (using Hamming distance) is the final decision of the ensemble.

Error Rate

Kai Ming Ting
Federation University, Mount Helen, VIC, Australia

Synonyms

Error

Definition

Error rate refers to a measure of the degree of prediction error of a model made with respect to the true model.

The term *error rate* is often applied in the context of ▶ classification models. In this context, *error rate* $= \mathrm{P}(\lambda(X) \neq Y)$, where XY is a joint distribution and the classification model λ is a function $X \rightarrow Y$. Sometimes this quantity is expressed as a percentage rather than a value between 0.0 and 1.0.

The error rate of a model is often assessed or estimated by applying it to ▶ test data for which the class labels (Y values) are known. The error rate of a classifier on test data may be calculated as *number of incorrectly classified objects/total number of objects*. Alternatively, a smoothing function may be applied, such as a ▶ Laplace estimate or an *m*-estimate.

Error rate is directly related to ▶ accuracy, such that *error rate* $= 1.0 -$ *accuracy* (or when expressed as a percentage, *error rate* $= 100 -$ *accuracy*).

Two common measures of *error rate* for ▶ regression models are ▶ mean squared error and ▶ mean absolute error.

Evaluation

Evaluation is a process that assesses some property of an artifact. In machine learning, two types of\break artifacts are most commonly evaluated, models and {algorithms}. ▸ Model evaluation often focuses on the predictive efficacy of the model, but may also assess factors such as its complexity, the ease with which it can be understood, or the computational requirements for its application. ▸ Algorithm evaluation often focuses on evaluation of the models an algorithm produces, but may also appraise its computational efficiency.

Evaluation of Learning Algorithms

Geoffrey I. Webb
Faculty of Information Technology, Monash University, Victoria, Australia

Abstract

It is often desirable to assess the properties of a learning algorithm. Frequently such evaluation take the form of comparing the relative suitability of a set of algorithms for a specific task or class of tasks. Learning algorithm evaluation is the process of performing such assessment of a learning algorithm.

Synonyms

Algorithm Evaluation; Learning Algorithm Evaluation

Definition

Learning algorithm evaluation is the process of assessing a property or properties of a learning algorithm.

Motivation and Background

It is often valuable to assess the efficacy of a learning algorithm. In many cases, such assessment is relative, that is, evaluating which of several alternative algorithms is best suited to a specific application.

Processes and Techniques

Many learning algorithms have been proposed. In order to understand the relative merits of these alternatives, it is necessary to evaluate them. The primary approaches to evaluation can be characterized as either theoretical or experimental. Theoretical evaluation uses formal methods to infer properties of the algorithm, such as its computational complexity (Papadimitriou 1994), and also employs the tools of computational learning theory to assess learning theoretic properties. Experimental evaluation applies the algorithm to learning tasks in order to study its performance in practice.

There are many different types of property that may be relevant to assess depending upon the intended application. These include algorithmic properties, such a time and space complexity. These algorithmic properties are often assessed separately with respect to performance when learning a model, that is, at *training time*, and performance when applying a learned model, that is, at *test time*.

Other types of property that are often studied are the properties of the models that are learned (see ▸ model evaluation). Strictly speaking, such properties should be assessed with respect to a specific application or class of applications. However, much machine learning research includes experimental studies in which algorithms are compared using a set of data sets with little or no consideration given to what class of applications those data sets might represent. It is dangerous to draw general conclusions about relative performance on any application from relative performance on such a sample of some unknown class of applications. Such experimental evaluation has become known disparagingly as a *bake-off*.

An approach to experimental evaluation that may be less subject to the limitations of bake-offs is the use of experimental evaluation to assess a learning algorithm's bias and variance profile. Bias and variance measure properties of an algorithm's propensities in learning models rather than being directly properties of the models that are learned. Hence they may provide more general insights into the relative characteristics of alternative algorithms than do assessments of the performance of learned models on a finite number of applications. One example of such use of bias-variance analysis is found in Webb (2000).

Techniques for experimental algorithm evaluation include bootstrap sampling, cross validation, and holdout evaluation.

Event Extraction from Media Texts

Gregor Leban[1], Blaž Fortuna[1], and
Marko Grobelnik[2]
[1]Jozef Stefan Institute, Ljubljana, Slovenia
[2]Artificial Intelligence Laboratory, Jožef Stefan Insitute, Ljubljana, Slovenia

Abstract

The chapter describes the topic of using news content to automatically detect world events mentioned in the news. Various tasks required for identifying events are presented, such as semantic annotation, article clustering and

cross-lingual cluster matching. Given the identified events we also describe how date, location, relevant entities and other core event details can be determined automatically.

Definition

Event extraction from text is an area of research that involves identifying mentions of significant world events described in media documents, such as news articles. The goal is to identify the world events and extract as much information as possible about them in a structured form. Ideally, the extracted information should contain details about what happened, when, where, and who was involved in the event. Since relevant events are reported in numerous articles, the methods for detection of events can exploit this fact when identifying events and extracting event properties.

Motivation and Background

News outlets produce large amounts of news content every day. Most of the news articles describe recent happenings in the world, such as meetings of important politicians, natural disasters, societal issues, sports events, or pastimes of celebrities. The importance of the generated news content varies significantly – news about an approaching hurricane can be considered as much more important and relevant than a news article about a party held by a local politician. For the purposes of this paper, we will call important happenings *events*. There is no objective way to distinguish between important and non-important news stories, but a practical approach that can be used is to treat news as important if it is being reported by several news publishers. For practical purposes we can therefore define an event as a happening that is being covered in news articles by several news publishers.

News articles are written in a natural language which makes them easy to understand by humans, but hard to process by computers. Understanding information being described in an article requires the use of common sense, common knowledge, implicit information, and knowledge on how to disambiguate. Since it's hard to extract knowledge from the articles, it is also difficult to perform accurate information retrieval. Imagine, for example, that you would like to learn from the news about the events that happened in Washington state in the last month. The word "Washington" is for the computer just a sequence of letters. One can use it to perform a keyword search, which will however return various articles – from the ones about the state of Washington, about any of the 40 cities names Washington, as well as numerous people who are also named Washington. Even if all articles would be relevant, they are not grouped – there would be tens or hundreds of articles describing the same event, and it would be up to the reader to find if an article describes some event you have already seen or not. Additionally, there would also be no summary of what the event was about – the reader would have to read the articles and learn about that himself.

To make learning about the events a more pleasant experience, we would like to convert the unstructured information expressed in news articles into a structured form that can be stored in a machine-readable way. This is not a trivial task and requires several steps of processing. These steps include syntactic analysis, semantic enrichment, entity linking, document clustering, and information extraction. The final result of the processing is a structured database of world events. Due to the extensive metadata, it is possible to find events based on the date, location, or relevant entities. Articles about an event are grouped together which helps significantly to reduce the information overload. A summary of an event can also be obtained by aggregating common information from multiple news articles.

To our knowledge, there are at least three systems that are identifying world events by analyzing news media. GDELT project (Gao et al. 2013; Leetaru et al. 2013) performs event detection by extracting information from individual sentences in the news articles. Since several events are potentially extracted from a single article, it contains a huge collection of events (over 200 million) that were extracted from 1979 to the present. European media monitor (Steinberger et al. 2005; Pouliquen et al. 2008) focuses on the identification of current political events by combining and processing news articles in multiple languages. Event Registry (Leban et al. 2014a,b) similarly extracts world events with the additional metadata from articles in several languages. In the next sections, we will describe some of the core components that are needed by these systems.

Structure of Learning System

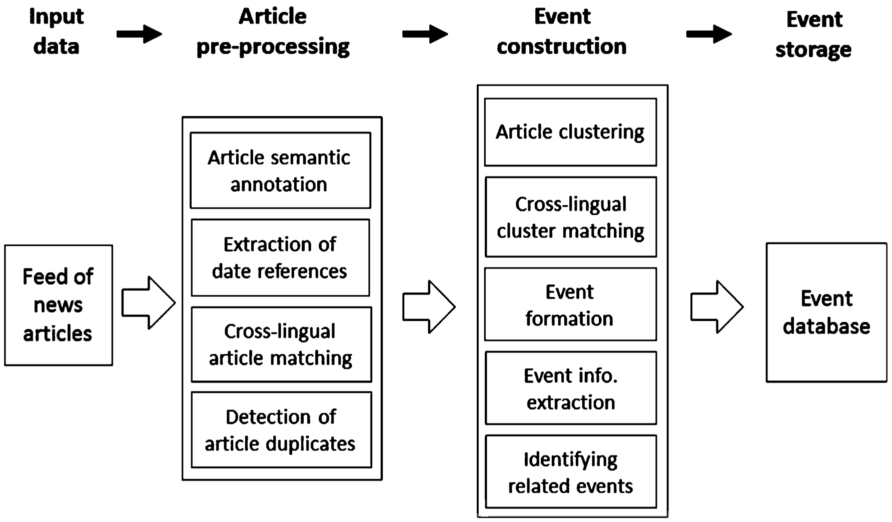
The identification of events from news articles requires a pipeline of services or components that provide specific functionalities. These services are shown in the Fig. 1 and will be described next.

News Collection

The first step in identification of events from news is to obtain the news content from a large set of news publishers. The content can be collected by either crawling the website of the news publishers or by identifying their RSS feeds and extracting article information from them. The use of RSS feeds, which are almost always available, is a better approach since they are significantly less data and time intensive compared to repeatedly crawling the whole websites. The RSS feeds do however often contain only article excerpts and crawling of the article page is therefore still needed. The main technical challenge with crawling the page is the identification of the article content and removal of the rest of the page. It is also important to extract as much metadata about the article as possible. This metadata can include the title of the article, publisher's name, date of publishing, author, etc.

Text Annotation

The collected news articles contain just plain text – there is no semantic information available about its content. In order to be able to extract semantic information about the described event, the text first needs to be annotated with semantic information that can be detected in the text. Common types of annotations are the named entities (people, locations, organizations) mentioned in the text and article topics. The challenge in annotation is twofold: first, the token or phrase that represents a named entity (such as "Paris") has to be identified, and second, it needs to be linked to a resource identifier that semantically represents the entity (such as a URI in a knowledge base). The first task is called



Input data
Article pre-processing

Article clustering
Cross-lingual cluster matching
Event formation
Event info. extraction
Identifying related events
Event database

Event Extraction from Media Texts, Fig. 1 Various components required in the process of extracting events from news articles named entity recognition and can be best solved using conditional random fields or more recently with convolutional neural networks. The second task is called entity linking and requires the use of a knowledge base containing an extensive set of relevant entities. Systems for entity linking such as Wikipedia Miner (Milne and Witten 2013) rely on the use of open knowledge bases such as DBpedia, Freebase, or YAGO.

An important type of data annotations are also temporal expressions mentioned in the text. Their detection is crucial in order to determine the date of the event that is being described in the news. Dates can be expressed in an absolute ("July 15th, 2015", "2015-07-12") or relative form ("yesterday morning," "last week"). The detection of absolute temporal expressions can be efficiently performed using a set of regular expressions. The relative expressions can either be identified using rule-based or sequence labeling approaches. The detected relative expressions can then be normalized into the absolute form using the article's publish date.

Clustering Approach to Event Identification

In order to identify events, a clustering approach can then be applied in order to group similar articles that describe the same event. The reasoning behind using clustering is the reasonable assumption that if articles are describing the same event, they will share similar vocabulary and mention similar entities. The most valuable features for the clustering algorithm are therefore the article text itself as well as the detected named entities and topics. The article text can be transformed into the bag-of-words form where each term in the document is normalized according to a chosen weighting scheme, such as TF-IDF. A feature vector can be generated for each article by concatenating the weights of the article terms and the mentioned named entities. A similarity measure, such as cosine similarity, can then be used to compute the similarity between individual articles.

Given the article feature vectors and the similarity measure, the clusters representing events can be identified using various clustering methods. European media monitor, for example, uses an agglomerative bottom-up clustering algorithm to group all articles published in a 24-h time window. Articles are grouped into the same cluster as long as their similarity is above the selected threshold. Centroid vectors of the obtained clusters are also compared with clusters identified on a previous day. The clusters that are found to be similar enough are merged and therefore represented as a single event. This allows the method to identify events that span across several days.

Event registry, on the other hand, uses an online approach to clustering. Each new article is clustered immediately after being added to the system. The clustering approach works as follows. The feature vector of the article is first being compared to the feature vectors of the centroids of all existing clusters. If the cosine similarity to the most similar centroid is above the selected threshold, the article is simply assigned to the cluster. Otherwise, a new, so-called *micro-cluster* is created containing only the single article. As new articles are added to the system, the micro-clusters can grow in size as articles are being added to them. Once they reach a certain size (depending on the language, this can be between three and ten articles), they are no longer considered as micro-clusters but instead as proper events. Micro-clusters that never reach the necessary size are not considered as events and are eventually removed. There are also different validation methods that are being called regularly in order to ensure the highest quality of the clusters. As clusters grow, for example, it can occur that the centroids of two clusters become more and more similar. One of the validation methods therefore checks different pairs of clusters and merges them in case their similarity, as measured by the cosine similarity of their centroid vectors, is above the threshold. Additionally, a separate method also checks each cluster if it is still sufficiently coherent or should instead be split into two separate clusters. The main idea behind splitting is to project all articles in the cluster onto a line and divide them into two groups depending on whether their projection was left or right of the centroid. This is repeated several times. In the first iteration the first principal component of the original cluster is used as the projection line. In the following steps, the articles are projected onto the line that passes the centroids of the two groups obtained in the previous iteration. Once the two groups become stable, the method compares the original cluster and the two identified groups using the Bayesian information criterion in order to determine whether the cluster should be split or not. The last maintenance method is responsible for removing obsolete clusters. An event is reported in the media only for a limited number of days. To avoid assigning new articles to obsolete clusters, the method removes (micro-) clusters once the oldest member articles reach a certain age. In case of Event Registry, clusters are removed after they become 5 days old.

Both described approaches for identifying events using clustering have their advantages and disadvantages. The approach used in European media monitor works in batch mode which makes the identified events more stable. The downside is however that it is not suitable for real-time monitoring and detection of breaking events. On the other hand, the approach used by Event Registry can identify new events as soon as the sufficient number of articles about it has been written. However, because of the online mode of the algorithm, the identified clusters can be merged or split during their lifetime which makes them more volatile.

Cross Lingual Event Detection

Until this point we have not considered the fact that news articles are written in different languages. Since the described clustering approaches rely on the article text, the methods are evidently language dependent. It is not sensible, for example, to compute cosine similarity between an English and German article; therefore content from each language has to be clustered separately. As a result, events represented by the clusters will contain only articles in a single language. Since most events are reported in multiple languages, we want to find methods for identifying clusters in different languages that describe the same event. This will allow us to see how the same news is reported in different languages, what topics are more or less likely to break the language barrier, how fast does the information spreads through the languages, etc.

In order to link the appropriate clusters, we can represent the problem as a binary classification problem. Given a cluster pair c_1 and c_2 in languages l_1 and l_2, we need to compute a set of discriminative features that will help us to determine if both clusters describe the same event or not. A machine learning model can then be trained to classify the cluster pairs based on the values of the computed features.

One set of learning features can be computed by inspecting individual articles assigned to the clusters. Using a method such as canonical correlation analysis (CCA), it is possible to compute an estimated score of relatedness of two articles in different languages. The method is trained on a comparable corpus, which is a collection of documents in multiple languages, with alignment between documents that are on the same topic or even rough translations of each other. An example of such corpus is Wikipedia, where each entry can be described in multiple languages. Using the CCA, we can compare pairs of documents in the tested clusters c_1 and c_2 and compute features such as the maximum or the average score of similarity between the documents in the two clusters.

Additional set of important learning features can be computed by aggregating the annotated entities mentioned in the articles. Given the articles in each cluster, we can analyze how often do individual entities appear in the articles in order to estimate their relevance for the event – entities that appear more frequently can be considered as more important to the event compared to entities that are mentioned fewer times. One way to score an entity in a cluster is simply to compute the ratio of articles in the cluster that mention it. A more advance approach can also take into account the number of times the entity is mentioned in each article and its mentioned location – an entity is likely more relevant if it is mentioned at the beginning of the article than if at the end. Since entities are language independent (same entity, although mentioned in different languages, is represented with the same identifier), we can construct for each cluster a weighted vector of relevant entities. For a pair of clusters, a similarity measure can again be used to compute similarity of the clusters according to the mentioned entities. Since events are mostly centered around entities, the similarity score can be an important feature when deciding if two clusters are about the same event or not.

Additionally, time similarity is also an important feature. If articles in one cluster were published in a similar time period as articles in another cluster, they are more likely about the same event as if they were published several days apart. If dates mentioned in the articles are being extracted, the ratio of common dates mentioned in the two clusters can also be a relevant feature.

In order to train the classification model, we first need the learning data. A human expert should therefore provide a set of positive and negative examples – cluster pairs that are about the same events as well as pairs that are not. For each cluster pair, values of the mentioned features can be computed and concatenated into a single feature vector. A machine learning classifier, such as SVM, can then be trained to best distinguish between the positive and negative examples based on the learning features. An experiment using the described approach (Rupnik et al. 2016) reports the cluster linking accuracy of 0.893 as measured using F1 score.

Extraction of Event Properties

Based on the described approach, an event consists of one or more clusters, where each cluster contains articles from a single language. As the final step, we wish to extract from the articles in the clusters as much structured information as possible about the event.

To determine the date of the event, we can analyze the publishing date of the articles in the clusters. The simplest method can be to use the date of the first article as the date of the event. This approach can generate erroneous results for events that are reported in advance (such as various meetings of politicians, product announcements, etc.) as well as when the collected publishing dates of the articles are potentially inaccurate. A more error-prone approach is to analyze the density of reporting and use the time point where the reporting intensified as the date of the event. Additional input can be provided by the mentioned date references – a particular date that is consistently mentioned across the articles is likely the correct date of the event.

In order to determine who is involved in the event, we can analyze and aggregate the entities mentioned in the articles. A list of relevant entities and their score of relevance can be obtained by analyzing the frequency of their occurrence in the articles as well as the locations of the mentions in text. Entities that appear in event's articles more frequently and early in the text are more important than entities that are just rarely mentioned and appear late. Entities can be scored and ranked according to this criterion which provides an accurate aggregated view on what and who is the event about.

Another core property of the event is also the location where the event occurred. Since the event location is commonly mentioned in the articles, we can identify it by analyzing the frequently mentioned entities that are of type location – knowledge about the entity type can be retrieved from the knowledge base used in entity linking. Additional signal for determining the location can be obtained by inspecting the datelines of the articles. A dateline is a brief piece of text at the beginning of the news article that describes where and when the described story happened. The problem with datelines is that they are not present in all news articles, and even when they are, they sometimes represent the location where the story was written and not the actual location of the event. To determine the event location, one can simply use the city that is mentioned the most in the articles. A more advanced approach can again rely on machine learning. Each city that is mentioned in the articles about an event can be considered as a candidate for the event location. For each city we therefore generate a set of features based on which a classification model can compute the probability that it is the location of the event. The features can be the number or ratio of times the city is mentioned in the articles, the number of times it is mentioned in the dateline, how commonly the city is mentioned in all the articles, etc. To train the classification model, we again need the experts to manually provide information about the correct location of various events. Using the training data, we can then train a model that will classify each candidate city independently. Because they are evaluated independently, it is possible that the model finds several locations to be the event location. To choose the most likely city, it is important to use a probabilistic classifier that can also return a degree of certainty – in such cases, one can simply choose the location with the highest probability.

There are many other properties that could be extracted which are specific for individual event types. In case of an earthquake, for example, important properties would include the number of casualties and the strength of the earthquake. Similarly, for a football game, the relevant information would be the names of the teams that played and the final score. Identifying such properties and their values is a cumbersome task. It first requires that each event is classified into an event type (such as earthquake, football game, meeting, etc.). To perform classification, a taxonomy of event types is first needed together with a model that can perform classification into the taxonomy. Next, for each event type, a set of properties/slots need to be identified that are relevant for the event type. A pattern or rule-based approach can then be used to determine the values for these properties.

Cluster optimization; Evolutionary grouping; Genetic clustering; Genetic grouping

Definition

Evolutionary clustering refers to the application of evolutionary algorithms (also known as genetic algorithms) to data clustering (or cluster analysis), a general class of problems in machine learning with numerous applications throughout science and industry. Different definitions of data clustering exist, but it generally concerns the identification of homogeneous groups of data (clusters) within a given data set. That is, data items that are similar to each other should be grouped together in the same cluster or group, while (usually) dissimilar items should be placed in separate clusters. The output of any clustering method is therefore a specific collection of clusters. If we have an objective way to evaluate (calculate the quality of) a given grouping into clusters, then we can consider the clustering task as an optimization problem. In general, this optimization problem is NP hard, and it is common to address it with advanced heuristic or meta-heuristic methods. Evolutionary algorithms are prominent among such methods and have led to a variety of promising and successful techniques for cluster optimization.

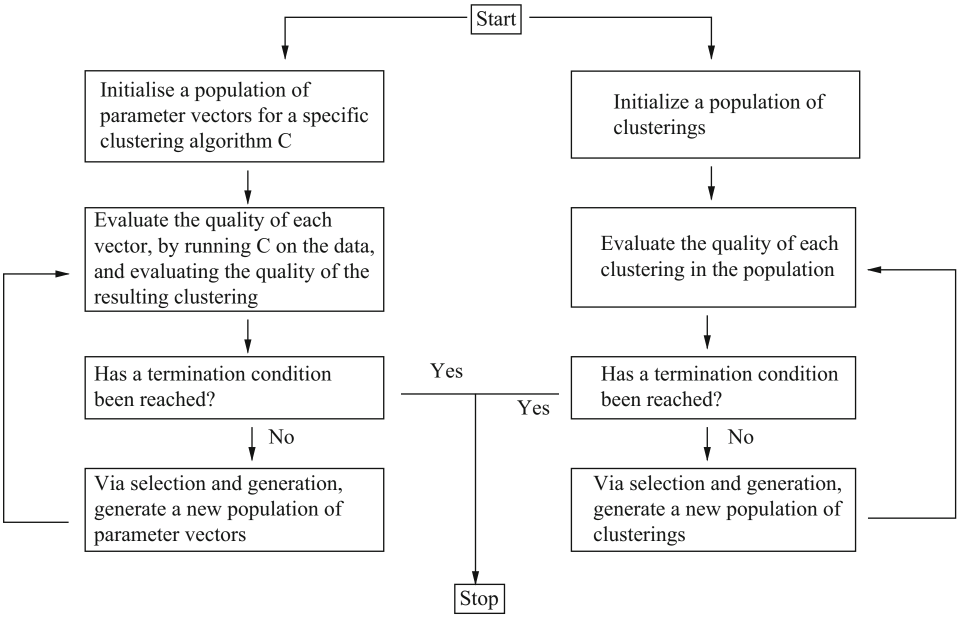
Motivation and Background

In many problem-solving scenarios, we have large amounts of data. We need to cluster those data sensibly into groups in order to help us understand the problem and decide how to proceed further (see clustering). It is common, in fact, for this initial "cluster analysis" stage to be the most important (or only) stage in the investigation. In bioinformatics, for example, a frequent activity is the clustering of gene expression data (data that indicate, for a specific cell, how active each of several thousands of genes are at different points in time or under different experimental conditions). A very important current challenge is to understand the role of each gene; by clustering such data, which means arranging genes into groups such that genes in the same group have similar patterns of activity, we find important clues about genes whose role is currently unknown, simply by assigning their putative role as being related to that of genes (whose role is known) that are in the same cluster. Meanwhile, a ubiquitous situation in industry and commerce is the clustering of data about customers or clients. Here, the role of clustering is all about identifying what types of clients (e.g., based on age, income, postcode, and many other attributes that may make up a customer's profile) buy or use certain kinds of products and services. Effective ways to identify groups enable companies to better target their products and their direct marketing campaigns and/or make more effective decisions about loans, credit, and overdrafts. Many machine learning techniques can be used to predict things about customers, predict things about genes, and so forth. However, the value of clustering (in a similar way to visualization of the data) is that it can lead to a much deeper understanding of the data, which in turn informs the continuing process of applying machine learning methods to it. In this general context, there are many well-known and well-used clustering methods, such as k-means, hierarchical agglomerative clustering, neighbor joining, and so forth. However, there are also well-known difficulties with these methods; in particular, there is often a need to choose in advance the number of clusters to find in the data, and they tend to be strongly biased toward finding certain types of groupings. For these reasons, methods that are more flexible have been recently investigated, and evolutionary clustering techniques are prominent among these. They are flexible in that (e.g., unlike k-means) the choice of the number of clusters does not have to be made a priori, and the method is not tied to any particular way of identifying the distance between two items of data, nor is there any a priori inductive bias concerning what counts as a good clustering. That is, in broad terms, an evolutionary clustering algorithm allows a user to flexibly make these decisions in view of the actual problem at hand; these decisions are then "plugged into" the algorithm which proceeds to search for good clusterings.

Given a data set to be clustered, the concept of evolutionary clustering covers two distinct ways in which we can address the problem of finding the best clustering. Each of these approaches is under continuing research and has proven successful under different conditions. The first approach is to use an evolutionary algorithm to search the space of candidate groupings of the data; this is the most straightforward approach and perhaps the most flexible in the sense discussed above. The second approach is to "wrap" an evolutionary algorithm around a simpler clustering algorithm (such as k-means) and either use the evolutionary algorithm to search the space of features for input to the clustering algorithm (i.e., the evolutionary algorithm is doing feature selection in this case) or to search a space of parameters, such as the number of clusters, feature weights, and/or other parameters of the clustering algorithm in use. Central in all of these approaches is a way to measure the quality of a clustering, which in turn depends on some given metric that provides a distance between any pair of data items. Although some applications come with pre-identified ways to measure distance and cluster quality, in the following we will assume the most common approach, in which distance is the Euclidean distance between the data items, and the measure of quality for a given clustering is some ratio of within-cluster and between-cluster similarities.

We illustrate the two main approaches to evolutionary clustering in Fig. 1.

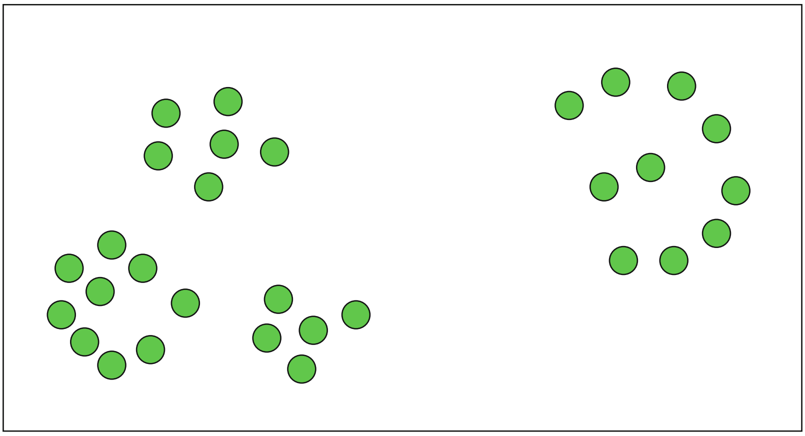
There are several examples of the first type of approach, called "indirect" evolutionary clustering in Fig. 1 (left). This approach is often used where the "internal" clustering method ("C" in the figure) is very sensitive to initialization conditions and/or parameters of the metric in use to measure distance between items. For example, if C is the k-means algorithm, then, for each application of C, we need choices for the parameter k and for each of k initial cluster center positions in the data space. The parameter vectors referred to in the figure would be precisely these; the evolutionary algorithm searches this parameter space, finding those that lead to an optimized clustering from k-means. Figure 2 illustrates why this will often be a more effective approach than k-means alone. In this case, it is entirely unclear whether these data form two, four, or even five clusters. There are two widely separated groups of points, and this two-cluster solution may be easily found by a 2-means algorithm. However,



Start
Initialise a population of parameter vectors for a specific clustering algorithm C
Evaluate the quality of each vector, by running C on the data, and evaluating the quality of the resulting clustering
Has a termination condition been reached?
No
Via selection and generation, generate a new population of parameter vectors
Yes
Yes
Initialize a population of clusterings
Evaluate the quality of each clustering in the population
Has a termination condition been reached?
No
Via selection and generation, generate a new population of clusterings
Stop

Evolutionary Clustering, Fig. 1 Evolutionary clustering. The two main approaches to evolutionary clustering: indirect (*left*) and direct (*right*)

Evolutionary Clustering, Fig. 2 An example data set with many potential interpretations of the number of clusters



to the human eye, there is also a clear four-cluster solution, further analysis of which may lead to better understanding of these data. This four-cluster solution is difficult for a 4-means algorithm to find, depending on very fortunate initial settings for the cluster centers. The embedding of k-means within an evolutionary algorithm allows for the iterative optimization of parameters and starting conditions to arrive at this optimal solution.

On the right in Fig. 1, we see the direct approach, in which the evolutionary algorithm searches the space of clusterings of the data. The key features in this approach are the encoding and genetic operators. After evaluating the quality of each of a population of clusterings, a new population is generated from the old one via selection and variation. Essentially, some individuals from the current population are treated as “parents,” and new ones are produced from these by using genetic operators. The encoding dictates precisely how a specific data clustering is represented, while the operators determine how new clusterings are derived from the old ones. To take a simple example, suppose we needed to cluster ten items (A, B, C,. . ., J) into an arbitrary number of groups. In a simple encoding, we might represent a clustering as a vector of ten labels, independently chosen from 1 to 10, in which the *i*th element gives the group label of the *i*th item. Hence, the following individual in our population of clusterings 2 3 5 5 1 5 7 3 2 7 would represent the following grouping: (A, I) (B, H) (C, D, F) (E) (G, I). Given such a representation, a typical genetic operator might be to randomly change a single label in a single parent. For example, we may choose the fifth element in the above vector and change it randomly to 7, effectively placing item E in the same group as items G and I. Further notes about operators for this and other encodings are given in a special subsection below. Going back to the example in Fig. 2, meanwhile, it is worth noting that there are potentially five clusters, as the group on the right can be perceived as a central group of two items, surrounded by a single backward-C-shaped group. The "backward-C" cluster is an example that cannot be reliably detected (as a distinct cluster from the group of two items contained within it) with most standard cluster analysis methods. Traditional approaches typically incorporate the assumption that clusters will be centered around a particular position, with the likelihood of a point belonging to that cluster falling monotonically with its distance from that position. One of the strengths of evolutionary clustering is that it provides the flexibility to work effectively with arbitrary definitions of what may constitute a valid cluster.

Objective Functions for Evolutionary Clustering

It can be strongly argued that the clustering problem is inherently multiobjective, yet most methods employ only a single performance criterion to optimize. In fact, there are at least three groups of criteria commonly used (but usually one at a time) in clustering (both evolutionary clustering and other methods). These are compactness, connectedness, and spatial separation. When an algorithm optimizes for compactness, the idea is that clusters should consist of highly homogeneous data items only – that is, the distance (or other measure of variation) between items in the same cluster should be small. In contrast, if we optimize the degree of connectedness, then we are increasing the extent to which neighboring data items should share the same cluster. This can deal with arbitrarily shaped clusters, but can lack robustness when there is little spatial separation between clusters. Finally, spatial separation is usually used as a criterion in combination with compactness or with a measure of the balance of cluster sizes.

In multiobjective clustering, the idea is to explicitly explore the solutions that are trade-offs between the conflicting criteria, exploiting the fact that these trade-off solutions are often the ones that most appeal as intuitively "correct" solutions to a clustering problem. Handl and Knowles (2007) introduced a multiobjective evolutionary algorithm, MOCK, which treats a clustering problem as a two-objective problem, using measures of compactness and connectedness for the two objectives. MOCK's multiobjective search process is based on the PESA-II evolutionary multiobjective optimizer (Corne et al. 2001). Following the use of MOCK for a clustering problem, an intermediate result (inherent in multiobjective optimization methods) is a (possibly large) collection of different clusterings. These will range from clusterings that score very well on compactness but poorly on connectedness through clusterings that achieve excellent connectedness at the expense of poor compactness. It is useful to note that the number of clusters tends to increase as we go from poor connectedness to high-connectedness clusters. Arguably, in many applications, such a collection of alternative solutions is useful for the decision-maker. Nevertheless, the MOCK approach incorporates an automated model selection process that attempts to choose an ideal clustering from the discovered approximate Pareto front. This process is oriented around the notion of determining the "right" number of clusters and makes use of Tibshirani et al. (2001) gap statistic (full details are in Handl and Knowles 2007). Extensive comparison studies, using a wide variety of clustering problems and comparing with many alternative clustering methods, show consistent performance advantages for the MOCK's approach. Recent work has explored different objectives, encodings, and model selection mechanisms for multiobjective clustering, including the interpretation of the approximation set as a clustering ensemble (Handl and Knowles 2013).

Encodings and Operators for Evolutionary Clustering

The encoding methods used in indirect approaches to evolutionary clustering are fairly straightforward, as they only require the specification of the parameters (and, potentially, initialization points) for the clustering method(s) used. Arguably, the development of direct approaches to evolutionary clustering is more involved, as the choice of a suitable encoding method is nontrivial and has been shown to have significant impact on optimization performance.

Encodings range from the straightforward representation noted above (with the ith gene coding for the cluster membership of the ith data item) to more complex representations, such as matrix-based or permutation-based representations. Before providing a brief description of other encodings, it is worth briefly examining a well-known disadvantage of the simple encoding. Given that they have a population, evolutionary algorithms offer the opportunity to use multi-parent genetic operators – that is, we can design operators that produce a new candidate clustering given two or more "parent" clusterings. Such operators are neither mandatory nor necessarily beneficial in evolutionary algorithms, and there is much literature discussing their merits and how this depends on the problem at hand. However, they are often found helpful, especially in cases where we can see some intuitive merit in combining different aspects of parent solutions, resulting in a new solution that seems to have a chance at being good, but which we would have been immensely unlikely to obtain from single-parent operators given the current population. In this context, we can see, as follows, that the opposite seems to be the case when we use standard multi-parent operators with the simple encoding. Suppose the following are both very good clusterings of ten items:

Clustering 1: 1111122222
Clustering 2: 2222211111

Clearly, a good clustering of these items places items 1–5 together, and items 6–10 together, in separate groups. It is also clear, however, that using a standard crossover operator between these two parents (e.g., producing a child by randomly choosing between clusterings for each item in turn) will lead to a clustering that mixes items from these two groups, perhaps even combining them all into one group. The main point is that a crossover operation destroys the very relationships between the items that underpinned the fitness of the parents. One of the more prominent and influential representations for clustering, incorporating a design for far more effective multi-parent operators, was that of Falkenauer's "Grouping Genetic Algorithm," which also provides a general template for the implementation of evolutionary algorithms for grouping problems. The essential element of Falkenauer's method is that multi-parent operators recombine entire groups rather than item labels. For example, suppose we encode two clusterings explicitly as follows:

Clustering 3: (A,I,B,H)(C,G)(D,E,F,J)
Clustering 4: (A,I,B,H)(C,D,J)(E,F,G)

A Falkenauer-style crossover operator works as follows. First, we randomly choose some entire groups from the first parent and some entire groups from the second parent; the child in this case might then be:

(A,I,B,H)(C,G)(E,F,G)

in which the groups that come from the first parent are underlined. Typically, we will now have some repeated items; we remove the entire groups that contain these items and came from the first parent, in this case leaving us with:

$$\underline{(A,I,B,H)}(E,F,G)$$

The final step is to add back the missing items, placing them one by one into one of the existing groups or perhaps forming one or more new groups. The application in hand will often suggest heuristics to use for this step. In clustering, for example, we could make use of the mean Euclidean distance from items in the groups so far. Whatever the end result in this case, note that the fact that A, I, B, and H were grouped together in both parents will be preserved in the child. Similarly, the E, F, G grouping is inherited directly from a parent.

A more recent and effective approach to encoding a clustering is one first proposed in Park and Song (1998) called a link-based encoding. In this approach, the encoding is simply a list of item indices and is interpreted as follows. If the ith element in the permutation is j, then items i and j are in the same group. So, for example,

B C E E A E G C B G

represents the following grouping:

(A,B,C,D,E,H,I)(F,G,J)

Standard crossover operators may be used with this encoding, causing (intuitively) a reasonable degree of exploration of the space of possible clusterings, yet preserving much of the essential "same-group" relationships between items that were present in the parents. In Handl and Knowles (2007) it is shown why this encoding is effective compared with some alternatives. We also briefly note other encodings that have been prominent in the history of this subfield. An early approach was that of Jones and Beltramo, who introduced a "permutation with separators" encoding. In this approach, a clustering is encoded by a permutation of the items to be clustered, with a number of separators indicating cluster boundaries. For example, if we have ten items to cluster (A–J) and use S as the separator, the following is a candidate clustering:

A I B H S C G S D E F J

representing the same grouping as that of "Clustering 3" above. Jones and Beltramo offered a variant of this encoding that is a cross between the direct and indirect approaches. In their greedy permutation encoding, a clustering is represented by a permutation (with no separator characters), with the following interpretation: the first k items in the permutation become the centers of the first k clusters. The remaining items, in the order they appear, are added to whichever cluster is best for that item according to the objective function (clustering quality metric) in use.

Applications for Evolutionary Clustering

Recent work on evolutionary clustering has focused on applications of evolu- tionary clustering to data-mining problems in a variety of disciplines, including market segmentation (by Ying, Sudha, Lusch, and Brusco) and social network analysis (by Pizutti). As mentioned above, evolutionary clustering brings key advantages in terms of its accuracy, but, possibly, its most important benefit lies in the flexibility of the approach. The capability to consider and explore trade-offs with respect to multiple clustering objectives opens up new opportu- nities for data integration, particularly in the context of exploratory analytics in applications that involve diverse, noisy (and sometimes poorly understood) data sources.

Definition

Evolutionary computation (EC) is a field in computational intelligence that takes its inspiration from nature to develop methods that resolve continuous optimization and combinatorial optimization problems. When it comes to economics, it is the area of research that involves the use of EC techniques, also subclassified as evolutionary algorithms (EAs), cultural algorithms, and self-organization algorithms, among others, in order to approach topics in economic science. The algorithms, defined as generic population-based metaheuristic optimization algorithms, are developed on the basis of the concept of biological evolution and use iterative processes such as reproduction, mutation, recombination, and selection. Some of these methods, such as genetic algorithms (GAs), genetic programming (GP), evolutionary programming (EP), estimation of distribution algorithms (EDA), evolutionary strategies (ESs), memetic algorithms, harmony search, and artificial life, have been studied and applied in computer science for more than 50 years. In mainstream economics, even though we can track the early application of GAs in game theory to as long ago as 30 years, the adoption of these methods has been slow. This area of knowledge is different from the field of evolutionary economics, which does not necessarily apply EC techniques to the study of economic problems. The use of EC in economics pursues different aims. One is to overcome some of the limitations of classical economic models and to loosen some of the strong assumptions such models make.

Motivation and Background

EC techniques, among many other machine-learning techniques, have proven to be quite flexible and powerful tools in many fields and disciplines, such as computational linguistics, computational chemistry, and computational biology. Economics-affiliated fields are by no means the exception for the widespread use of these evolutionary-inspired methods. In addition to the undeniable necessity of computing in almost every aspect of our modern lives, numerous problems in economics possess an algorithmic nature. Economists should consider computational complexity to be an important analytical tool due to the fact that some of such problems belong to the class of NP-complete (The NP-complete computational complexity class is a subset of harder problems within the NP computational class, which is the set of all the decision problems which can be solved using a nondeterministic Turing machine in polynomial time (Papadimitriou 1994).) problems. This having been said, EC has been intensively used as an alternative approach to analytical methods used to tackle numerous NP-complete problems with considerable success, mainly in the areas of game theory, econometrics, and agent-based economic modeling. Game theory is a branch of applied mathematics that attempts to model an individual's strategic behavior. The first study considered to establish the fundamentals of the field is the book Theory of Games and Economic Behavior (John von and Oskar 1944). The idea behind this theory is that the success of an individual's decisions depends on the decisions of others. Whereas originally, the aim of the theory was to study competition, in which one agent does better at another expense (zero-sum games), now it has been extended to the study of a wider class of interactions among individuals. Furthermore, it is used extensively in economics, biology, and political science, among other disciplines.

The first work in economics (The first such work approached a classic game known as the prisoner's dilemma.) that involved the use of EC dates to the 1980s. In Robert and Hamilton (1981) and Robert (1987) the authors used GAs to derive strategies for the Iterated Prisoner's Dilemma (IPD). From then on, EC techniques in economics were used in areas such as macroeconomics, econometrics, game theory, auctions, learning, and agent-based models. There is even a school of thought in economics known as evolutionary economics (See, for example, Ulrich (2008) for an introduction.) in which the approach to the study of economics involves concepts in evolution but does not necessarily rely on EC techniques.

Econometrics is a field within the wider area of economics which involves the use of statistics and its tools to measure relationships postulated by economic theory (William 2003). In particular, it is applied to macroeconomic analysis to make out the relationships between the aggregated variables that explain broad sectors of an economy. One of the first applications of GP to econometrics was made by the creator of GP himself in John (1992).

Regarding agent-based computational economics, this field can be thought of as a branch of a wider-area, agent-based modeling (Wooldridge 2002). The field of agent-based modeling is not restricted to economics. It has been applied to social sciences in general (Robert 2003), to some classical and not so classical problems in computer science, and in some other disciplines. Axelrod provides an account of his experience using agent-based methodology for several problems, and he suggests that agent-based modeling can be seen as a bridge between disciplines. Axelrod and Tesfatsion provide a good guide to the literature relevant to agent-based modeling in Robert and Leigh (2006). In Shu-Heng (2007) there is a thorough introduction to agents in economics and finance. In this work, Chen conceives of the agents not just as economic agents but also as computational intelligent units.

Structure of the Evolutionary Computation in Economics

The main areas addressed by EC in economics are game theory, econometrics and economic models, and agent-based economic modeling. In game theory, a well-defined mathematical object, the game, consists of a set of players and a set of strategies (decisions) available to those players. In addition, for each combination of strategies, specification of payoffs is provided. The aim of traditional applications of game theory was to find a Nash equilibrium, a solution concept, in which each player of the game adopts a strategy that is unlikely to be changed. This solution concept was named after John Nash, whose work was published in the early 1950s (John 1950). Nevertheless, it took almost 20 years to fully realize what a powerful tool Nash had created. Nowadays, game theory is one of the best established theories in economics, and it has been used extensively to model interactions among economic agents. However, games typically have many Nash equilibria, and one key assumption is that the agents behave in a rational way. In more realistic games, the equilibrium selection problem does not have an easy solution. Human behavior observed in real life, indeed, is frequently irrational. Given these constraints, evolutionary game theory was proposed as an application of the mathematical theory of games to biological contexts. In this field, Maynard Smith is considered to be the first to define the concept of an evolutionary stable strategy in John Maynard (1972). Furthermore, the possibility of using computer modeling as an extension of game theory was first explored in Robert and Hamilton (1981). Since then, computer science has been used in traditional game theory problems, like the strategic behavior of agents in auctions, auction mechanism design, etc. By providing approximate solutions to such complex problems, this approach can be useful where analytical solutions have not been found. For instance, the iterative prisoner's dilemma is one of the games most studied by researchers from computer science (Robert 1987). The prisoner's dilemma is a classic game that consists of the decision-making process for two prisoners who can choose to cooperate or defect from a group. In the case that the two prisoners choose to cooperate, they get a payoff of three each. In the case that both choose to defect, they get a payoff of one each, and in the case that one decides to defect and the other to cooperate, the former gets a payoff of five and the later a payoff of zero. In equilibrium, both players decide to defect despite the fact that it would be better for them to cooperate.

Game theory is one of the most important areas of economics because it has applications to many other fields, such as corporate decision-making, microeconomics, market modeling, public policy analysis, and environmental systems. We can find more applications of EC to game theory than IPD. For example, other work related to game theory and EC is that done by John and Engle-Warnick (2001), which deals with the well-known two-player, repeated ultimatum game. In this work they used GP as a means of inferring the strategies that were played by subjects in economic decision-making experiments. Other research related to game theory includes the duopoly and oligopoly games (Shu-Heng and Ni 2000). References regarding cooperation, coalition, and coordination are also frequent and usually driven by EC techniques (Vriend 1995). In 2006, the authors applied GP to find strategies for sequential bargaining procedure and confirmed that equilibria can be approximated by GP. This provides an opportunity to find approximate solutions to more complex situations for which theoretical solutions have yet to be found.

Regarding econometrics, in Adriana and Alexandr (2001) the authors use GAs and simulated annealing (SA) for econometric modeling; they found that the performance of the evolutionary algorithms (EAs) is better than the performance of traditional gradient techniques on the specific models in which they performed the comparison. Finally, Ralf Östermark (1999) uses a hybrid GA in several ill-conditioned econometric and mathematical optimization problems with good results.

In addition to the use of EC in econometrics, some classical economic models like the cobweb model and exchange-rate models have been approached with EC techniques. For instance, in Jasmina (1994) and Shu-Heng and Chia-Hsuan (1996), in the former work, the author uses GAs to approach the cobweb model, whereas in the latter the authors use GP. Furthermore, Arifovic explores the use of GAs in foreign exchange markets in Jasmina (1996). The GA mechanism elaborated in such works developed decision rules that were used to determine the composition of agents' portfolios in a foreign exchange market. Arifovic made two observations rarely seen in the standard overlapping generations (OLG) model with two currencies. First, she noted that the returns and exchange rates were generated endogenously and, second, that the models' equilibrium dynamics were not stable and showed bounded oscillations (the theoretical model implies a constant exchange rate).

The use of GAs in economic modeling is not restricted to the abovementioned works. In James et al. (1995), the authors studied a version of the growth model in which physical capital is accumulated in a standard form, but human capital accumulation is subject to increasing returns. In their model, the agents make two decisions when they are young: how much to save by renting physical capital to the companies and how much to invest in training. Returns on training depend on the average level of human capital in the economy. The authors introduce agents' learning by means of GAs. In 1990, Marimon develops an economic model in which the agents adapt by means of a GA.

The final approach is agent-based computational models built with EAs for applications in economics (ACEs). In ACEs, one of the main goals is to explain the macro-dynamics of an economy by means of the micro-interactions of the economic agents. This approach to the study of an economy has been called a bottom-up approach in contrast to more traditional approaches. An additional purpose of ACEs is to handle real-world issues, something now possible due to technological advances in computational tools.

Nevertheless, to achieve a realistic representation of the agent in a model allows us to start with a critical revision of the assumptions behind classical economic theory. One of the most important concepts in this context is rationality. It is at the core of most economic models. It is frequently assumed that economic agents behave in a fully rational way. Unfortunately, it is not clear what this assumption holds, especially in view of irrational behavior observed during recurrent financial crises.

Herbert A. Simon is probably the best known scientist to claim that "decision-making" under uncertainty is not a fully rational process. He developed his theory based on the concept of bounded rationality (Herbert 1957). He was one of the pioneers in the field of artificial intelligence (AI), as well as a highly respected psychologist and economist. Later, in Brian (1991), the author made important contributions to the development of agents with bounded rationality using computational tools. Some more recent ideas about rationality from a computer scientist's point of view are found in Edward (2008).

Some other common assumptions behind classical economic theory are that the participants of the model have *homogeneous preferences* and they *interact globally* (Robert 2000). Departing from the assumption of full rationality and homogeneous expectations, the horizon and the design issues vary widely. The modeling of the learning behavior of the agents is a central part of the research agenda in computational economics. Regarding the agents' learning process, Lucas' definition for adaptive behavior from the economic point of view is of extreme importance (Robert 1986). There are many useful techniques to implement this adaptive learning. The application of genetic algorithms

(GAs) in James and John (1999) and genetic programming (GP) in Serafin and Edward (2009) are good examples. GP has been previously described as a suitable way to model economic learning in Bruce (1999). In Thomas (2006), the author provides us a summary of the available options to model agent behavior and learning in economics.

With the use of programming languages, the agent-based approach allows us to represent explicitly agents with bounded rationality and heterogeneous preferences. Given a specific social structure, the simulation of the interaction among agents is the strength and heart of agent-based modeling (ABM). Nowadays ABM is a promising area of research, which has opened the way to social scientists to look for new insights in resolving important real-world issues. Considered the third way of doing science (Robert 2003), modeling the behavior of the autonomous decision-making entities allows researchers to simulate the emergence of certain phenomena in order to gain better understanding of the object of study (Robert 2000). In this sense ACE, defined as the computational study of economic processes modeled as dynamic systems of interacting agents (Leigh 2006), is a growing area inside the field of agent-based modeling. ACE research is developing rapidly. By using machine-learning techniques, researchers model the agents as software programs able to make autonomous decisions. Consequently, the interactions among the individuals at the microlevel give rise to regularities at the macrolevel (globally). The intention is to observe the emerging self-organizing process for a certain period of time, in order to study the presence of patterns or the lack of them. Currently, the study of this self-organizing capability is one of the most active areas of ACE research. EAs have been used for the modeling of the agents' learning in multi-agent simulations. In economics, it is possible to find very different approaches and topics. The following is a small selection from a large body of literature:

Electricity Markets (Massoud 2002) (Learning Classifier System)

Foreign Exchange Markets (Jasmina 1994; Kiyoshi and Kazuhiro 2001) Genetic Algorithms

Payment Card Markets (Biliana et al. 2011) (Population Based Incremental Learning)

Retail Petrol Markets (Heppenstall et al. 2007) (Genetic Algorithms)

Stock Markets (Brian et al. 1997) (Learning Classifier Systems) and;

(Serafin and Edward 2009) (GP)

Definition

Evolutionary computation (EC) in finance is an area of research and knowledge which involves the use of EC techniques in order to approach topics in finance. This area of knowledge is similar to EC in economics; in fact, the areas frequently overlap in some of the topics they approach. The application of EC in finance pursues two main purposes: first, to overcome the limitations of some theoretical models, also departing from some of the assumptions made in those models, and, second, to innovate in this extremely competitive area of research, given the powerful economic incentives to do so.

EC techniques have been widely used in a variety of topics in finance. Among the most relevant we find: financial forecasting, algorithmic and automatic trading, option pricing, portfolio optimization, artificial financial markets, credit rating, credit scoring, bankruptcy prediction, and filtering techniques.

Motivation and Background

Evolutionary computation (EC) is a field in machine learning (ML) in which the techniques developed apply the principle of evolution in different ways. Among the many techniques which have been used in financial applications, one can find genetic algorithms (GAs), genetic programming (GP), learning classifier systems (LCSs), population-based incremental learning (PBIL), grammatical evolution (GE), evolutionary strategies (ESs), memetic algorithms (MAs), and evolutionary nearest neighbor classifier algorithm (ENPC), among many others. In addition, many of the above mentioned techniques are used in combination or as meta-techniques on top of other machine-learning tools. In many financial markets, competition is at the center of everyday activities undertaken by individuals and companies. As a consequence, given this fierce competition and the necessity for innovation, it is natural to find numerous problems in finance being approached by existing EC techniques. For example, in stock markets, individual and institutional investors try to beat the market in order to make more profits than other market participants. Coming up with novel algorithms or techniques is crucial to maintaining their performance and status in relation to competitors.

This area of research has been given many different names, including computational finance and computational intelligence in finance, among others. Research in this area is still evolving. Therefore, it is difficult to define the field clearly or to establish its limits. Moreover, nowadays it is almost impossible to provide a full account of all the relevant work that involves any form of EC in finance. It is also hard to organize the vast amount of human knowledge implicit in the field. The number of specialized journals, meetings, and books is indeed very large and getting larger. Chen (2002a), Chen and Wang (2004), and Chen et al. (2007) exemplify important research in this dynamic field.

Computing in finance is an almost unavoidable tool, from Monte Carlo simulation to computer intensive methods used to price complex derivatives. Furthermore, some of the most crit-

The views expressed here are those of the authors and do not represent the views of the Mexican central bank. The authors are grateful with Alberto Romero Aranda and Dorothy Walton for their valuable comments on this entry.

ical processes in finance make heavy use of computers. Computational finance is a frequently mentioned term, sometimes associated with financial engineering. However, in this context we refer to computational finance as the use of nonconventional computational techniques, like EC or other machine-learning techniques, to tackle problems in finance. See, for example, Tsang and Martinez-Jaramillo (2004) for a good introduction to the field. Additionally, Chen (2002b), Brabazon and O'Neill (2008), and Brabazon and O'Neill (2009) illustrate relevant works in the field.

Financial Forecasting and Algorithmic and Automatic Trading

In recent years, computers have shown themselves to be a powerful tool in financial applications. For that reason, many machine-learning techniques have been applied to financial problems. Financial forecasting is one of the most important fields in the area of computational finance (Tsang and Martinez-Jaramillo 2004). EC has been used to solve a great variety of financial forecasting problems, such as prediction of stock prices changes and their volatility, forecasting in foreign exchange markets, and more. Let us introduce some of the most important research in the financial forecasting area. This does not pretend to be either an extensive or detailed survey of literature in the field. The objective is just to illustrate the use of EC in financial forecasting applications.

Machine-learning classifiers, like other forecasting techniques, extend past experiences into the future. The aim is to analyze past data in order to identify patterns in the interest of creating a model or a set of rules to predict future events. In particular, EC techniques have some characteristics that make them useful for financial forecasting. For example, evolutionary techniques are able to produce interpretable solutions. This characteristic is especially important for predictions, since the main goals of classification are to (1) generate an accurate classification model that should be able to predict unseen cases and (2) discover the predictive structure of a problem (Breiman et al. 1984).

Models which help to understand the structural patterns in data provide information that can be useful for recognizing the variables' interactions. There are classification models that have good predictive power. However, these models provide a poor representation of the solution (take, e.g., the artificial neural networks). Since EC techniques provide not just good predictions but interpretable solutions, they have been used in financial problems to acquire knowledge of the event to predict. For example, Tsang et al. (2004) trained a GP using past data from the financial stock markets to predict price movements of at least $r\,\%$ within a period of at most n time units. The attributes used to train the GP were indicators from technical analysis. Due to the possibility of interpreting the solution, the authors were able to analyze the most successful indicators in the result. In fact, some researchers have used EC in order to discover new financial indicators. This include Allen and Karjalainen (1999), who made use of a GP system to infer technical trading rules from past prices. The algorithm was applied to the S&P 500. Bhattacharyya et al. (2002) used GP to discover trading decision models from high-frequency foreign exchange (FX) market data.

In other related works, Bhattacharyya et al. (2002) used GA for mining financial time series to identify patterns, with the aim of discovering trading decision models. Potvin et al. (2004) applied GP to automatically generate short-term trading rules on the stock markets. The authors used historical pricing and transaction volume data reported for 14 Canadian companies from the Toronto Stock Exchange market. Another approach called grammatical evolution (GE) (Brabazon and O'Neill 2004) was applied to discover new technical trading rules, which can be used to trade on foreign exchange markets. In that approach, each of the evolved programs represents a market trading system.

Additionally, EC techniques are able to generate a set of solutions for a single problem. This characteristic has been used to obtain a set of results with the aim of applying the most suitable solution to the particular problem. For instance, Lipinski (2004) analyzed high-frequency data. The independent variables were composed by 350 expert rules and observations of stock price quotations and order books recorded from the Paris Stock Exchange. In that model, stock market trading rules were combined into stock market trading experts, which defined the trading expertise. The author used a simple GA, a population-based incremental learning (PBIL), a compact genetic algorithm (CGA), and an extended compact genetic algorithm (ECGA) to discover optimal trading experts in a specific situation. The author argues that the optimal solution depends on the specific situation in the stock market, which varies with time. Thus, optimal trading experts must be rebuilt. EC plays an important role in learning and continual adaptation to the changing environment.

Taking advantage of the EC's ability to generate multiple solutions, Garcia-Almanza and Tsang (2008) proposed an approach, called Evolving Comprehensible Rules (ECR), to discover patterns in financial data sets to detect investment opportunities. ECR was designed to classify the minority class in unbalanced environments, which is particularly useful in financial forecasting given that very often the number of profitable opportunities is scarce. That approach offers a range of solutions to suit an investor's risk guidelines. Thus, the user can choose the best trade-off between misclassification and false alarm costs according to the investor's requirements. The approach proposed by Ghandar et al. (2008) was designed to generate trading rules. The authors implemented an adaptive computational intelligent system by using an evolutionary algorithm and a fuzzy logic rule-based representation. The data used to train the system was composed just of volume and price. The authors' objective was to create a system to generate rules to buy recommendations in dynamic market conditions. An analysis of the results was provided by applying the system for portfolio construction to historical data for companies listed on the MSCI Europe Index from 1990 to 2005. The results showed that their approach was able to generate trading rules that beat traditional fixed rule-based strategies, such as price momentum and alpha portfolios, and the approach also beat the market index.

Given that EC can be used as an optimization technique, EC techniques have been combined with other approaches. For example, Chen et al. (1999) used a genetic algorithm to determine the number of input variables and the number of hidden layers in an NN for forecasting Dollar/Deutsche mark foreign exchange rates. Chen and Lu (1999) used GP to optimize a NN. That approach is called evolutionary neural trees (ENTs). The objective was to forecast the high-frequency stock returns of the Heng Seng stock index. Schoreels et al. (2004) investigated the effectiveness of an agent-based trading system. The system employs a simple GA to optimize the trading decisions for every agent; the knowledge is based on a range of technical indicators generating trading signals. In Dempster et al. (2001) the authors aim to detect buy and sell signals in the FX markets. The authors analyze and compare the performance of a GP combined with a reinforcement learning (RL) system to a simple linear program (LP) characterizing a Markov decision process (MDP) and a heuristic in high-frequency (intraday) FX trading. The authors consider eight popular technical indicators used by intraday FX traders based on simple trend indicators such as moving averages as well as more complex rules. From experimental results, the authors found that all methods were able to create significant in-sample and out-of-sample profits when transaction costs are zero. The GP approach generated profits for nonzero transaction costs, although none of the methods produce significant profits at realistic transaction costs.

As is evident, EC techniques allow the representation of solutions using different structures, such as decision trees (Potvin et al. 2004), finite-state automata, graphs, grammar (Brabazon and O'Neill 2004), networks, and binary vectors (Lipinski 2004), among many others. This characteristic lets us choose the best representation for the problem.

Portfolio Optimization

Portfolio optimization is an all-important field in finance. The portfolio selection problem can be described in a simple way as the problem of choosing the assets and the proportion of such assets in an investor's wealth in an effort to maximize profits and minimize risk.

As the name suggests, *portfolio optimization* is an optimization problem and EC has proven to be very useful in difficult (sometimes intractable) optimization problems. In Maringer (2005), the author explains extensively the portfolio optimization problem and the possible heuristic approaches, including Ant Systems (AS), memetic algorithms (MAs), genetic algorithms (GAs), and evolutionary strategies (ESs). For an extensive review from a financial economic perspective, see Brandt (2009).

Being a multi-objective optimization problem, EC provides plenty of opportunities to approach the portfolio optimization problem. For example, Hassan and Clack (2008) uses a multi-objective GP to approach this problem. In Diosan (2005), the author compares different multi-objective evolutionary algorithms for the portfolio optimization problem.

The number of papers on portfolio optimization using machine-learning techniques is large. Streichert et al. (2004), Doerner et al. (2004), and Maringer (2006) are some significant works on portfolio optimization that use some form of evolutionary computation or artificial intelligence.

Multi-objective evolutionary optimization is an important field within EC, and the portfolio optimization problem is not the only application in finance which can be approached. In Coello (2006), the author surveys the literature on multi-objective optimization in economics and finance.

Financial Markets

This section introduces the applications of EC in artificial financial markets. Due to the extensiveness of the literature, only a general overview will be provided. For a more complete and detailed guide to the applications of EC techniques in artificial financial markets, see Martinez-Jaramillo and Tsang (2009a).

Financial markets are essential for financial systems. Such markets represent one of the most efficient ways to allocate financial resources to companies. However, bubbles and crashes are recurrent phenomena which have enormous repercussions for the global economy. Indeed, nowadays we can see as never before that one single crash in one market can lead to a worldwide slump on most of the other stock markets. Moreover, crisis in financial markets can affect other aspects of the (real) economy, for example, interest rates, inflation, unemployment, etc. This, in turn, can cause even more instability on the financial markets.

Financial markets are very important in our lives, whether we like it or not. For example, everyone suffers the consequences of a stock market crash such as the international market crash in 1987. Moreover, this phenomena (market crashes) occurs with an unpleasantly higher frequency than predicted by standard economic theory. Important references on rare disasters and asset markets are Barro (2009), Gabaix (2012), and Gourio (2008). One of the most important research issues in financial markets is an explanation for the process that determines asset prices and, as a result, rates of return. There are many models that can be used to explain such processes, such as the capital asset pricing model (CAPM) (Sharpe 1964), arbitrage pricing theory (APT) (Ross 1976), or Black-Scholes option pricing (Black and Scholes 1973).

Nevertheless, financial markets are very complex to analyze due to the wide variety of participants and their ever-changing nature. The most common approach to study them is by means of analytical models. However, such models have some limitations which, in turn, have led to the search for alternative methods to approach them. Agent-based computational economics (ACE) (Tesfatsion 2002) and computational finance (Tsang and Martinez-Jaramillo 2004) have risen as alternative ways to overcome some of the problems of the analytical models.

Agent-based financial markets with varying characteristics have been developed for the study of such markets in the last decade, since the influential Santa Fe Artificial Market (The Santa Fe Artificial Stock Market is a simulated stock market developed at the Santa Fe Institute. The market was developed by a team of highly regarded researchers, among them is John Holland, the inventor of genetic algorithms Holland 1975.) (Arthur et al. 1997). Some of them differ from the original Santa Fe market in the type of agents used, such as Chen and Yeh (2001), Gode and Sunder (1992), Yang (2002), and Martinez-Jaramillo and Tsang (2009b), and in market mechanisms, such as Bak et al. (1997), Gode and Sunder (1992), and Yang (2002). Other markets borrow ideas from statistical mechanics, such as Levy et al. (1994) and Lux (1998). Some important research has been done modeling stock markets inspired by the minority game (The minority game was first proposed by Yi-Cheng Zhang and Damien Challet (1997) inspired by the El Farol bar problem introduced by Brian Arthur 1994.) like Challet et al. (2000). There are financially simulated markets in which several stocks are traded, such as in Cincotti et al. (2005). However, criticism of this approach centers on the problem of calibration, the numerous parameters needed for the simulation program, and the complexity of simulation, among other problems. The contradictions between existing theory and the empirical properties of stock market returns are the main driving force for some researchers to develop and use different approaches to study financial markets. An additional aspect of the study of financial markets is the complexity of the analytical models of such markets. Prior to the development of some new simulation techniques, very important simplifying (unrealistic) assumptions had to be made in order to allow for the tractability of the theoretical models.

Artificial intelligence and, in particular, EC have been used in the past to study financial and economic problems. However, the development of a well-established community known as the agent-based computational economics community facilitates the study of phenomena in financial markets that was not previously possible. Within this community, a vast number of studies and approaches are being produced in order to solve or gain more understanding of economic problems.

The influential study (Arthur et al. 1997) and previously the development of the concept of bounded rationality in Simon (1982) and Arthur (1991) changed the way in which we conceive and model economic agents. This change in conception dramatically altered the possibilities for studying some economic phenomena and, in particular, financial markets. The new models of economic agents have changed. There is no longer any need for fully rational representative agents or for homogeneous expectations and information symmetry. Furthermore, the development of artificially adapted agents (Holland and Miller 1991) provides a way forward for economic science to study economic systems.

Although they all differ in the sorts of assumptions made, methodology, and tools, these markets share the same essence: the macrobehavior of such markets (usually the price) should emerge endogenously as a result of the microinteractions of the (heterogeneous) market participants. This approach is in opposition to traditional techniques used in economics and finance. Moreover, in Lux and Ausloos (2002) the authors declare:

> Unfortunately, standard modelling practices in economics have rather tried to avoid heterogeneity and interaction of agents as far as possible. Instead, one often restricted attention to the thorough theoretical analysis of the decisions of one (or few) *representative* agents.

The *representative agent* is a common, yet very strong, assumption in the modeling of financial markets. This concept has been the source of controversy and strong criticism. For example, in Kirman (1992), the author criticizes the *representative individual* approach in economics.

In order to understand the approaches in artificial (simulated) financial markets, it is useful to describe the different types of markets on the basis of the framework proposed in LeBaron (2001). In this study, LeBaron identifies the key design issues present in every artificial financial market and describes some of the most important studies up to then. In LeBaron (2006), LeBaron surveys again the literature existing until then. The main design issues identified in LeBaron (2001) are:

- Agents
- Market mechanisms
- Assets
- Learning
- Calibration
- Time

In addition to describing the different approaches in artificial financial markets by using the above-described framework, there is a fairly detailed extension of it in Grothmann (2002) that is worth looking at. In this study, the basic design issues proposed in LeBaron (2001) are extended and given more detail.

Option Pricing

Derivatives (See Hull (2008) for an introduction to derivatives.) are financial instruments whose main purpose is to hedge risk. However, derivatives can also be used to speculate with very negative effects on the financial health of companies, as we all know now. Derivative markets have seen significant expansion in recent years. Futures, forwards, swaps, and options are the best known types of derivatives. Option pricing is an extremely important task in finance. The Black-Scholes model for option pricing is the reference analytical model since it has an important theoretical framework behind it. However, in practice, prices deviate from the prices obtained with this model. One possible reason for the departure is the assumptions being made in the model (the assumption of constant volatility and the assumption that prices follow a geometric Brownian motion). This is why GP was used as an alternative to perform option pricing in Chen et al. (1998), Chidambaran et al. (2002), Fan et al. (2007), and Yin et al. (2007). Interestingly, not only has GP been used to perform option pricing, but also ant colony optimization (ACO) has been explored to approach this important problem in finance (Kumar et al. 2008).

Credit Rating, Credit Scoring, and Bankruptcy Prediction

Credit rating and credit scoring are two examples of financial problems that have been traditionally approached through statistical analysis. A credit rating is an estimate of a corporation's worthiness to be given a credit and is generally expressed in terms of an ordinal value. Credit scoring is a technique used to express the potential risk of lending money to a given consumer in terms of a probability measure. Both techniques are similar in their ends but applied to different domains.

The seminal work in the field of credit scoring is that of Altman (1968), who proposed the application of linear discriminant analysis (Fisher 1936) to a set of measurements known as financial ratios, i.e., indicators of a corporation's financial health obtained from the corporation's financial statements. One of the main applications of Altman's method, also known as the Z-score, is bankruptcy prediction. Understandably, a series of improvements have been achieved by means of applying more powerful classifiers, such as decision trees, genetic programming, neural networks, and support vector machines, among others. References that apply such techniques or conduct a review of the literature on their application are Atiya (2001), Sung et al. (1999), West (2000), Ong et al. (2005), Shin and Lee (2002), Martens et al. (2007), and Huang et al. (2007).

Another method to evaluate credit worthiness is that provided by specialized agencies. The so-called credit ratings are nothing more than ordinal values expressing the financial history, current assets, and liabilities of entities such as individuals, organizations, or even sovereign countries, such that they represent the likelihood of default on any type of debt. Although each rating agency uses its own methodology and scale and these are usually not disclosed, in the academic realm, nevertheless, several superseding techniques to ordinal regression have been applied. For example, Huang et al. (2004), Dutta and Shekhar (1988), Paleologo et al. (2009), and Zhou et al. (2006) have proposed computationally oriented methods to solve this problem.

Related to bankruptcy prediction, NNs have been the standard selection apart from the traditional statistical methods (discriminant analysis, logit and probit models). Quintana et al. (2008) explore the feasibility of using the evolutionary nearest neighbor classifier (ENPC) algorithm suggested by Fernández and Isasi (2004) in the domain of early bankruptcy prediction. They assess its performance comparing it to six alternatives; their results suggest that this algorithm might be considered as a good choice. Another relevant study is Turku et al. (1996) in which the authors compare discriminant analysis, logit analysis, and GAs for the selection of the independent variables used for the prediction model.

Filtering Techniques

Many real-life problems involve the estimation of unknown data from observed (probably noisy) values. Direct estimation methods like the Markov chain Monte Carlo (Andrieu et al. 2003), the sequential Monte Carlo (Doucet et al. 2001), and the particle filter (Gordon et al. 1993) methods are very useful for this task. In addition to the many applications of filtering techniques, filters are also very important tools in finance and economics. Their applications in the fields of macroeconomics, microeconomics, and finance are numerous. To enumerate them all is beyond the scope of this entry.

Among the many variations of filtering techniques, the Kalman filter (Kalman 1960), the extended Kalman filter (Jazwinski 1970), the unscented Kalman filter (Julier and Uhlmann 1997), the particle filter (Gordon et al. 1993), and the hidden Markov model (Baum et al. 1970) are some of those which practitioners use most widely in finance. In economics the Hodrick-Prescott filter (Hodrick and Prescott 1997) is one of the most widely used.

These methods have benefited from the application of EC techniques to optimize over the parameter space and to improve the performance of the methods in particular applications. For example, in O'Sullivan (2007), the authors optimize over the parameter space by using an evolutionary optimizer known as differential evolution (DE) for a Cox, Ingersoll, and Ross term-structure model. The authors in Rezaei et al. (2008) make use of EC techniques to improve the performance of a Kalman filter by means of GAs. In Kumar et al. (2010) the authors tune an extended Kalman filter using different EAs.

In an interesting application of EC techniques in the tuning of Kalman filters, (Huo et al. 2014) determines the initial parameterization of a Kalman filter with a GA, and the parameterization is adaptively updated by means of a Fuzzy Inference System (FIS).

Motivation and Background

The Internet and social networks are key factors that have strongly affected market competition, as they provide customers with more choice in products, services, and prices. For instance, well-established electronic commerce companies such as Amazon, Booking, TripAdvisor, and others provide rankings of their products based on past customer reviews. In the same vein, social networks are a powerful tool to spread good or bad comments about products or services, and they can directly influence potential clients, since the members of the same social network usually share interests and have similar economic levels. For those reasons, marketing teams have focused efforts on creating intelligent business strategies. New artificial intelligence approaches to marketing have emerged, especially evolutionary algorithms used to solve a variety of marketing problems such as the design of attractive products and services for consumers, the analysis of populations or social networks to target potential clients, the design of new marketing strategies, and more. Nowadays, a huge amount of data on almost any kind of human activity has been stored in structured and unstructured forms. The data is a gold mine, the analysis of which can provide useful information for competing more efficiently in the market. For that reason, machine learning techniques have been used to discover useful patterns for creating user-friendly interfaces and new market segments, among other aims. Many evolutionary computational techniques have been applied to marketing problems in order to obtain a commercial advantage over competitors.

Applications

Marketing is a very dynamic area, as it evolves alongside technology and aims to keep promoted products alive in the market.

The Design of New Products

One of the goals of marketing is to discover products of superior value and quality. To achieve this goal in Fruchter et al. (2006), the authors propose to design a product line rather than a single product. The authors argue that by offering a product line, the manufacturer can customize products according to the needs of different market niches, which would result in higher customer satisfaction and more buyers. Nevertheless, as the time required by the amount of data on customer preferences increases, the optimization process of the product line becomes very hard to manage. For that reason, the authors applied the use of genetic algorithms (GAs) to solve the problem heuristically, and the performance of each solution was valued according to the manufacturer's profits. In a similar way, Liu and Ong (2008) used a GA to solve a marketing segmentation problem. In this case, the evolutionary algorithm was applied to reach all customers effectively.

In the approach proposed by Sundar Balakrishnan and Jacob (1996), a GA was used to optimize for customer preference in product design. The authors followed a three-step methodology in order to create a new product. First, the set of attributes subject to adjustment, such as color or shape, was determined. Second, customer preferences were collected. Finally, a GA was applied to select those attributes that satisfy a larger number of customers.

Targeting Potential Clients

Bhattacharyya (2000) proposed a GA in combination with a case-based reasoning (CBR) system to predict customer purchasing behavior. The objective was to identify potential customers for a specific product or service. This approach was developed and tested with real cases by direct marketing from a worldwide insurance company. An optimization mechanism was integrated into the classification system in order to select those customers most likely to acquire an insurance.

Advertisement

Advertisement is an important area of marketing. It is defined as the activity of attracting public attention to a product or business. Since personalized advertisement improves marketing efficiency, Kwon and Moon (2001) proposed a personalized prediction model to be used in email marketing. A circuit model combined with genetic programs (GPs) was proposed to analyze customer information. The result was a set of recommended rules. It was tested over a general mass marketing. According to the authors, the model showed a significant improvement in sales. In another approach, Naik et al. (1998) used a GA combined with a Kalman filter procedure to determine the best media schedule for advertisement, which at the time was constrained by a budget. This approach evaluated a large number of alternative media schedules to decide upon an optimal media planning solution. The Internet has become very popular and convenient for offering and purchasing, since many products and services can be found easily in a very short time, increasing competition among providers. Since these kinds of sales do not directly involve human interaction, it is essential to design new and better strategies to personalize Web pages. For instance, Abraham and Ramos (2003) proposed an ant clustering algorithm to discover Web usage patterns and a linear genetic programming to analyze visitor behavior. The objective was to discover useful knowledge from user interactions with the Web. The knowledge was used to design adaptive Web sites, business and support services, personalization, network traffic flow analysis, and more.

According to Scanlon (2008), the company Staples used a software called Affinnova to redesign and relaunch its paper brand. Affinnova was designed by Waltham, and it uses a GA to simulate the evolution of consumer markets where strong products survive and weak ones die out. The strongest possible design emerges after several generations. A panel of 750 consumers selected their favorite options from each generation. The software analyzed customer choices over multiple generations to identify preference patterns. Surveys included consumer profiles that contain basic demographic information, customer beliefs, and consumer habits. Clients can also segment results and understand how different designs appeal to different consumers. Affinnova's research also helped to identify the imagery and messaging that would most appeal to consumers.

To summarize, EC has been used to solve a wide variety of marketing problems. Given that ECs are global optimization methods, they can be applied to forecasting and data mining. In this respect, they have great potential for use in the field of marketing. EC techniques allow for the extraction and analysis of customer patterns among large amounts of data, and forecasts of purchasing tendencies, among many other aims.

Evolutionary Feature Selection and Construction

Krzysztof Krawiec
Poznan University of Technology, Poznan,
Poland

Abstract

Representation of input data has an essential influence on the performance of machine learning systems. Evolutionary algorithms can be used to transform data representation by selecting some of the existing features (evolutionary feature selection) or constructing new features from the existing ones (evolutionary feature construction). This entry provides the rationale for both these approaches and systematizes the research and applications in this area.

Synonyms

EFSC; Evolutionary constructive induction; Evolutionary feature selection; Evolutionary feature synthesis; Genetic attribute construction; Genetic feature selection

Definition

Evolutionary feature selection and construction (EFSC) is a bio-inspired methodology for explicit modification of input data of a learning system. It uses evolutionary computation (EC) to construct a mapping from the original data representation space onto a *secondary* representation space. In evolutionary feature selection (EFS), that mapping consists in dropping off some of the features (▸ attributes) from the original representation so that the dimensionality of the resulting representation space is not greater than that of the original space. In evolutionary feature construction (EFC), an evolutionary algorithm creates (synthesizes) new features (derived attributes) that complement and/or replace the original ones. Therefore, EFS may be considered as a special case of EFC.

A typical EFSC algorithm maintains a population of solutions, each of them encoding a specific mapping. The best mapping found in evolutionary search becomes the data preprocessor for the classifier. Usually, EFSC takes place in the training phase only, and the evolved mapping does not undergo further changes in the testing phase.

Though EFSC is technically a form of data preprocessing (see ▸ Data Preparation), some of its variants may as well involve an internal inductive process in the fitness function. Also, EFS and EFC may be considered as special cases of ▸ Feature Selection and ▸ Feature Construction, respectively. EFC is also partially inspired by ▸ Constructive Induction.

Motivation and Background

Real-world machine-learning problems often involve a multitude of attributes, which individually have low informative content and cannot provide satisfactory performance of the learning system. This applies in particular to data-abundant domains like image analysis and signal processing. When faced with many low-quality attributes, induction algorithms tend to build classifiers that perform poorly in terms of classification accuracy. This problem may be alleviated by removing some features from the original representation space (*feature selection*) or introducing new features defined as informative expressions (arithmetic, logical, etc.) built of *multiple* attributes (*feature construction*).

Many learning algorithms lack the ability of discovering intricate dependencies between attributes, which is a necessary precondition for successful feature selection and construction. This gap is filled out by EFSC, which uses EC to get rid of superfluous attributes and to construct new features. Benefits of EFSC are similar to those of general ▸ Feature Selection and ▸ Feature Construction and include reduced dimensionality of the input space, better predictive accuracy of the learning system, faster training and querying, and better readability of the acquired knowledge.

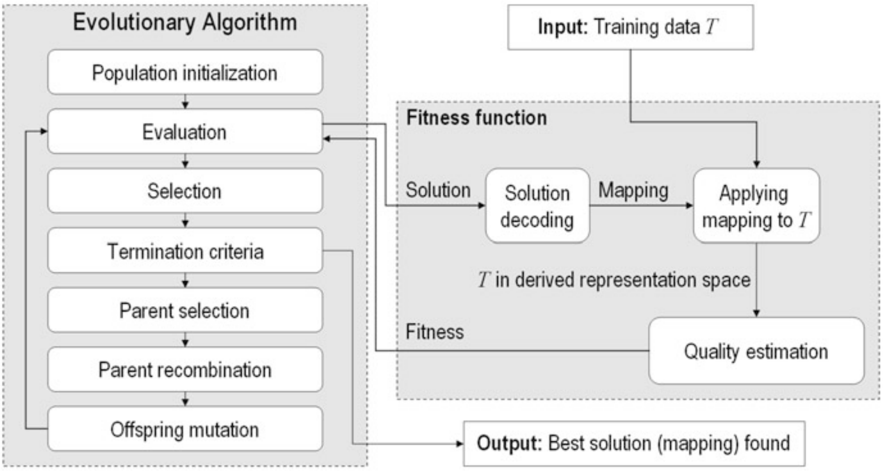
Feature selection and feature construction may be conveniently formulated as an optimization problem with each solution corresponding to a particular feature subset (for feature selection) or to a particular definition of new features (for feature construction). The number of such solutions grows exponentially with the number of original features, rendering the exact search methods infeasible. EC techniques are particularly well-suited to heuristically search these solution spaces. They do not make any assumptions about the optimized function (in contrast to, e.g., the branch-and-bound algorithm) and perform global heuristic search, typically finding high-quality solutions in acceptable time. These virtues are important in EFSC, where the objective function depends on the training data, and it is difficult to predict its properties.

Another strength of EC is easy tailoring to a given task. For instance, a subset of features in EFS is usually encoded as a bit-string solution in genetic algorithm (GA), where a bit at a particular position determines the selection or exclusion of the corresponding feature (Vafaie and Imam 1994; Yang and Honavar 1998). In EFC, definitions of constructed features may be conveniently represented as genetic programming (GP) expressions (Rizki et al. 2002; Teller and Veloso 1997). Also, an evolutionary algorithm naturally produces *many* solutions. This makes it a convenient tool for, e.g., parallel construction of multiple representations (feature subsets) that may be subsequently used in a compound classifier.

Structure of Learning System

Typically, EFSC uses a variant of evolutionary algorithm (usually GA for EFS or genetic programming for EFC) to maintain a population of solutions (individuals), each of them encoding a particular subset of features (for EFS) or definition of new features (for EFC). Solutions undergo mutations, recombinations, and selection. Selective pressure is exerted by a fitness function that estimates a solution's quality by analyzing selected properties of the secondary representation space (see Fig. 1). This usually involves three steps:

1. *Decoding* of solution (retrieving the mapping from the encoded solution).
2. *Transforming* the training set into the secondary representation space according to the mapping.
3. Estimating the *quality* of the secondary representation space, which becomes a solution's fitness.



Evolutionary Feature Selection and Construction, Fig. 1 Evolutionary feature selection and construction

The quality measures employed in step 3 may be grouped into two categories. *Filter approach* relies on the measures that characterize the desired properties of training data in the secondary space (e.g., class separability), abstracting from any particular induction algorithm. *Wrapper approach* estimates the predictive ability in the secondary representation space by a *specific* induction algorithm, usually by partitioning the training set into several subsets and performing multiple train-and-test experiments (e.g., cross-validation). The wrapper approach, though computationally more expensive, takes into account the inductive and representational biases of the employed induction algorithm and thanks to that often proves superior in terms of classification accuracy.

The result of a typical EFSC procedure is the best solution found in an evolutionary run, i.e., the most fit representation mapping. This mapping serves as a preprocessor of input data and is subsequently used to induce the final classifier from the training set. The trained classifier together with the preprocessing provided by the mapping is the final outcome of the EFSC-enriched training process and may be used for classification of new examples.

EFS is the simplest variant of EFSC. In this case, a solution encodes the indices of attributes that should remain in the resulting secondary representation. This leads to straightforward encoding characteristic for GA, with each solution being a bit string as long as the number of original attributes. EFS may be thus easily implemented using off-shelf EA software packages. More sophisticated EFS approaches have been also considered, like evolving GP individuals that *rank* or *score* features (Zhang and Rockett 2011).

Evolutionary feature weighting (EFW) is a direct generalization of EFS, where the evolutionary search weighs the features instead of selecting them. Solutions in EFW are real-valued vectors. EFW requires a wrapper fitness function that can take attribute weights into account. In Komosiński and Krawiec (2000), EFW has been used with a nearest neighbor-based wrapper fitness function to weigh features for a medical diagnosing problem.

EFC usually employs genetic programming to represent feature transformation. Each GP solution encodes an expression tree that uses the original attributes and numeric constants as leaves (terminals) and functions from a predefined vocabulary as internal tree nodes (nonterminals). The value returned by such an expression when applied to an example is interpreted as the new feature. Function set usually encompasses simple arithmetics and elementary functions. The evolved features replace or extend the original ones. If a single new feature is insufficient to provide satisfactory discriminative ability, several GP trees can be encoded within each solution.

EFC is particularly useful in image analysis and computer vision tasks, which naturally tend to involve large numbers of attributes. In such contexts, an EFC algorithm evolves GP solutions that construct higher-level features from low-level image attributes (Krawiec and Bhanu 2005) or implement advanced feature detectors (Howard et al. 2006; Puente et al. 2009). Alternatively, solutions encode chains of operations that process the entire image globally according to the goal specified by the fitness function. Other representations of EFC solutions have been studied as well in GP, including, e.g., graphs (Teller and Veloso 1997) or sequences of operations (Bhanu et al. 2005).

It has been demonstrated that an EFC task may be decomposed into several semi-independent subtasks using cooperative coevolution, a variant of evolutionary algorithm that maintains several populations hosting individuals that encode partial solutions (Krawiec and Bhanu 2005). Other work demonstrates that fragments of GP expressions encoding feature definitions may help to discover good features in other learning tasks (Jaśkowski, Krawiec, and Wieloch 2007).

Applications

Real-world applications of EFSC are numerous and include medical and technical diagnosing, genetics, detection of intrusions in computer networks, air quality forecasting, brain-computer interfaces, seismography, robotics, face recognition, handwriting recognition, vehicle detection in visual, infrared, and radar modality, image segmentation, satellite imaging, and stereovision. EFS has been built into several machine learning and neural network software packages (e.g., WEKA, Statistica). A ready-to-use implementation of EFC is available in RapidMiner; alternatively, it can be facilitated with the existing EC frameworks like ECJ (http://cs.gmu.edu/~eclab/projects/ecj/). More examples of real-world applications of EFSC may be found in Langdon et al. (2009).

Future Directions

Nowadays, EFC becomes more and more unified with GP-based classification and regression, where solutions are expected to perform the complete classification or regression task rather than to implement only feature definitions. Recently, EFSC has also witnessed the growing popularity of the *multiobjective* evolutionary techniques. In EFC, it is now common to include the complexity of feature definition (reflected by program size in GP) as an additional objective alongside the accuracy of classification (Neshatian and Zhang 2011). This is intended to reduce the so-called *program bloat* (the excessive growth of programs that often pesters GP systems) and so curtail overfitting, because complex features are less likely to generalize well. Other studies involve more "helper objectives," like Bayes error estimate (Olague and Trujillo 2012) or Fisher criterion. Domain-specific measures are also occasionally employed in this character. For instance, in a computer vision study (Arnaldo et al. 2014), interest point detectors are evolved using three objectives that capture detector's stability, spatial dispersion of detected points, and their information content.

The online genetic programming bibliography (Langdon et al. 2009) covers most of the works in evolutionary feature selection and construction. A concise review of contemporary GP research involving feature construction for image analysis and object detection may be found in Krawiec et al. (2007). A systematization of different evolutionary approaches to feature construction is also presented in Bhanu et al. (2005).

Evolutionary Fuzzy Systems

Carlos Kavka
University of Trieste, Trieste, Italy

Definition

An evolutionary fuzzy system is a hybrid automatic learning approximation that integrates ▶ fuzzy systems with ▶ evolutionary algorithms, with the objective of combining the optimization and learning abilities of evolutionary algorithms together with the capabilities of fuzzy systems to deal with approximate knowledge. Evolutionary fuzzy systems allow the optimization of the knowledge provided by the expert in terms of linguistic variables and fuzzy rules, the generation of some of the components of fuzzy systems based on the partial information provided by the expert, and in some cases even the generation of fuzzy systems without expert information. Since many evolutionary fuzzy systems are based on the use of genetic algorithms, they are also known as *genetic fuzzy systems*. However, many models presented in the scientific literature also use genetic programming, evolutionary programming, or evolution strategies, making the term *evolutionary fuzzy systems* more adequate. Highly related is the concept of *evolutionary neuro-fuzzy systems*, where the main difference is that the representation is based on neural networks. Recently, the related concept of *evolving fuzzy systems* has been introduced, where the main objective is to apply evolutionary techniques to the design of fuzzy systems that are adequate to the control of nonstationary processes, mainly on real-time applications.

Motivation and Background

One of the most interesting properties of a fuzzy system is its ability to represent expert knowledge by using linguistic terms of everyday common use, allowing the description of uncertainty, vagueness, and imprecision in the expert knowledge. The linguistic terms, which are imprecise by their own nature, are, however, defined very precisely by using fuzzy theory concepts.

The usual approach to build a fuzzy system consists in the definition of the membership functions and the rule base in terms of expert knowledge. Compared with other rule-based approaches, the process of extracting knowledge from experts and representing it formally is simpler, since linguistic terms can be defined to match the terms used by the experts. In this way, rules are defined establishing relations between the input and output variables using these linguistic terms. However, even if there is a clear advantage of using the terms defined as ▸ fuzzy sets, the knowledge extraction process is still difficult and time consuming, usually requiring a very difficult manual fine tuning process. It should be noted that no automatic framework to determine the parameters of the components of the fuzzy system exists yet, generating the need for methods that provide adaptability and learning ability for the design of fuzzy systems.

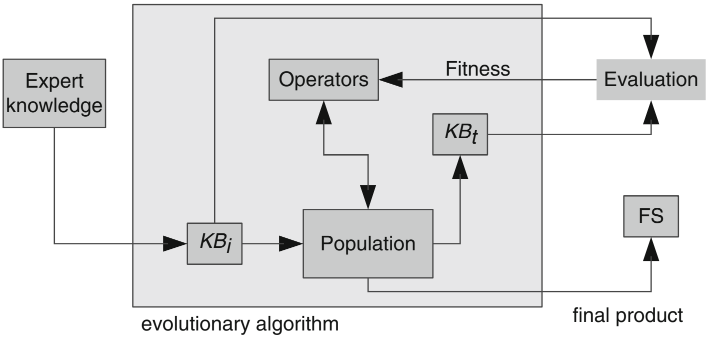
Since it is very easy to map a fuzzy system into a feedforward neural network structure, it is not surprising that many methods based on neural network learning have been proposed to automate the fuzzy system building process (Hoffmann 2001; Karr and Gentry 1993). The combined approach provides advantages from both worlds: the low level learning and computational power of neural networks is joined together with the high level human-like thinking and reasoning of fuzzy systems. However, this approach can still face some problems, such as the potential risk of its learning algorithms to get trapped in local minimum, the possible need for restriction of the membership functions to follow some mathematical properties (like differentiability), and the difficulties of inserting or extracting knowledge in some approaches, where the obtained linguistic terms can exhibit a poor semantic due to the usual black-box processing of many neural networks models.

Evolutionary algorithms provide a set of properties that make them ideal candidates for the optimization and design of fuzzy systems, and in fact, there are many methods that have been proposed in the literature to design or tune the different components of fuzzy systems. Evolutionary systems exhibit robust performance and global search characteristics, while requiring only a simple quality measure from the environment. There is no need for gradient information or input/output patterns. Other strengths come from its parallel nature: instead of selecting a single solution and refining it, in most evolutionary methods, a set of alternative solutions is considered and evolved in parallel.

Structure of the Learning System

The learning process defined by an evolutionary fuzzy system starts from the knowledge provided by the expert, which can include all or just some of the components of the knowledge base of a fuzzy system. The evolutionary algorithm that is behind this learning approach can perform the optimization of all the parameters that are provided by the expert, plus the generation of the missing components of the fuzzy system based on the partial specifications provided by the expert.

The model shown in Fig. 1 presents a general architecture of the learning and optimization process in evolutionary fuzzy systems. An initial knowledge base KB_i is built based on the knowledge provided by the expert. Note that KB_i could be (and usually is) a incompletely specified knowledge base. Based on this initial expert knowledge, the evolutionary algorithm creates a population of individuals, which can represent complete fuzzy systems or just a few components of them. The evaluation of the individuals is performed by creating a temporary knowledge base KB_t, which can also be complete or not. By using the information in KB_t, combined with the initial knowledge base KB_i, the individuals are evaluated by determining the error in the approximation of patterns if there are examples available, computing the reinforcement signal (typical situation in control problems), or in any other way depending on the problem characteristics (Babuska 1998; Cordon et al. 2004). The result



Evolutionary Fuzzy Systems, Fig. 1 The general model of the evolutionary fuzzy systems learning and optimization

of the evaluation is typically a single fitness measure, which provides the necessary information for the selection and the variational operators of the evolutionary algorithm. These operators, which can be standard or defined specifically for the problem, combine and mute the individuals based on the fitness value and their specific parameters. The process is repeated till a predefined criterion is fulfilled, obtaining as a final result the fuzzy system *FS*.

Depending on the information provided by the expert, the learning or optimization process performed by the evolutionary fuzzy system can be applied to the database, the fuzzy rule base or both of them. These three approaches are described below.

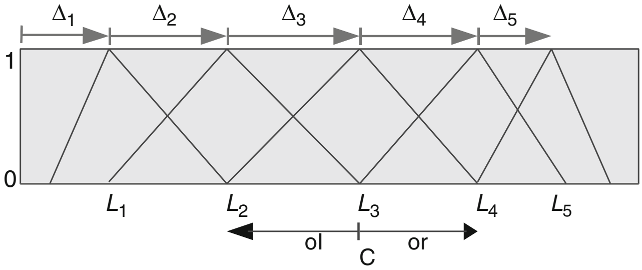
Optimization and Learning of the Fuzzy Database

In this case, it is assumed that the fuzzy rule base is known and provided by the expert. The initial knowledge base KB_i contains the fuzzy rule base, and if provided, the initial approximation of the parameters of antecedents and/or consequents. Since the expert has to define the rule base, and in order to do that, he/she needs to know the labels of the linguistic terms used for the antecedents and consequents, it is usual that the number of fuzzy sets is predefined and kept constant during the evolution.

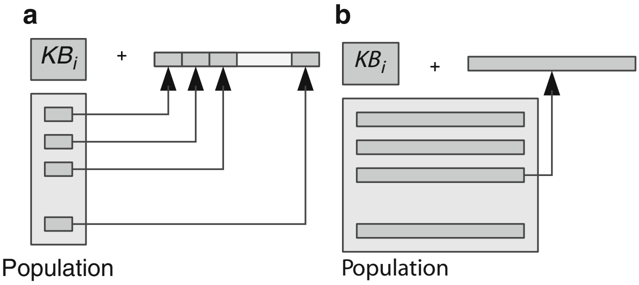
The representation of the individuals contains only the parameters of the fuzzy sets associated to the input linguistic variables, and the fuzzy sets associated to the output variables in the case of a Mamdani fuzzy system, or the associated lineal approximators in the case of a Takagi-Sugeno fuzzy system. Other parameters could also be specified if necessary (scale factors, etc.). Usually, individuals are represented as a fixed length string that is defined as the concatenation of all parameters of the input and output fuzzy sets or approximators. Of course, the representation for the fuzzy sets depends on their particular class: for example, three values are required to represent triangular fuzzy sets, four values to represent trapezoidal fuzzy sets, and two for sigmoidal fuzzy sets. As an example, Fig. 2 shows that three values are necessary to represent a triangular fuzzy set: the center, the left width, and the right width, labeled as c, ol, and od, respectively. From this example, it can be seen that 15 values are required in order to represent the 5 fuzzy sets associated to this single linguistic variable.

However, it is usual to apply fuzzy logic concepts (Zadeh 1988) to simplify the representation, with the implied reduction in the search space, and also, to en- hance the interpretability (Casillas et al. 2003) of the resulting fuzzy system. As an example, it is desirable that the partition associated to a linguistic variable fulfills the completeness property, which establishes that for each point in the input domain, the summation of the membership values of all membership functions must be equal to 1. It is also desirable that the position of the fuzzy sets remains always the same during the evolution, for example in Fig. 2, it means that it is expected that the fuzzy set L_1 will be always at the left of L_2, L_2 always at the left of L_3, and so on. A representation that considers these two requirements can be defined by representing the whole partition specifying the distance from the center of a fuzzy set to the

Evolutionary Fuzzy Systems, Fig. 2 A linguistic variable represented with five fuzzy sets



Evolutionary Fuzzy Systems, Fig. 3 The evaluation of individuals in the (**a**) Michigan and (**b**) Pittsburgh approaches



center of the next one (Hoffmann 2001). The representation of five fuzzy sets then requires only five values (labeled in the figure as Δ_i), which reduces largely the search space and keeps the order of fuzzy sets, while fulfilling the completeness property. Most implementations use real values to represent the parameters.

The operators of the evolutionary algorithm can be standard operators or can be defined specifically based on the selected representation. As an example, operators that modify the width of fuzzy sets, shift the centers, or perform other operations on the fuzzy set representations, linear approximators, or other parameters have been defined in the scientific literature.

Optimization and Learning of the Fuzzy Rule Base

In this case, the fuzzy rule base is not known, or only an initial approximation to it is provided. The other parameters of the knowledge base are known and provided by the expert. The three most usual approximations are

1. Michigan approximation: Each individual of the population codifies a single rule (Bonarini 1996), which means that each individual by itself cannot represent a complete solution to the problem. The knowledge base for evaluation KB_t is built based on the information defined in KB_i and the rules defined by all the individuals from the population combined together (see Fig. 3a). Rules are penalized or rewarded based on its performance during the evaluation. The fuzzy system is then built through the competition of a set of independent rules that have to be learned to collaborate during the evolution.
2. Pittsburgh approximation: Each individual represents the complete rule base. If dynamic creation and removal of rules is allowed, it is necessary to define special variational operators to deal with variable length individuals. Compared with the Michigan approach the evaluation is simpler, since by just combining each individual with KB_i it is possible to build KB_t for evaluation (see Fig. 3b). However, usually, the search space is larger when compared with the Michigan approach.
3. Iterative approximation: Each individual codifies a single rule (Cordon et al. 2001) like in the Michigan approach. However, in each iteration of the algorithm, only the best rule is selected discarding all the others. This selection is based by considering the properties of the rule, such as for example, its covering

degree on a set of examples. The algorithm is then competitive and not cooperative. It is usually necessary to apply algorithms to refine the fuzzy rule set obtained at the end of the evolutionary process, which can include operations, such as for example, the removal of similar rules.

The representation in all of these approximations usually consists of individuals that contain references to the fuzzy sets already defined in KB_i. The representation of each individual can be a sequence of integers where each one is an index to the fuzzy sets associated to the corresponding linguistic variable. As an example, the fuzzy rule base could be represented as a matrix where each cell corresponds to the intersection of the input fuzzy sets, containing the index of the output fuzzy set associated to the rule. It is also possible to represent the fuzzy rule base as a decision table or simply as a list of rules. In these last two cases, the representation can have variable length, allowing to represent fuzzy rule sets with variable size.

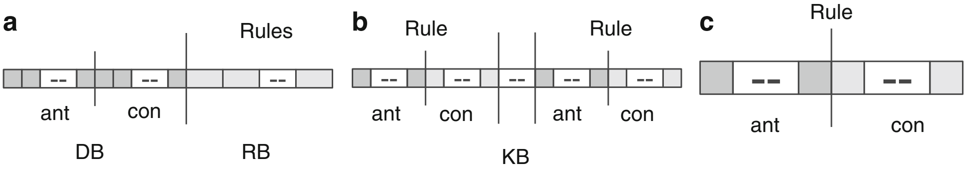
The fitness calculation depends on the selected approximation. On a Pittsburgh approximation, the fitness corresponds to the evaluation of the complete fuzzy system on the corresponding problem. It is also possible to include in the fitness calculation other factors, such as for example, penalization for fuzzy rule bases that contains many rules or fuzzy rules with superposed application areas, etc. On a Michigan or Iterative model, the fitness indicates the degree of adequacy of the rule measured independently, considering also in the Michigan model its degree of cooperation with the other rules in the population.

The definition of the variational operators depends of course on the selected approximation. If the representation allows it, standard operators of crossover and mutation can be used. However, it can be convenient (or necessary) to define specific operators. As an example, variational operators can consider factors such as the time period since the rule has been used for the last time, its overall contribution to the final result, its performance when evaluated on the set of examples, etc.

Optimization and Learning of the Complete Knowledge Base

This case is a combination of the two models described before. The knowledge base KB_i contains the initial approximation to the definition of the antecedents and consequents, and the initial approximation to the fuzzy rule base as provided by the expert. Note that KB_i can also be empty if it is expected that the algorithm must generate all the parameters of the fuzzy system by itself.

The representation of the individuals contains all the parameters that define a knowledge base in order to allow its learning or optimization. The three most used representation schemes are shown in Fig. 4. In the first scheme, each individual contains the representation of all fuzzy sets, and the representation of all fuzzy rules using indexes to refer to the corresponding fuzzy sets. In the second scheme, each individual is structured as a set of rules, where each one specifies its own input and output fuzzy sets by directly including the parameters that define them. The representation (a) is adequate for descriptive fuzzy systems, since the rules contain references



Evolutionary Fuzzy Systems, Fig. 4 Representations for the complete knowledge base adequate for (**a**) descriptive and (**b**) approximative fuzzy systems in the Pittsburgh approximation, and (**c**) representation of a single independent rule adequate for Michigan and Iterative approximations to the fuzzy sets used in their definition and can be shared by all of them. The representation (b) is adequate for approximative fuzzy systems, where each rule defines its own fuzzy sets. These two representations are adequate for the Pittsburgh approximation, while the third one (c) is adequate for the Michigan and the Iterative approximation. Of course, there can be many variations of this representations. For example, the input space partition can be predefined or obtained through fuzzy clustering algorithms, and if this partition is not expected to go under optimization, then it is not necessary to include the parameters of the input fuzzy sets in the representation.

Since this model is a combination of the two previous models, everything that was mentioned before concerning the fitness function and the variational operators also applies in this context. However, the fact that all parameters of the knowledge base are included in the representation allows to define more powerful variational operators. As an example, it is possible to define operators that decide the creation of new fuzzy sets, the elimination of some of them, and at the same time, the adaptation of the associated fuzzy rules, when for example, it is detected that there are areas in the input space that are not well covered, many rules with superimposed areas, etc. It is also possible to apply genetic programming techniques (Pedrycz 2003), which are usually used to modify the structure of the fuzzy system, adding, removing, or combining sections of the fuzzy system with the objective of generating the most adequate structure.

Final Remarks

Clearly, the integration of fuzzy systems with evolutionary algorithms allows to overcome the limitations of each model considered independently, obtaining a powerful hybrid approach, which allows to learn and optimize fuzzy systems based on expert knowledge. Previous sections have discussed in general terms the evolutionary learning model. However, in order to get more details about particular implementations, it is recommended to read the publications referenced in the next section. The presentation from Karr and Gentry (1993) is interesting, not only because it provides a nice introduction and application of evolutionary fuzzy systems, but it has the additional value of being one of the first publications in the area. The presentation of Hoffmann (2001) is an excellent introduction to evolutionary fuzzy systems used for control applications. The other publications present details on evolutionary fuzzy systems (Babuska 1998; Bonarini 1996; Cordon et al. 2001; Juang et al. 2000; Lee and Takagi 1993), including representations based on neural networks (Hoffmann 2001; Karr and Gentry 1993), evolution strategies (Alpaydtn et al. 2002), genetic programming (Pedrycz 2003) and applications of evolutionary fuzzy systems to the domain of recurrent fuzzy systems (Kavka et al. 2005). The paper by Cordon et al. (2004) provides a very comprehensive reference list about the main developments on evolutionary fuzzy systems.

It should be stressed that a very important aspect to consider in the definition of evolutionary fuzzy systems is the interpretability of the resulting fuzzy systems (Casillas et al. 2003). Even if it has been mentioned that it is possible to design an evolutionary fuzzy system without expert information, by allowing the evolutionary algorithm to define all the components of the knowledge base by itself, it must always be considered that the interpretability of the results is essential. Designing a system that solves the problem, but that works as a black box, can be adequate in other contexts, but it is not desirable at all in the context of evolutionary fuzzy systems. An evolutionary fuzzy system algorithm must provide the means so that the expert knowledge defined in fuzzy terms can be considered and used appropriately during the evolution, and also, it must guarantee an adequate interpretability degree of the resulting fuzzy system.

Evolutionary Games

Moshe Sipper
Ben-Gurion University, Beer-Sheva, Israel

Definition

Evolutionary algorithms are a family of algorithms inspired by the workings of evolution by natural selection, whose basic structure is to:

1. Produce an initial *population* of individuals, these latter being candidate solutions to the problem at hand.
2. Evaluate the *fitness* of each individual in accordance with the problem whose solution is sought.
3. *While* termination condition not met *do*:
   (a) *Select* fitter individuals for reproduction
   (b) *Recombine* (*crossover*) individuals
   (c) *Mutate* individuals
   (d) *Evaluate* fitness of modified individuals
4. *End while*

Evolutionary games is the application of evolutionary algorithms to the evolution of game-playing strategies for various games, including chess, backgammon, and Robocode.

Motivation and Background

Ever since the dawn of artificial intelligence in the 1950s, games have been part and parcel of this lively field. In 1957, a year after the Dartmouth Conference that marked the official birth of AI, Alex Bernstein designed a program for the IBM 704 that played two amateur games of chess. In 1958, Allen Newell, J.C. Shaw, and Herbert Simon introduced a more sophisticated chess program (beaten in 35 moves by a 10-year-old beginner in its last official game played in 1960). Arthur L. Samuel of IBM spent much of the 1950s working on game-playing AI programs, and by 1961, he had a checkers program that could play at the master's level. In 1961 and 1963, Donald Michie described a simple trial-and-error learning system for learning how to play tic-tac-toe (or Noughts and Crosses) called MENACE (for Matchbox Educable Noughts and Crosses Engine). These are but examples of highly popular games that have been treated by AI researchers since the field's inception.

Why study games? This question was answered by Susan L. Epstein, who wrote:

> There are two principal reasons to continue to do research on games... First, human fascination with game playing is long-standing and pervasive. Anthropologists have cataloged popular games in almost every culture... Games intrigue us because they address important cognitive functions... The second reason to continue game-playing research

> is that some difficult games remain to be won, games that people play very well but computers do not. These games clarify what our current approach lacks. They set challenges for us to meet, and they promise ample rewards (Epstein 1999).

Studying games may thus advance our knowledge in both cognition and artificial intelligence, and, last but not least, games possess a competitive angle which coincides with our human nature, thus motivating both researcher and student alike.

Even more strongly, Laird and van Lent proclaimed that:

> . . . interactive computer games are the killer application for human-level AI. They are the application that will soon need human-level AI, and they can provide the environments for research on the right kinds of problems that lead to the type of the incremental and integrative research needed to achieve human-level AI (Laird and van Lent 2000).

Recently, evolutionary algorithms have proven a powerful tool that can automatically "design" successful game-playing strategies for complex games (Azaria and Sipper 2005a,b; Hauptman and Sipper 2005b, 2007a,b; Shichel et al. 2005; Sipper et al. 2007).

Structure of the Learning System

Genetic Programming

Genetic programming is a subclass of evolutionary algorithms, wherein a *population* of individual programs is evolved, each program comprising *functions* and *terminals*. The functions are usually arithmetic and logic operators that receive a number of arguments as input and compute a result as output; the terminals are zero-argument functions that serve both as constants and as sensors, the latter being a special type of function that queries the domain environment.

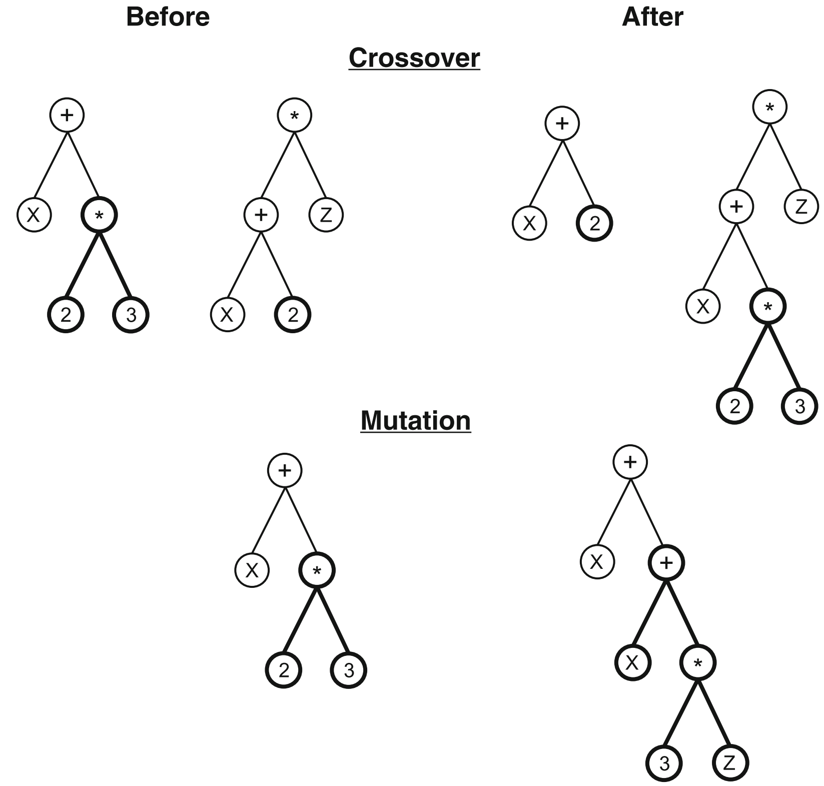
The main mechanism behind genetic programming is precisely that of a generic evolutionary algorithm (Sipper 2002; Tettamanzi and Tomassini 2001), namely, the repeated cycling through four operations applied to the entire population: evaluate-select-crossover-mutate. Starting with an initial population of randomly generated programs, each individual is evaluated in the domain environment and assigned a *fitness* value representing how well the individual solves the problem at hand. Being randomly generated, the first-generation individuals usually exhibit poor performance. However, some individuals are better than others, that is, (as in nature) variability exists, and through the mechanism of natural (or, in our case, artificial) selection, these have a higher probability of being selected to parent the next generation. The size of the population is finite and usually constant.

Specifically, first a genetic operator is chosen at random; then, depending on the operator, one or two individuals are selected from the current population using a *selection operator*, one example of which is *tournament selection*: Randomly choose a small subset of individuals, and then select the one with the best fitness. After the probabilistic selection of better individuals, the chosen genetic operator is used to construct the next generation. The most common operators are:

- Reproduction (unary): Copy one individual to the next generation with no modifications. The main purpose of this operator is to preserve a small number of good individuals.
- Crossover (binary): Randomly select an internal node in each of the two individuals and swap the subtrees rooted at these nodes. An example is shown in Fig. 1.
- Mutation (unary): Randomly select a node from the tree, delete the subtree rooted at that node, and then "grow" a new subtree in its stead. An example is shown in Fig. 1 (the growth operator as well as crossover and mutation are described in detail in Koza 1992).

The generic genetic programming flowchart is shown in Fig. 2. When one wishes to employ genetic programming, one needs to define the following six desiderata:

1. Program architecture
2. Set of terminals



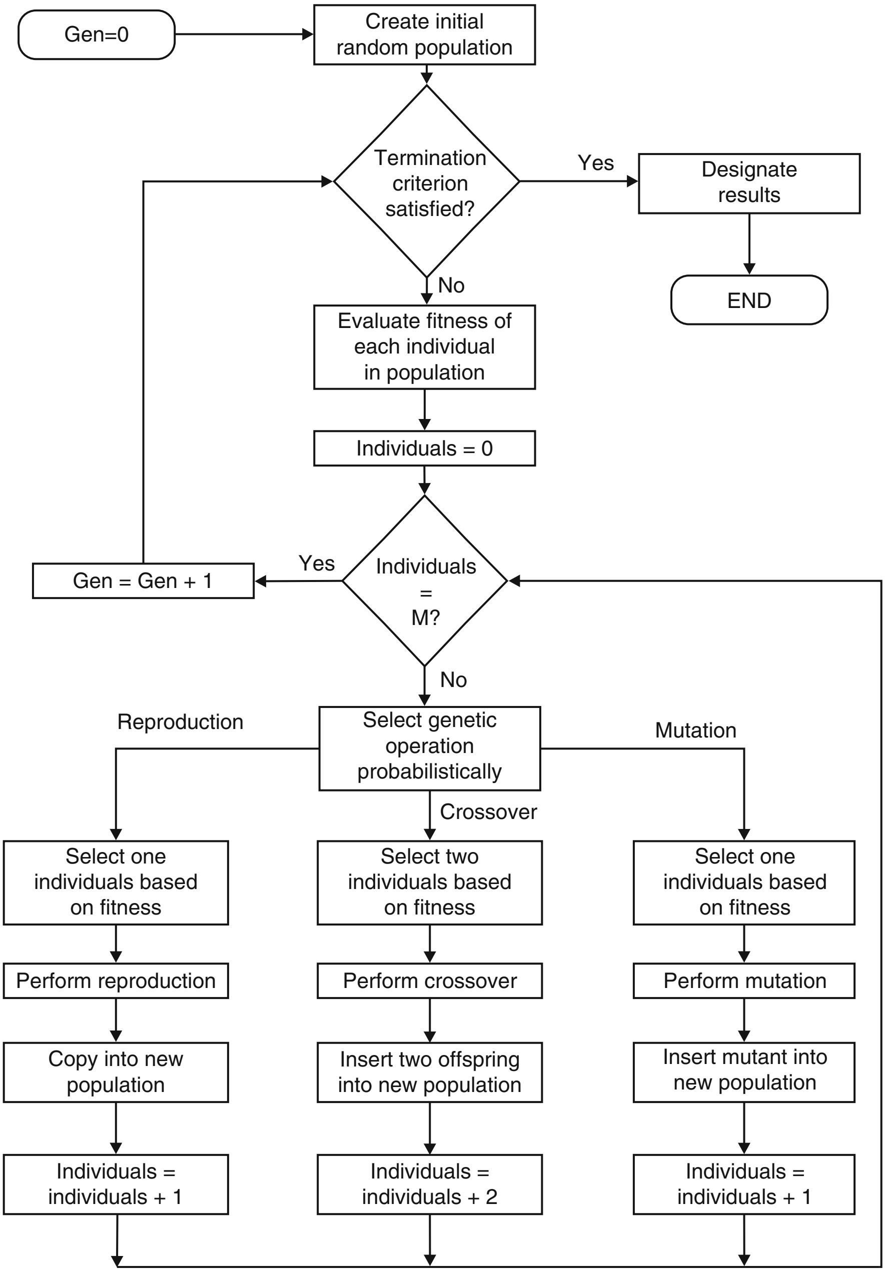
Evolutionary Games, Fig. 1 Genetic operators in genetic programming. LISP programs are depicted as trees. Crossover (*top*): Two subtrees (marked in *bold*) are selected from the parents and swapped. Mutation (*bottom*): A subtree (marked in *bold*) is selected from the parent individual and removed. A new subtree is grown instead

3. Set of functions
4. Fitness measure
5. Control parameters
6. Manner of designating result and terminating run

Evolving Game-Playing Strategies

Recently, we have shown that complex and successful game-playing strategies can be attained via genetic programming. We focused on three games (Azaria and Sipper 2005a,b; Hauptman and Sipper 2005b, 2007a,b; Shichel et al. 2005; Sipper et al. 2007):

1. *Backgammon.* Evolves a full-fledged player for the nondoubling-cube version of the game (Azaria and Sipper 2005a,b; Sipper et al. 2007).
2. *Chess* (endgames). Evolves a player able to play endgames (Hauptman and Sipper 2005b, 2007a,b; Sipper et al. 2007). While endgames typically contain but a few pieces, the problem of evaluation is still hard, as the pieces are usually free to move all over the board, resulting in complex game trees – both deep and with high branching factors. Indeed, in the chess lore, much has been said and written about endgames.
3. *Robocode.* A simulation-based game in which robotic tanks fight to destruction in a closed arena (robocode.alphaworks.ibm.com). The programmers implement their robots in the Java programming language and can test their creations either by using a graphical environment in which battles are held or by submitting them to a central Web site where



Gen=0

Select one individuals based on fitness
Select two individuals based on fitness
Select one individuals based on fitness
Perform reproduction
Perform crossover
Perform mutation
Copy into new population
Insert two offspring into new population
Insert mutant into new population
Individuals = individuals + 1
Individuals = individuals + 2
Individuals = individuals + 1

Evolutionary Games, Fig. 2 Generic genetic programming flowchart (based on Koza 1992). M is the population size, and Gen is the generation counter. The termination criterion can be the completion of a fixed number of generations or the discovery of a good-enough individual

online tournaments regularly take place. Our goal here has been to evolve Robocode players able to rank high in the international league (Shichel et al. 2005; Sipper et al. 2007).

A strategy for a given player in a game is a way of specifying which choice the player is to make at every point in the game from the set of allowable choices at that point, given all the information that is available to the player at that point (Koza 1992). The problem of discovering a strategy for playing a game can be viewed as one of seeking a computer program. Depending on the game, the program might take as input the entire history of past moves or just the current state of the game. The desired program then produces the next move as output. For some games, one might evolve a complete strategy that addresses every situation tackled. This proved to work well with Robocode, which is a dynamic game, with relatively few parameters and little need for past history.

In a two-player game, such as chess or backgammon, players move in turn, each trying to win against the opponent according to specific rules (Hong et al. 2001). The course of the game may be modeled using a structure known as an adversarial game tree (or simply game tree), in which nodes are the positions in the game and edges are the moves. By convention, the two players are denoted as MAX and MIN, where MAX is the player who moves first. Thus, all nodes at odd-numbered tree levels are game positions where MAX moves next (labeled MAX nodes). Similarly, nodes on even levels are called MIN nodes and represent positions in which MIN (opponent) moves next.

The complete game tree for a given game is the tree starting at the initial position (the root) and containing all possible moves (edges) from each position. *Terminal nodes* represent positions where the rules of the game determine whether the result is a win, a draw, or a loss. Although the game tree for the initial position is an explicit representation of all possible paths of the game, therefore theoretically containing all the information needed to play perfectly, for most (nontrivial) games, it is extremely large, and constructing it is not feasible. For example, the complete chess game tree consists of roughly 10^{43} nodes (Shannon 1950).

When the game tree is too large to be generated completely, only a partial tree (called a search tree) is generated instead. This is accomplished by invoking a *search algorithm*, deciding which nodes are to be developed at any given time and when to terminate the search (typically at nonterminal nodes due to time constraints). During the search, some nodes are evaluated by means of an *evaluation function* according to given heuristics. This is done mostly at the leaves of the tree. Furthermore, search can start from any position and not just at the beginning of the game.

Because we are searching for a winning strategy, we need to find a good next move for the current player, such that no matter what the opponent does thereafter, the player's chances of winning the game are as high as possible. A well-known method called the *minimax* search (Campbell and Marsland 1983; Kaindl 1988) has traditionally been used, and it forms the basis for most methods still in use today. This algorithm performs a depth-first search (the depth is usually predetermined), applying the evaluation function to the leaves of the tree and propagating these values upward according to the minimax principal: at MAX nodes, select the maximal value and at MIN nodes – the minimal value. The value is ultimately propagated to the position from which the search had started.

With games such as backgammon and chess, one can couple a current-state evaluator (e.g., board evaluator) with a next-move generator. One can then go on to create a minimax tree, which consists of all possible moves, counter moves, counter counter-moves, and so on; for real-life games, such a tree's size quickly becomes prohibitive. The approach we used with backgammon and chess is to derive a very shallow, single-level tree and evolve "smart" evaluation functions. Our artificial player is thus created by combining an evolved board evaluator with a simple program that generates all next-move boards (such programs can easily be written for backgammon and chess).

In what follows, we describe the definition of the six items necessary in order to employ genetic programming, as delineated in the previous section: program architecture, set of terminals, set of functions, fitness measure, control parameters, and manner of designating result and terminating run. Due to lack of space, we shall elaborate upon one game – Robocode – and only summarize the major results for backgammon and chess.

Example: Robocode

Program Architecture

A Robocode player is written as an event-driven Java program. A main loop controls the tank activities, which can be interrupted on various occasions, called *events*. The program is limited to four lines of code, as we were aiming for the HaikuBot category, one of the divisions of the international league with a four-line code limit. The main loop contains one line of code that directs the robot to start turning the gun (and the mounted radar) to the right. This insures that within the first gun cycle, an enemy tank will be spotted by the radar, triggering a *ScannedRobotEvent*. Within the code for this event, three additional lines of code were added, each controlling a single actuator and using a single numerical input that was supplied by a genetic programming-evolved subprogram. The first line instructs the tank to move to a distance specified by the first evolved argument. The second line instructs the tank to turn to an azimuth specified by the second evolved argument. The third line instructs the gun (and radar) to turn to an azimuth specified by the third evolved argument (Fig. 3).

Terminal and Function Sets

We divided the terminals into three groups according to their functionality (Shichel et al. 2005) (Fig. 4):

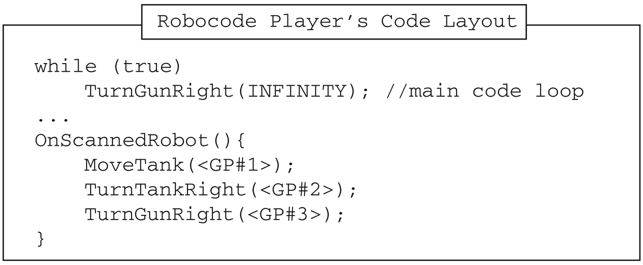
1. Game-status indicators: A set of terminals that provide real-time information on the game status, such as last enemy azimuth, current tank position, and energy levels.
2. Numerical constants: Two terminals, one providing the constant 0 and the other being an ephemeral random constant (ERC). This latter terminal is initialized to a random real numerical value in the range [−1, 1] and does not change during evolution.
3. Fire command: This special function is used to curtail one line of code by not implementing the fire actuator in a dedicated line.

Fitness Measure

We explored two different modes of learning: using a fixed external opponent as teacher and coevolution – letting the individuals play against each other; the former proved better. However, not just one but three external opponents were used to measure performance; these adversaries were downloaded from the HaikuBot league (robocode.yajags.com). The fitness value of an individual equals its average fractional score (over three battles).

Control Parameters and Run Termination

The major evolutionary parameters (Koza 1992) were population size (256), generation count (between 100 and 200), selection method (tournament), reproduction probability (0), crossover probability (0.95), and mutation probability (0.05). An evolutionary run terminates when fitness is observed to level off. Since the game is highly nondeterministic, a "lucky" individual might attain a higher fitness value than better overall individuals. In order to obtain a more accurate measure for the evolved players, we let each of them do battle for 100 rounds against 12 different adversaries (one at a time). The results were used to extract the



Robocode Player's Code Layout

```
while (true)
    TurnGunRight(INFINITY); //main code loop
...
OnScannedRobot(){
    MoveTank(<GP#1>);
    TurnTankRight(<GP#2>);
    TurnGunRight(<GP#3>);
}
```

Evolutionary Games, Fig. 3 Robocode player's code layout (HaikuBot division)

a

Energy()	Returns the remaining energy of the player
Heading()	Returns the current heading of the player
X()	Returns the current horizontal position of the player
Y()	Returns the current vertical position of the player
MaxX()	Returns the horizontal battlefield dimension
MaxY()	Returns the vertical battlefield dimension
EnemyBearing()	Returns the current enemy bearing, relative to the current player's heading
EnemyDistance()	Returns the current distance to the enemy
EnemyVelocity()	Returns the current enemy's velocity
EnemyHeading()	Returns the current enemy heading, relative to the current player's heading
EnemyEnergy()	Returns the remaining energy of the enemy
Constant()	An ERC (Ephemeral Random Constant) in the range [–1,1]
Random()	Returns a random real number in the range [–1,1]
Zero()	Returns the constant 0

b

Add(F, F)	Add two real numbers
Sub(F, F)	Subtract two real numbers
Mul(F, F)	Multiply two real numbers
Div(F, F)	Divide first argument by second, if denominator non-zero, otherwise return zero
Abs(F)	Absolute value
Neg(F)	Negative value
Sin(F)	Sine function
Cos(F)	Cosine function
ArcSin(F)	Arcsine function
ArcCos(F)	Arccosine function
IfGreater(F, F, F, F)	If first argument greater than second, return value of third argument, else return value of fourth argument
IfPositive(F, F, F)	If first argument is positive, return value of second argument, else return value of third argument
Fire(F)	If argument is positive, execute fire command with argument as firepower and return 1; otherwise, do nothing and return 0

Evolutionary Games, Fig. 4 Robocode representation. (**a**) Terminal set (**b**) Function set (*F*: Float)

top player – to be submitted to the international league.

Results

We submitted our top player to the HaikuBot division of the international league. At its very first tournament, it came in third, later climbing to first place of 28 (robocode.yajags.com/20050625/haiku-1v1.html). All other 27 programs, defeated by our evolved strategy, were written by humans. For more details on GP-Robocode see Shichel et al. (2005) and Sipper et al. (2007).

Backgammon and Chess: Major Results

Backgammon

We pitted our top evolved backgammon players against *Pubeval*, a free, public-domain board evaluation function written by Tesauro. The program – which plays well – has become the de facto yardstick used by the growing commu-

Evolutionary Games, Table 1 Percent of wins, advantages, and draws for the best GP-EndChess player in the tournament against two top competitors

	%Wins	%Advs	%Draws
Master	6.00	2.00	68.00
CRAFTY	2.00	4.00	72.00

nity of backgammon-playing program developers. Our top evolved player was able to attain a win percentage of 62.4 % in a tournament against Pubeval, about 10 % higher (!) than the previous top method. Moreover, several evolved strategies were able to surpass the 60 % mark, and most of them outdid all previous works. For more details on GP-Gammon, see Azaria and Sipper (2005a) and Sipper et al. (2007).

Chess (Endgames)

We pitted our top evolved chess-endgame players against two very strong external opponents: (1) a program we wrote ("Master") based upon consultation with several high-ranking chess players (the highest being Boris Gutkin, ELO 2400, International Master) and (2) CRAFTY – a world-class chess program, which finished second in the 2004 World Computer Speed Chess Championship (www.cs.biu.ac.il/games/). Speed chess ("blitz") involves a time limit per move, which we imposed both on CRAFTY and on our players. Not only did we thus seek to evolve good players, but ones who play well *and fast*. Results are shown in Table 1. As can be seen, GP-EndChess manages to hold its own, and even wins, against these top players. For more details on GP-EndChess, see Sipper et al. (2007) and Hauptman and Sipper (2005b).

Deeper analysis of the strategies developed (Hauptman and Sipper 2005a) revealed several important shortcomings, most of which stemmed from the fact that they used deep knowledge and little search (typically, they developed only *one* level of the search tree). Simply increasing the search depth would not solve the problem, since the evolved programs examine each board very thoroughly, and scanning many boards would increase time requirements prohibitively. And so we turned to evolution to find an optimal way to overcome this problem: How to add more search at the expense of less knowledgeable (and thus less time-consuming) node evaluators, while attaining better performance. In Hauptman and Sipper (2007b) *we evolved the search algorithm itself*, focusing on the *Mate-In-N* problem: find a key move such that even with the best possible counterplays, the opponent cannot avoid being mated in (or before) move N. We showed that our evolved search algorithms successfully solve several instances of the Mate-In-N problem, for the hardest ones developing 47 % less game-tree nodes than CRAFTY. Improvement is thus not over the basic alpha-beta algorithm, but over a world-class program using all standard enhancements (Hauptman and Sipper 2007b).

Finally, in Hauptman and Sipper (2007a), we examined a strong evolved chess-endgame player, focusing on the player's emergent capabilities and tactics in the context of a chess match. Using a number of methods, we analyzed the evolved player's building blocks and their effect on play level. We concluded that evolution has found combinations of building blocks that are far from trivial and cannot be explained through simple combination – thereby indicating the possible emergence of complex strategies.

Evolutionary Kernel Learning

Christian Igel
Department of Computer Science, University of Copenhagen, Copenhagen, Denmark

Definition

Evolutionary kernel learning stands for using ▶ evolutionary algorithms to design the ▶ kernel function for a ▶ kernel method.

Motivation and Background

In kernel-based learning algorithms, the kernel function implicitly defines the feature space in which the algorithm operates. The kernel determines the scalar product and thereby the metric in the feature space. Choosing the right kernel function is crucial for the training accuracy and generalization performance of the learning machine. The choice may also influence the runtime and storage complexity during and after training.

The kernel is usually not adapted by the kernel method itself; choosing it is a ▶ model selection problem. In practice, the kernel function is selected from an a priori fixed class. When a parameterized family of kernel functions is considered, kernel adaptation reduces to finding appropriate parameters. The most frequently used method to determine these values is grid search. In simple grid search, the parameters are varied with a fixed step-size through a range of values, and the performance of each combination is measured. Because of its computational complexity, grid search is only suitable for the adjustment of a few parameters. Furthermore, the choice of the discretization of the search space may be crucial. Gradient-based approaches are perhaps the most elaborate techniques for adapting real-valued kernel parameters, see the articles by Chapelle et al. (2002) and Glasmachers and Igel (2005) and references therein. To use these methods, however, the class of kernel functions must have a differentiable structure. Furthermore, score functions for assessing the parameter performance that are not differentiable and/or piecewise constant may cause problems. Evolutionary kernel learning does not suffer from these limitations. Additionally, it allows for ▶ multi-objective optimization (MOO) to address several kernel design criteria.

Structure of Learning System

Canonical evolutionary kernel learning can be described as an evolutionary algorithm (EA) in which the individuals encode kernel functions, see Fig. 1. These individuals are evaluated by determining the task-specific performance of the kernel they represent. Two special aspects must be considered when designing an EA for kernel learning. First, one must decide how to assess the performance (i.e., the fitness) of a particular kernel. That is, model selection criteria have to be defined depending on the problem at hand. Second, one must also specify the subset of possible kernel functions to be searched by the EA. This leads to the questions of how to encode the kernels and which variation operators to employ.

Assessing Fitness: Model Selection Criteria

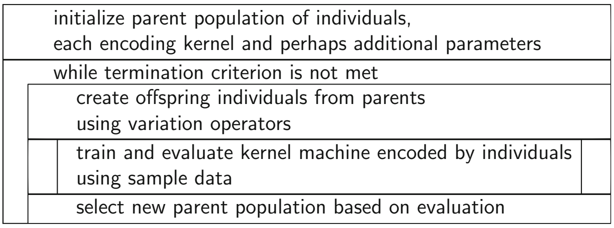
The following presents some performance indices that have been considered for evolutionary kernel learning. They can be used individually or in linear combination for single-objective optimization. In MOO several of these criteria can be used as different objectives.

It is important to note that, although many of these measures are designed to improve ▶ generalization, kernel learning can lead to ▶ overfitting if only limited data are used in the model selection process (e.g., if in every generation, the same small data sets are used to assess performance). Regularization (e.g., in a Bayesian framework) can be used to prevent overfitting. If enough data are available, it is advisable to monitor the generalization behavior of kernel learning using independent data. For example, external data can be used for the early stopping of evolutionary kernel learning (Igel 2013).

Accuracy on Sample Data

The most straightforward way to evaluate a model is to consider its performance on sample data. The empirical risk given by the error on the training data can be considered, but it does not measure generalization. To estimate the generalization performance, the accuracy on data not used for training is evaluated. In the simplest case, the available data are split into a training and validation set, with the first used for learning and the second for subsequent performance assessment. A theoretically sound and simple method is ▶ cross-validation (CV). Cross-validation makes better use of the available data, but it is more computationally demanding.

Using holdout validation sets alone does not prevent overfitting if the validation sets are small and are reused in every generation. If sufficient data are available, it is advisable to resample the data used for fitness evaluation in each generation to prevent overfitting (Igel 2013).



```
initialize parent population of individuals,
each encoding kernel and perhaps additional parameters
while termination criterion is not met
    create offspring individuals from parents
    using variation operators
    train and evaluate kernel machine encoded by individuals
    using sample data
    select new parent population based on evaluation
```

Evolutionary Kernel Learning, Fig. 1 Canonical evolutionary kernel learning algorithm

If ▶ classification is considered, it may be reasonable to split the classification error into false negative and false positive rates and to view ▶ sensitivity and ▶ specificity as two separate objectives (Suttorp and Igel 2006).

Measures Derived from Bounds on the Generalization Performance

Statistical learning theory provides estimates of and bounds on the expected generalization error of learning machines. These results can be utilized as criteria for model selection. One has to keep in mind that the model selection process may lead to violations of the assumptions underlying the corresponding theorems from statistical learning theory, in which case the computed performance indicators can not be strictly interpreted as bounds and unbiased estimates.

An example drawing inspiration from radius-margin bounds for evolving kernels for ▶ support vector machines (SVMs) for classification is given by Igel (2005). Furthermore, the number of support vectors (SVs) was optimized in combination with the empirical risk (Igel 2005). For hard-margin SVMs, the fraction of SVs is an upper bound on the leave-one-out error (e.g., Chapelle et al. 2002).

Number of Input Variables

Variable selection refers to the ▶ feature selection problem of choosing input variables that are best suited for the learning task. Masking a subset of variables can be viewed as modifying the kernel. Considering only a subset of feature dimensions decreases the computational complexity of the learning machine. When deteriorating feature dimensions are removed, the overall performance may increase. Reducing the number of input variables is therefore a common objective, which can be achieved by using single-objective (Eads et al. 2002; Fröhlich et al. 2004; Jong et al. 2004; Miller et al. 2003) or multi-objective (Pang and Kasabov 2004; Shi et al. 2004) evolutionary kernel learning.

Space and Time Complexity of the Classifier

Sometimes it can be very important to have fast kernel methods (e.g., for meeting real-time constraints). Thus, the execution time may be considered in the performance assessment during evolutionary kernel learning.

Reducing the number of input variables speeds up kernel methods. The space and time complexity of SVMs also scales with the number of SVs. This is an additional reason to consider minimization of the number of SVs as an objective in evolutionary model selection for SVMs (Igel 2005; Suttorp and Igel 2006).

Multi-objective Optimization

The design of a learning machine can be considered as a MOO problem. For example, accuracy and complexity can be viewed as different, and probably conflicting, objectives. The goal of MOO is to approximate a diverse set of Pareto-optimal solutions (i.e., solutions that cannot be improved in one objective without getting worse in another one), which provide insights into the trade-offs between the objectives. Evolutionary multi-objective algorithms have become popular for MOO. Applications of multi-objective evolutionary kernel learning combining some of the performance measures listed above can be found in the work of Igel (2005), Pang and Kasabov (2004), Shi et al. (2004), and Suttorp and Igel (2006).

Coevolution

▶ Coevolutionary learning also finds application in evolutionary kernel design. For instance, Gagné et al. (2006) suggest coevolution to speed up the evaluation and optimization of kernel nearest neighbor classifiers. They evolve three different species. The first encodes the kernels, the second a subset of the training examples used for building the classifier, and the third a subset of examples used for fitness evaluation. Kernels and training examples cooperate, while the third species competes with the kernels.

Encoding and Variation Operators

The sheer complexity of the space of possible kernel functions makes it necessary to restrict the search to a particular class of kernel functions. This restriction essentially determines the representation and the operators used in evolutionary kernel learning.

When a parameterized family of mappings is considered, the kernel parameters can be encoded more or less directly in a real-valued EA. This is a frequently used representation, for example, for Gaussian kernel functions.

For variable selection, a binary encoding can be appropriate. For choosing a subset out of d variables, bitstrings of length d can be considered, where each bit indicates whether a particular input variable is considered in the kernel computation or not (Pang and Kasabov 2004; Shi et al. 2004).

Kernels can be built from other kernels. For example, if k_1 and k_2 are kernel functions on X, then $ak_1(\boldsymbol{x}, z) + bk_2(\boldsymbol{x}, z)$ and $a \exp(-bk_1(\boldsymbol{x}, z))$ for $\boldsymbol{x}, z \in X, a, b \in \mathbb{R}^+$ are also kernels on X. This suggests a variable-length representation in which the individuals encode expressions that evaluate to kernel functions.

Given these different search spaces, it is not surprising that the aspects of all major branches of evolutionary computation have been used in evolutionary kernel learning: genetic algorithms (Fröhlich et al. 2004), genetic programming (Howley and Madden 2005; Gagné et al. 2006), evolution strategies (Igel 2005; Friedrichs and Igel 2005), and evolutionary programming (Runarsson and Sigurdsson 2004).

In general, kernel methods assume that the kernel (or at least the ▶ Gram matrix in the training process) is ▶ positive semidefinite (psd). Therefore, it is advisable to restrict the search space such that only psd functions evolve. Other ways of dealing with the problem of ensuring positive semidefiniteness are to assign lethal fitness values to individuals not encoding proper kernels or to construct a psd Gram matrix from the matrix $\boldsymbol{M}$ induced by the training data and a non-psd "kernel" function. The latter can be achieved by subtracting the smallest eigenvalue of $\boldsymbol{M}$ from its diagonal entries.

Gaussian Kernels

Gaussian kernel functions are prevalent. Their general form is $k(\boldsymbol{x}, z) = \exp\left(-(\boldsymbol{x} - z)^{\mathrm{T}} \boldsymbol{A}(\boldsymbol{x} - z)\right)$ for $\boldsymbol{x}, z \in \mathbb{R}^n$ and symmetric positive definite (pd) matrix $\boldsymbol{A} \in \mathbb{R}^{n \times n}$. When adapting $\boldsymbol{A}$, the issue of ensuring that the optimization algorithm only generates pd matrices $\boldsymbol{A}$ arises. This can be achieved by an appropriate parametrization of $\boldsymbol{A}$. Often the search is restricted to matrices of the form $\gamma \boldsymbol{I}$, where $\boldsymbol{I}$ is the unit matrix and $\gamma \in \mathbb{R}^+$ is the only adjustable parameter. However, allowing more flexibility has proven to be beneficial in certain applications (e.g., see Chapelle et al. 2002; Friedrichs and Igel 2005; Glasmachers and Igel 2005). It is straightforward to consider diagonal matrices with positive elements to allow for independent scaling factors weighting the input components. However, only by dropping this restriction one can achieve invariance against both rotation and scaling of the input space. A real-valued encoding that maps onto the set of all symmetric pd matrices can be used such that all modifications of the parameters result in feasible kernels, see the articles by Friedrichs and Igel (2005), Glasmachers and Igel (2005), and Suttorp and Igel (2006) for different parametrizations.

Optimizing Additional Hyperparameters

One of the advantages of evolutionary kernel learning is that it can be easily combined with an optimization of additional hyperparameters of the kernel method. The most prominent example is to encode not only the kernel but also the regularization parameter in evolutionary model selection for SVMs.

Application Example

Notable applications of evolutionary kernel learning include the design of classifiers in bioinformatics (Mersch et al. 2007; Pang and Kasabov 2004; Shi et al. 2004). Let us consider the work by Mersch et al. (2007) as an instructive example. Here, the parameters of a sequence kernel are evolved to improve the prediction of gene starts in DNA sequences. The kernel can be viewed as a weighted sum of 64 kernels, each measuring similarity with respect to a particular trinucleotide sequence (codon). The 64 weights $w_1, \ldots, w_{64}$ are optimized together with an additional global kernel parameter σ and a regularization parameter C for the SVM. Each individual stores $\boldsymbol{x} \in \mathbb{R}^{66}$, where $(w_1, \ldots, w_{64}, \sigma, C)^{\mathrm{T}} = (\exp(x_1), \ldots, \exp(x_{64}), |x_{65}|, |x_{66}|)^{\mathrm{T}}$. An evolution strategy is applied, using additive multivariate Gaussian mutation and weighted global recombination for variation and rank-based selection. The fitness is determined by five fold cross-validation. The evolved kernels lead to higher classification rates, and the adapted weights reveal the importance of particular codons for the task at hand.

Abstract

Evolutionary robotics uses evolutionary search methods to fully or partially design robotic systems, including their control

systems and sometimes their morphologies and sensor/actuator properties. Such methods are used in a range of ways from the fine-tuning or optimization of established designs to the creation of completely novel designs. There are many applications of evolutionary robotics from wheeled to legged to swimming to flying robots. A particularly active area is the use of evolutionary robotics to synthesize embodied models of complete agent behaviors in order to help explore and generate hypotheses in neurobiology and cognitive science.

Synonyms

Embodied evolutionary learning; Evolution of agent behaviors; Evolution of robot control

Definition

Evolutionary robotics involves the use of ▸ evolutionary computing techniques to automatically develop some or all of the following properties of a robot: the control system, the body morphology, and the sensor and motor properties and layout. Populations of artificial genomes (usually lists of characters and numbers) encode properties of autonomous mobile robots required to carry out a particular task or to exhibit some set of behaviors. The genomes are mutated and interbred creating new generations of robots according to a Darwinian scheme in which the fittest individuals are most likely to produce offspring. Fitness is measured in terms of how good a robot's behavior is according to some evaluation criteria; this is usually automatically measured but may, in the manner of eighteenth-century pig breeders, be based on the experimenters' judgment.

Motivation and Background

Turing's (1950) paper, *Computing Machinery and Intelligence*, is widely regarded as one of the seminal works in artificial intelligence. It is best known for what came to be called the Turing test – a proposal for deciding whether or not a machine is intelligent. However, tucked away toward the end of Turing's wide-ranging discussion of issues arising from the test is a far more interesting proposal. He suggests that worthwhile intelligent machines should be adaptive and should learn and develop but concedes that designing, building, and programming such machines by hand is probably completely infeasible. He goes on to sketch an alternative way of creating machines based on an artificial analog of biological evolution. Each machine would have hereditary material encoding its structure, mutated copies of which would form offspring machines. A selection mechanism would be used to favor better adapted machines – in this case, those that learned to behave most intelligently. Turing proposed that the selection mechanism should largely consist of the experimenter's judgment.

It was not until more than 40 years after their publication that Turing's long forgotten suggestions became reality. Building on the development of principled evolutionary search algorithm by, among others, Holland (1975), researchers at CNR, Rome, Case Western University, the University of Sussex, EPFL, and elsewhere independently demonstrated methodologies and practical techniques to evolve, rather than design, the control systems for primitive autonomous intelligent machines (Beer and Gallagher 1992; Cliff et al. 1993; de Garis 1990; Floreano and Mondada 1994; Husbands and Harvey 1992; Parisi and Nolfi 1993). Thus, the field of *Evolutionary Robotics* was born in the early 1990s. Initial motivations were similar to Turing's: the hand design of intelligent adaptive machines intended for operation in natural environments is extremely difficult, would it be possible to wholly or partly automate the process?

Today, the field of evolutionary robotics has expanded in scope to take in a wide range of applications, including promising new work on autonomous flying machines (Floreano et al. 2008; Vargas et al. 2014; Shim and Husbands 2007), as well as research aimed at exploring specific scientific issues – for instance, principles from neuroscience or questions in cognitive science (Harvey et al. 2005; Philippides et al. 2005; Floreano et al. 2008; Husbands et al. 2014). Such work is able to exploit the fact that evolutionary robotics operates with fewer assumptions about neural architectures and behavior-generating mechanisms than other methods; this means that whole general classes of designs and processes can be explored.

Structure of the Learning System

The key elements of the evolutionary robotics approach are the following:

- An artificial genetic encoding specifying the robot control systems, body plan, sensor properties, etc., along with a mapping to the target system
- A method for measuring the fitness of the robot behaviors generated from these genotypes
- A way of applying selection and a set of "genetic" operators to produce the next generation from the current

The structure of the overall evolutionary process is captured in Fig. 1. The general scheme is like that of any application of an evolutionary search algorithm. However, many details of specific parts of the process, particularly the evaluation step, are peculiar to evolutionary robotics.

The more general parts of the evolutionary process (selection, breeding, genetic operators such as mutation and crossover, replacement, and population structure) are also found in most other applications of evolutionary computing, and, just as in those other applications, there are many well-documented ways of implementing each (De Jong 2006; Eiben and Smith 2003). Hence, this section focuses on genetic encoding and evaluation as a route to more evolutionary robotics-specific issues. For a much fuller treatment of the subject, see Vargas et al. (2014), Doncieux et al. (2011), Floreano et al. (2008), and Nolfi and Floreano (2000).

Genetic Encoding

While, as already mentioned, many aspects of the robot design can potentially be under genetic control, *at least* the control system always is. By far the most popular form of controller is some sort of neural network. These range from straightforward feedforward networks of simple elements (Floreano and Mondada 1994) to relatively complex, dynamic, and plastic recurrent networks (Beer and Gallagher 1992; Floreano and Urzelai 2000; Philippides et al. 2005), as illustrated in Fig. 2. In the simplest case, a fixed architecture network is used to control a robot whose sensors feed into the network which in turn feeds out to the robot motors. In this scenario, the parameters of the network (connection weights and relevant properties of the units such as thresholds or biases) are coded as a fixed length string of numerical values.

A more complex case, which has been explored since the very early days of evolutionary robotics (Cliff et al. 1993), involves the evolution of the network architecture as well as the properties of the connections and units. Typically, the size of the network (number of units and connections) and its architecture (wiring diagram) are unconstrained and free to evolve. This involves more complex encodings which can grow and shrink, as units and connections are added or lost, while allowing a coherent decoding of connections between units. These range from relatively simple strings employing blocks of symbols that encode a unit's properties and connections relative to other units (Cliff et al.) to more indirect schemes that make use of developmental, growth processes in some geometric or topological space (Philippides et al. 2005; Stanley et al. 2009) or employ genetic programming-like tree representations in which whole subbranches can be added, deleted, or swapped over (Gruau 1995).

The most general case involves the encoding of control network and body and sensor properties. Various kinds of developmental schemes have been used to encode the construction of body morphologies from basic building blocks, both in simulation and in the real world. The position and properties of sensors can also be

The connection weights, and sometimes the neuron properties, are put under evolutionary control. On the *right* a more complex architecture is illustrated. In this case, the whole architecture, including the number of neurons and connections, is under evolutionary control, along with connection and neuron properties and the morphology of a visual sensor that feeds into the network

put under evolutionary control. Sometimes one complex encoding scheme is used for all aspects of the robot under evolutionary control, and sometimes the different aspects are put on separate genotypes.

Fitness Evaluation

The fitness of members of the population is measured, via an evaluation mechanism, in terms of the robot behaviors produced by the control system or control system plus robot morphology that it encodes. Fitness evaluation, therefore, consists of translating the genome in question into a robot instantiation and then measuring the aspects of the resulting behavior. In the earliest work aimed at using evolutionary techniques to develop neurocontrollers for particular physical robots, members of a population were downloaded in turn onto the robot and their behavior was monitored and measured either automatically by clever experimental setups (Floreano and Mondada 1994; Harvey et al. 1994) or manually by an observer (Gruau and Quatramaran 1997). The machinery of the evolutionary search algorithm was managed on a host computer, while the fitness evaluations were undertaken on the target robot.

One drawback of evaluating fitness on the robot is that this cannot be done any quicker than in real time, making the whole evolutionary process rather slow. However, in the early work in the field, this approach was taken because it was felt that it was unlikely that simulations could be made accurate enough to allow proper transfer of evolved behavior onto the real robot. However, a careful study of accurate physics-based simulations of a Khepera robot, with various degrees of noise added, proved this assumption false (Jakobi et al. 1995). This led to the development of Jakobi's minimal simulation methodology (Jakobi 1998a), whereby computationally very efficient simulations are built by modeling only those aspects of the robot–environment interaction deemed important to the desired behavior and masking everything else with carefully structured noise (so that evolution could not come to rely on any of those features). These ultrafast, ultralean simulations have successfully been used with many different forms of robot and sensing, with very accurate transfer of behavior from simulation to reality. An alternative approach uses plastic controllers that further adapt through self-organization to help smooth out the differences between an inaccurate simulation and the real world (Urzelai and Floreano 2001). Instead of evolving connection weights, in this approach "learning rules" for adapting connection strengths are evolved – this results in controllers that continually adapt to changes in their environment. For details of further approaches, see Floreano et al. (2008). Much evolutionary robotics work now makes use of simulations; without them it would be impossible to do the most ambitious work on the concurrent evolution of controllers and body morphology (Lipson and Pollack 2000) (to be briefly described later). However, although simulation packages and techniques have developed rapidly in the past few years, there will still inevitably be discrepancies between simulation and reality, and the lessons and insights of the work outlined above should not be forgotten.

An interesting distinction can be made between implicit and explicit fitness functions in evolutionary robotics (Nolfi and Floreano 2000). In this context, an explicit fitness function rewards specific behavioral elements – such as traveling in a straight line – and hence shapes the overall behavior from a set of specific behavioral primitives. Implicit fitness functions operate at a more indirect, abstract level – fitness points are given for completing some task but they are not tied to specific behavioral elements. Implicit fitness functions might involve components such as maintaining energy levels or covering as much ground as possible, components that can be achieved in many different ways. In practice, it is quite possible to define a fitness function that has both explicit and implicit elements. Often fitness entails multiple and potentially conflicting elements, so methods from multi-objective optimisation have been introduced by some researchers, which can also encourage diversity in robot behavior (Mouret and Doncieux 2012).

Advantages

Potential advantages of this methodology include:

- The ability to explore potentially unconstrained designs that have large numbers of free variables. A *class* of robot systems (to be searched) is defined rather than specific, fully defined robot designs. This means fewer assumptions and constraints are necessary in specifying a viable solution.

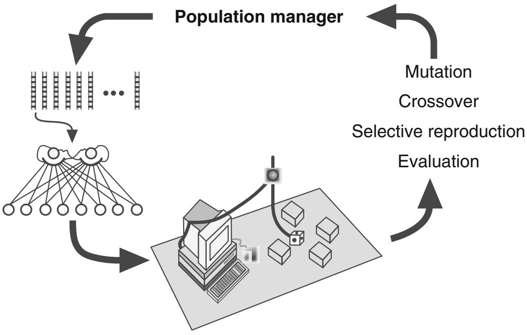
- The ability to use the methodology to fine-tune the parameters of an already successful design.
- The ability, through the careful design of fitness criteria and selection techniques, to take into account multiple, and potentially conflicting, design criteria and constraints (e.g., efficiency, cost, weight, power consumption, etc.).
- The possibility of developing highly unconventional and minimal designs.
- The ability to explicitly take into account robustness and reliability as major driving force behind the fitness measure, factors that are particularly important for certain applications.

Applications

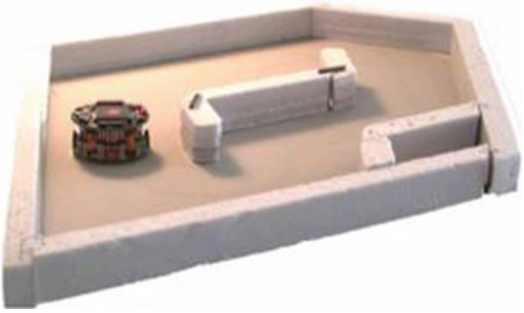
For a detailed survey of applications of evolutionary robotics, see Floreano et al. (2008) and Vargas et al. (2014); this section gives a brief overview of some areas covered by the methodology to give a better idea of the techniques involved and to indicate the scope of the field.

Prominent early centers for research in this area were EPFL and Sussex University, both of which are still very active in the field. Much of the early EPFL work used the miniature Khepera robot (Mondada et al. 1993), which became a popular tool in many areas of robotics research. In its simplest form, it is a two-wheeled cylindrical robot with a ring of IR sensors around its body. The first successful evolutionary robotics experiments at EPFL employed the setup illustrated in Figs. 3 and 4. A population of bit strings encoded the connection weights and node thresholds for a simple fixed architecture feedforward neural network. Each member of the population was decoded into a particular instantiation of a neural network controller which was then downloaded onto the robot (Floreano and Mondada 1994). This controlled the robot for a fixed period of time as it moved around the environment shown in Fig. 4.

The following simple fitness function was used to evolve obstacle avoidance behaviors:



Evolutionary Robotics, Fig. 3 Setup for early EPFL evolutionary robotics experiments with the Khepera robot (see text for details). Used with permission

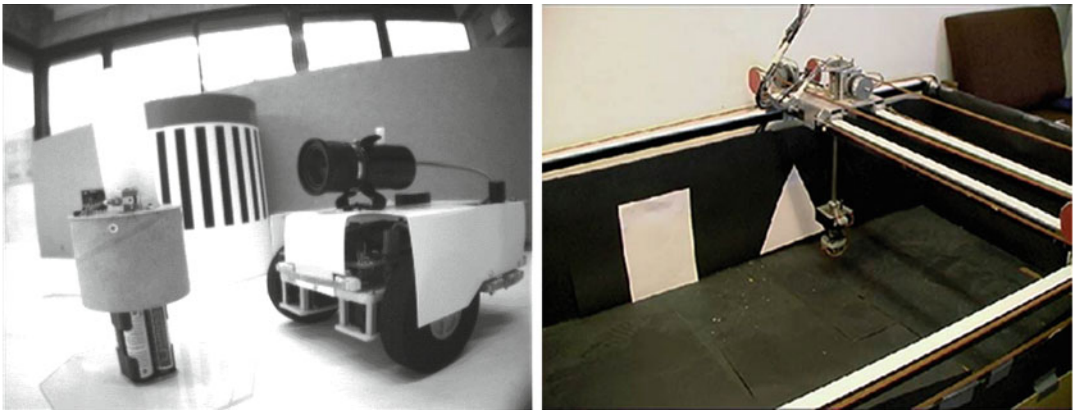


Evolutionary Robotics, Fig. 4 The simple environment used for evolving obstacle avoidance behaviors with a Khepera robot. Used with permission

$$F = V + (1 - \sqrt{DV}) + (1 - I)$$

where V is the average rotation speed of opposing wheels, DV is the difference between signed speed values of opposing wheels, and I is the activation value of the IR sensor with the highest input (readings are high if an obstacle is close to a sensor). Maximizing this function ensures high speed, a tendency to move in straight lines, and avoidance of walls and obstacles in the environment. After about 36 h of real-world evolution using this setup, controllers were evolved that successfully generated efficient motion around the course, avoiding collisions with the walls.

At the same time as this work was going on at EPFL, a series of pioneering experiments on evolving visually guided behaviors were being performed at Sussex University (Cliff et al. 1993; Harvey et al. 1994) in which discrete-



Evolutionary Robotics, Fig. 5 An early version of the Sussex gantry robot (*right*) was a "hardware simulation" of a robot such as that shown on the *left*. It allowed real-world evolution of visually guided behaviors in an easily controllable experimental setup (see text for further details)

time dynamical recurrent neural networks and visual sampling morphologies were concurrently evolved to allow a gantry robot (as well as other more standard mobile robots) to perform various visually guided tasks. An early instantiation of the Sussex gantry robot is shown in Fig. 5.

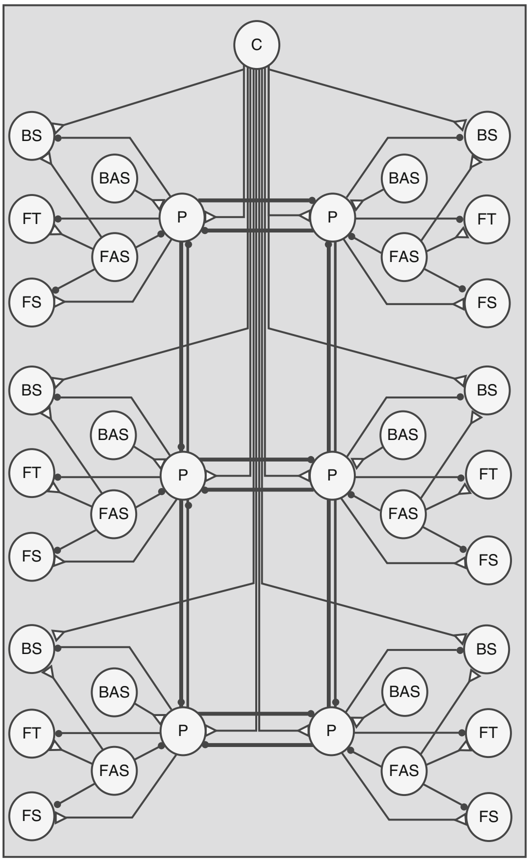
A CCD camera points down toward a mirror angled at 45°. The mirror can rotate around an axis perpendicular to the camera's image plane. The camera is suspended from the gantry allowing motion in the X, Y, and Z dimensions. This effectively provides an equivalent to a wheeled robot with a forward facing camera when only the X and Y dimensions of translation are used (see Fig. 5).

The apparatus was initially used in a manner similar to the real-world EPFL evolutionary robots setup illustrated in Fig. 3. A population of strings encoding robot controllers and visual sensing morphologies are stored on a computer to be downloaded one at a time onto the robot. The exact position and orientation of the camera head can be accurately tracked and used in the fitness evaluations. A number of visually guided navigation behaviors were successfully achieved, including navigating around obstacles and discriminating between different objects. In the experiment illustrated in Fig. 5, starting from a random position and orientation, the robot has to move to the triangle rather than the rectangle. This has to be achieved irrespective of the relative positions of the shapes and under very noisy lighting conditions. The architecture and all parameters of recurrent neural network controllers were evolved in conjunction with visual sampling morphologies – only genetically specified patches from the camera image were used (by being fed to input neurons according to a genetic specification), the rest of the image is thrown away. This resulted in extremely minimal systems only using two or three pixels of visual information yet still able to very robustly perform the task under highly variable lighting conditions. Behaviors were evolved in an incremental way, with more complex capabilities being evolved from populations of robots that were successful at some simpler task (for details see Harvey et al. 1994 and Harvey et al. 1997). The highly minimal yet very robust systems developed highlighted the potential for evolutionary robotics techniques in areas such as space exploration where there is a great pressure to minimize resources while maintaining reliability (Hobbs et al. 1996).

Since this early work, many different behaviors have been successfully evolved on a wide range of robots (Floreano et al. 2008; Nolfi and Floreano 2000; Vargas et al. 2014; Doncieux et al. 2011). There is not enough room to give an adequate summary of the whole field, so a few interesting subareas are highlighted below.

Over the past 15 years or so, there has been a growing body of work on evolving controllers for various kinds of walking robots – a nontrivial sensorimotor coordination task. Early work in this area concentrated on evolving dynamical network controllers for simple simulated insects (often inspired by cockroach studies), which were required to walk in uncomplicated environments (e.g., de Garis 1990; Beer and Gallagher 1992). The promise of this work soon led to versions of this methodology being used on real robots. Probably, the first success in this direction was by Lewis et al. (1992) who evolved a neural controller for a simple hexapod robot, using coupled oscillators built from continuous-time, leaky-integrator, artificial neurons. The robot was able to execute an efficient tripod gait on flat surfaces. All evaluations were done on the actual robot with each leg connected to its own pair of coupled neurons, leg swing being driven by one neuron, and leg elevation by the other. These pairs of neurons were cross-connected, in a manner similar to that used in the neural architecture shown in Fig. 6, to allow coordination between the legs. This architecture for locomotion, introduced by Beer et al. (1989), was based on the studies of cockroaches and has been much used ever since. Gallagher et al. (1996) used a generalization of it to evolve controllers for generating locomotion in a hexapod robot. This machine was more complex than Lewis et al.'s, with a greater number of degrees of freedom per leg. In this work, each leg was controlled by a fully connected network of five continuous-time, leaky-integrator neurons, each receiving a weighted sensory input from that leg's angle sensor. The connection weights and neuron time constants and biases were under genetic control. This produced efficient tripod gaits for walking on flat surfaces. In order to produce a wider range of gaits operating at a number of speeds such that rougher terrain could be successfully negotiated, a slightly different distributed architecture, more inspired by stick insect studies, was found to be more effective (Beer et al. 1997).

Jakobi (1998b) successfully used his minimal simulation techniques to evolve controllers for an eight-legged robot. Evolution in simulation took less than 2 h on what would today be regarded as a very slow computer and then transferred successfully to the real robot. Jakobi evolved modular controllers based on Beer's continuous recurrent network architecture to control the robot as it engaged in walking about its environment, avoiding obstacles and seeking out goals. The robot could smoothly change gait, move backward and forward, and even turn on the spot. More recently, related approaches have been successfully used to evolve controllers for more mechanically sophisticated robots such as the Sony Aibo (Tllez et al. 2006). In the last few years, there has also been successful work on evolving coupled oscillator style neural



Evolutionary Robotics, Fig. 6 Schematic diagram of a distributed neural network for the control of locomotion as used by Beer et al. Excitatory connections are denoted by *open triangles*, and inhibitory connections are denoted by *filled circles*. *C*, command neuron; *P*, pacemaker neuron; *FT*, foot motor neuron; *FS* and *BS*, forward swing and backward swing motor neurons; *FAS* and *BAS*, forward and backward angle sensors. Reproduced with permission controllers for the highly unstable dynamic problem of biped walking. Reil and Husbands (2002) showed that accurate physics-based simulations using physics engine software could be used to develop controllers able to generate successful bipedal gaits. Reil and colleagues have now significantly developed this technology to exploit its commercial possibilities in the animation and games industries (see www.naturalmotion.com for further details). Vaughan has taken related work in another direction. He has successfully applied evolutionary robotics techniques to evolve a simulation of a 3D ten degree of freedom bipedal robot. This machine demonstrates many of the properties of human locomotion. By using passive dynamics and compliant tendons, it conserves energy while walking on a flat surface. Its speed and gait can be dynamically adjusted and it is capable of adapting to discrepancies in both its environment and its body's construction (Vaughan et al. 2004). In general, the evolutionary development of neural network walking controllers, with their intricate dynamics, produces a wider range of gaits and generates smoother, more adaptive locomotion than the more standard use of finite state machine-based systems employing parameterized rules governing the timing and coordination of individual leg movements.

Early single robot research was soon expanded to handle interactions between multiple robots. Floreano and Nolfi did pioneering work on the coevolution of predator–prey behaviors in physical robots (Floreano et al. 2007). The fitness of the prey robot was measured by how quickly it could catch the prey; the fitness of the prey was determined by how long it could escape the predator. Two Khepera robots were used in this experiment, each had the standard set of proximity sensors but the predator also has a vision system, and the prey was able to move twice as fast as the predator. A series of interesting chasing and evasion strategies emerged. Later Quinn et al. (2003) demonstrated the evolution of coordinated cooperative behavior in a group of robots. A group of robots equipped only with IR proximity sensors were required to move as far as possible as a coordinated group starting from a random configuration. The task was solved by the robots adopting and then maintaining a specific formation. Analysis of the best evolved solution showed that it involved the robots adopting different roles, with the identical robots collectively "deciding" which robot would perform each role. Given the minimal sensing constraints, the evolved system would have proved extremely difficult to have designed by hand. For discussion of other multiple robot behaviors, see Floreano et al. (2008) and Vargas et al. (2014).

In the work described so far, control systems have been evolved for preexisting robots: the brain is constrained to fit a particular body and set of sensors. Of course in nature, the nervous system evolved simultaneously with the rest of the organism. As a result, the nervous system is highly integrated with the sensory apparatus and the rest of the body: the whole operates in a harmonious and balanced way – there are no distinct boundaries between the control system, the sensors, and the body.

Karl Sims started to explore the concurrent evolution of the brain and the body in his highly imaginative work involving simulated 3D "creatures" (Sims 1994). In this work, the creatures coevolved under a competitive scenario in which they were required to try and gain control of a resource (a cube) placed in the center of an arena. Both the morphology of the creatures and the neural system controlling their actuators were under evolutionary control.

Lipson and Pollack (2000), working at Brandeis University, pushed the idea of fully evolvable robot hardware about as far as was reasonably technologically feasible at the time. In an important piece of research, directly inspired by Sims' earlier simulation work, autonomous "creatures" were evolved in simulation out of basic building blocks (neurons, plastic bars, and actuators). The bars could connect together to form arbitrary truss structures with the possibility of both rigid and articulated substructures. Neurons could be connected to each other and to the bars whose length they would then control via a linear actuator. Machines defined in this way were required to move as far as possible in a limited time. The fittest individuals were then fabricated robotically

Evolutionary Robotics, Fig. 7 A fully automatically evolved robot developed on the Golem project (see text for details). Used with permission

using rapid manufacturing technology (plastic extrusion 3D printing) to produce results such as that shown in Fig. 7. They thus achieved autonomy of design and construction using evolution in a "limited universe" physical simulation coupled to automatic fabrication. The highly unconventional designs thus realized performed as well in reality as in simulation. The success of this work points the way to new possibilities in developing energy-efficient fault-tolerant machines.

Pfeifer and colleagues at Zurich University have explored issues central to the key motivation for fully evolvable robot hardware: the balanced interplay between body morphology, neural processing, and environment in the generation of adaptive behavior, and have developed a set of design principles for intelligent systems in which these issues take center stage (Pfeifer and Bongard 2007). Examples of interesting current work in this direction includes (Bongard 2011; Johnson et al. 2014).

Future Directions

Major ongoing challenges – methodological, theoretical, and technological – include finding the best way to incorporate development and lifetime plasticity within the evolutionary framework (this involves trends coming from the emerging field of epigenetic robotics), understanding better what the most useful building blocks are for evolved neurocontrollers, and finding efficient ways to scale work on concurrently evolving bodies and brains, especially in an open-ended way in the real world. For some grand challenges in the field, see (Eiben 2014).

There are very interesting developments in the evolution of group behaviors and the emergence of communication (Di Paolo 1998; Floreano et al. 2007; Quinn 2001; Vargas et al. 2014), the use of evolutionary robotics as a tool to illuminate problems in cognitive science (Beer 2003; Harvey et al. 2005) and neuroscience (Di Paolo 2003; Philippides et al. 2005; Seth 2005; Husbands et al. 2014), in developing flying behaviors (Floreano et al. 2007; Shim and Husbands 2007; Vargas et al. 2014), and in robots that have some form of self-model (Bongard et al. 2006), to name but a few.

Expectation Maximization Clustering

Xin Jin[1] and Jiawei Han[2]
[1]PayPal Inc., San Jose, CA, USA
[2]University of Illinios at Urbana-Champaign, Urbana, IL, USA

Abstract

The expectation maximization (EM) based clustering is a probabilistic method to partition data into clusters represented by model parameters. Extensions to the basic EM algorithm include but not limited to the stochastic EM algorithm (SEM), the simulated annealing EM algorithm (SAEM), and the Monte Carlo EM algorithm (MCEM).

Synonyms

Mixture model

Definition

The expectation maximization (EM) algorithm (Dempster et al. 1977; Fraley and Raftery 1998) finds maximum likelihood estimates of parameters in probabilistic models. EM is an iterative method which alternates between two steps, expectation (E) and maximization (M). For clustering, EM makes use of the finite Gaussian mixtures model and estimates a set of parameters iteratively until a desired convergence value is achieved. The mixture is defined as a set of K probability distributions and each distribution corresponds to one cluster. An instance is assigned with a membership probability for each cluster.

The EM algorithm for partitional clustering works as follows:

1. Guess initial parameters of the models: mean and standard deviation (if using normal distribution model).
2. Iteratively refine the parameters with E and M steps. In the E step: compute the membership possibility for each instance based on the initial parameter values. In the M step: recompute the parameters based on the new membership possibilities.
3. Assign each instance to the cluster with which it has highest membership possibility.

Refer to Celeux and Govaert (1995) for details about the E and M steps for multivariate normal mixture models parameterized via the eigenvalue decomposition.

The EM algorithm for clustering becomes time consuming to compute for models with very large numbers of components, because the number of conditional probabilities associated with each instance is the same as the number of components in the mixture.

Extensions

There are many extensions to the EM-based clustering algorithm. Celeux et al. (1996) compared three different stochastic versions of the EM algorithm: the stochastic EM algorithm (SEM), the simulated annealing EM algorithm (SAEM), and the Monte Carlo EM algorithm (MCEM). SEM was shown to be efficient for locating significant maxima of the likelihood function. The classification EM (CEM) algorithm (Celeux and Govaert 1992) incorporates a classification step between the E-step and the M-step using a maximum a posteriori (MAP) principle. The K-means algorithm becomes a particular version of the CEM algorithm corresponding to the uniform spherical Gaussian model. Yang et al. (2012) proposed an EM clustering algorithm for Gaussian mixture models, which is robust to initialization and different cluster sizes with a schema to automatically obtain an optimal number of clusters.

Softwares

The following softwares have implementations of the EM clustering algorithm:

- Weka. Open Source Data Mining Software in Java (Hall et al. 2009), from Machine Learning Group at the University of Waikato:
  http://www.cs.waikato.ac.nz/ml/weka/index.html
- LNKnet Software. Written in C. A public domain software from MIT Lincoln Laboratory:
  http://www.ll.mit.edu/mission/communications/cyber/softwaretools/lnknet/lnknet.html
- EMCluster (Chen et al. 2012). R package. It provides EM algorithms and several efficient initialization methods for clustering of finite mixture Gaussian distribution with unstructured dispersion in both unsupervised and semi-supervised learning.

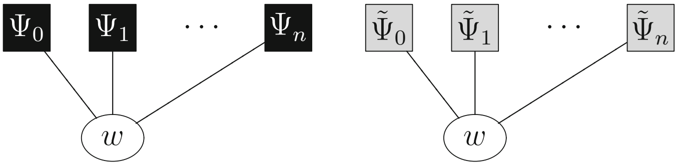
Definition

Expectation propagation is an algorithm for Bayesian machine learning. It tunes the parameters of a simpler approximate distribution (e.g., a Gaussian) to match the exact posterior distribution of the model parameters given the data. Expectation propagation operates by propagating messages, similar to the messages in (loopy) ▶ belief propagation. Whereas messages in belief propagation correspond to exact belief states, messages in expectation propagation correspond to approximations of the belief states in terms of expectations, such as means and variances. It is a deterministic method especially well suited to large databases and dynamic systems, where exact methods for Bayesian inference fail and ▶ Monte Carlo methods are far too slow.

Motivation and Background

One of the main problems for ▶ Bayesian methods is their computational expense: computation of the exact posterior given the observed data typically requires the solution of high-dimensional integrals that have no analytical expressions. Approximation algorithms are needed to approximate this posterior as accurately as possible. These techniques for approximate inference can be subdivided in two categories: deterministic approaches and stochastic sampling (Monte Carlo) methods. Having the important advantage that (under certain conditions) they give exact results in the limit of an infinite number of samples, ▶ Monte Carlo methods are the method of choice in Bayesian statistics. However, in particular, when dealing with large databases, the time needed for stochastic sampling to obtain a reasonably accurate approximation of the exact posterior can be prohibitive. This explains the need for faster, deterministic approaches, such as the Laplace approximation, ▶ variational approximations, and expectation propagation.

Expectation propagation was first described by Thomas Minka in his thesis Minka (2001). It can be viewed as a generalization and reformulation of the earlier ADATAP algorithm of Manfred Opper and Ole Winther (2001). Expectation propagation quickly became one of the most popular deterministic approaches for approximate Bayesian inference. Expectation propagation improves upon assumed density filtering, a classical method from stochastic control, by iteratively refining local approximations instead of computing them just once. Furthermore, it encompasses loopy belief propagation, a popular method for approximate inference in probabilistic graphical models, as a special case. Where loopy belief propagation is restricted to models of discrete variables only, expectation propagation applies to



Expectation Propagation, Fig. 1 (*left-hand side*) A so-called factor graph corresponding to the i.i.d. assumption in Bayesian machine learning. Each box corresponds to a factor or term. A *circle* corresponds to a variable. Factors are connected to the variables that they contain. Ψ_0 corresponds to the prior, and $\Psi_1 \ldots \Psi_n$ are the likelihood terms for the n data points. The *right-hand side* is a factor graph of the approximating distribution. The original terms have been replaced by term approximations

a much wider class of probabilistic ▸ graphical models with discrete and continuous variables and complex interactions between them.

Structure of Learning System

Bayesian Machine Learning

In the Bayesian framework for machine learning, you should enumerate all reasonable models of the data and assign a prior belief $P(w)$ to each of these models w. Then, upon observing the data D, you compute the likelihood $P(D|w)$ to evaluate how probable the data was under each of these models. The product of the prior and the likelihood gives you, up to a normalization constant, the posterior probability $P(w|D)$ over models given the data:

$$P(w|D) = \frac{P(D|w)P(w)}{P(D)} \, ,$$

where the normalization term $P(D)$ is called the probability of the data or "evidence." This posterior probability incorporates all you have learned from the data D regarding the models w under consideration. As indicated above, exact calculation of this posterior probability is often infeasible, because the normalization term requires the solution of intractable sums or integrals.

In its simplest setting, the data D consists of n observations, $x_1, \ldots, x_n$, which are assumed to be i.i.d. (independent and identically distributed). The posterior probability then factorizes into $n + 1$ terms, one for each observation and one for the prior. With definitions $\Psi_0(w) \equiv P(w)$ and $\Psi_i(w) \equiv P(x_i|w)$, we can rewrite

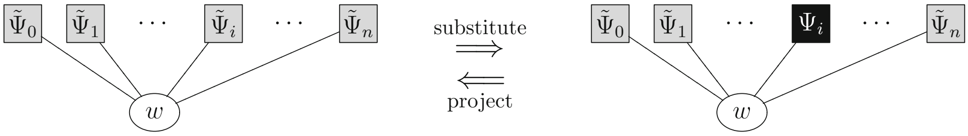
$$P(w|D) = \frac{P(w)\prod_{i=1}^{n} P(x_i|w)}{P(D)} \equiv \frac{\prod_{i=0}^{n} \Psi_i(w)}{P(D)} \, .$$

This factorization is visualized in the so-called factor graph in Fig. 1. We will use it as a running example in the following.

Assumed Density Filtering

Expectation propagation can be interpreted by an iterative refinement of assumed density filtering. In assumed density filtering, we add terms one by one and project in each step back to the "assumed density." For example, suppose that our prior probability $P(w) = \Psi_0(w)$ is a (known) Gaussian distribution over model parameters w, the terms corresponding to the data points are non-Gaussian, and we aim to find an appropriate Gaussian approximation $Q(w)$ to the exact (non-Gaussian) posterior $P(w|D)$. Our first approximation is the prior itself. Assumed-density filtering now proceeds by adding terms one at a time, where at each step we approximate the resulting distribution as closely as possible by a Gaussian. The pseudo-code is given in Algorithm 1, where $Q_{0:i}(w)$ denotes the approximation obtained after incorporating the prior and the first i observations.

If we use the Kullback-Leibler divergence as the distance measure from the non-Gaussian (but normalized) product of $Q_{0:i-1}(w)$ and $\Psi_i(w)$ and the Gaussian approximation, projection becomes "moment matching": the result of the projection



Expectation Propagation, Fig. 2 Visualization of expectation propagation when recomputing the term approximation for observation i

is the Gaussian that has the same mean and covariance matrix as the non-Gaussian product.

Expectation Propagation

When in assumed density filtering we add the term $\Psi_i(w)$, the Gaussian approximation changes from $Q_{0:i-1}(w)$ to $Q_{0:i}(w)$. We will call the quotient of the two the *term approximation* (here and in the following we ignore normalization constants):

$$\tilde{\Psi}_i(w) = \frac{Q_{0:i}(w)}{Q_{0:i-1}(w)} .$$

In our running example, term approximations are quotients between two different Gaussian densities and therefore have a Gaussian form themselves. Since the prior $\Psi_0(w)$ is a Gaussian density, $\tilde{\Psi}_0(w) = \Psi_0(w)$. The approximation $Q_{0:n}(w)$ is equal to the product of all term approximations and is visualized on the right-hand side of Fig. 1. In assumed density filtering, the resulting approximation depends on the ordering in which the terms have been added. For example, if the terms had been added in reverse order, their term approximations might have been (slightly) different.

Expectation propagation now generalizes assumed density filtering by iteratively refining these term approximations. When successful, the final approximation will be independent of the ordering. Pseudo-code of expectation propagation is given in Algorithm 2. In step 1 through 5, the term approximations are initialized; in step 6 through 12, these term approximations are iteratively refined until they no longer change. In step 8, we take out the previous term approximation from the current approximation. In step 9, we put back in the exact term and project back to a Gaussian, like we did in assumed density filtering. It is easy to check that the approximation $Q(w)$ after the first loop equals the approximation $Q_{0:n}(w)$ obtained with assumed density filtering. The recalculation of the term approximation corresponding to observation i is visualized in Fig. 2.

Computational Aspects

With expectation propagation, we have to do a little more bookkeeping than with assumed density filtering: we have to keep track of the term approximations. One loop of expectation propagation is about as expensive as running assumed density filtering. Typically, about five iterations are sufficient for convergence.

The crucial operation is in step 3 of Algorithm 1 and step 9 of Algorithm 2. Here we have to compute the moments of the (non-Gaussian) probability distribution on the right-hand side. In most cases, we do not have analytical expressions for these moments and have to compute them numerically, e.g., using Gaussian quadrature. We then obtain the moments (mean and covariance matrix) of the new approximation $Q(w)$. Divisions and multiplications correspond to a simple subtraction and addition of so-called canonical parameters. For the Gaussian these canonical parameters are the inverse of the covariance matrix (precision matrix) and the product of the precision matrix and the mean. The bottom line is that we go back and forth between distributions in terms of moments and in terms of canonical parameters. For a Gaussian, this requires computing the inverse of the covariance matrix, which is roughly on the order of d^3, where d is the dimension of w. A practical point of concern is that matrix inversion is numerically instable, in particular, for matrices that are close to singular, which can lead to serious roundoff errors.

Convergence Issues

Sadly enough, expectation propagation is not guaranteed to converge to a fixed point. If it does, this fixed point can be shown to correspond to an extremum of the so-called Bethe free energy, an approximation of the "evidence" $\log P(D)$, under particular consistency and normalization constraints (Minka 2001; Herbrich and Graepel 2006; Heskes and Zoeter 2002; Heskes et al. 2005). These constraints relate to the projection step in Algorithm 2: after convergence, the moments of $Q(w)$ should be equal to the moments of the distribution obtained by taking out a term approximation and putting back the corresponding exact term. This should hold for all i.i.d. observations $i = 1, \ldots, n$ in the factor graph of Fig. 1: so we conclude that, after convergence, the moments ("expectations") of all distributions constructed in this way should be the same. Expectation consistent approximations are based on the exact same idea and indeed turn out to be equivalent to expectation propagation (Heskes et al. 2005).

When expectation propagation does not converge, we can try "damping": instead of replacing the old term approximation by the new one, we replace it by a logconvex combination of the old and the new one. In many cases, damping with a step size 0.1 makes expectation propagation converge, at the expense of requiring more iterations. However, even damping with an infinitesimally small step size is not guaranteed to lead to convergence. In those cases, we can try to minimize the Bethe free energy more explicitly with a so-called double-loop algorithm (Heskes and Zoeter 2002): in the outer loop we compute a convex bound on the Bethe free energy, which we then minimize in the inner loop with an algorithm very similar to standard expectation propagation. Double-loop algorithms are an order of magnitude slower than standard expectation propagation. Recent approaches such as Seeger and Nickisch (2010) provide guaranteed convergence at a much faster rate, but only for specific models.

Generalizations

The running example above serves to illustrate the main idea, but is of course rather restrictive. Expectation propagation can be applied with any member of the exponential family as approximating distribution (Minka 2001; Seeger 2008). The crucial operations are the projection step and the transformation from moment to canonical form: if these can be performed efficiently and robustly, expectation propagation is into play.

In many interesting cases, the model to be learned (here represented as a single variable w) contains a lot of structure. This structure can be exploited by expectation propagation to make it more efficient. For example, when a term only contains a subset of the elements of w, so does its term approximation. Also, we might take as the approximating distribution a distribution that factorizes over the elements of w, instead of a "full" distribution coupling all elements. For a Gaussian, this would amount to a diagonal instead of a full covariance matrix. Such a factorization will lead to lower memory requirements and faster computation, perhaps at the expense of reduced accuracy. More advanced approximations include Tree-EP, where the approximating structure is a tree, and generalized expectation propagation, which generalizes expectation propagation to include higher-order interactions in the same way as generalized belief propagation generalizes loopy belief propagation (Welling et al. 2005). Systematic higher-order corrections on top of standard expectation propagation lead to improved approximate inference in Gaussian latent variable models (Cseke and Heskes 2011; Opper et al. 2013).

Power expectation propagation (Minka 2005) generalizes expectation propagation by considering a different distance measure in the projection step. Instead of taking the Kullback-Leibler divergence, we can take any so-called α-divergence. $\alpha = 1$ corresponds to the Kullback-Leibler divergence and $\alpha = -1$ to the Kullback-Leibler divergence with the two probabilities interchanged. In the latter case, we obtain a variational method called variational Bayes.

Programs and Data

Code for expectation propagation applied to Gaussian process classification can be found at http://www.gaussianprocess.org/gpml/code/matlab/doc/ or http://becs.aalto.fi/en/research/bayes/gpstuff/. Kevin Murphy's Bayes Net toolbox (https://code.google.com/p/bnt/) can provide a good starting point to write your own code for expectation propagation. Expectation propagation is one of the approximate inference methods implemented in Infer.NET, Microsoft's framework for running Bayesian inference in graphical models (http://research.microsoft.com/en-us/um/cambridge/projects/infernet/).

Applications

Expectation propagation has been applied for, among others, Gaussian process classification (Csato et al. 2002), inference in Bayesian networks and Markov random fields, text classification with Dirichlet models and processes (Minka and Lafferty 2002), logistic regression models for rating players (Herbrich and Graepel 2006), and inference and learning in hybrid and nonlinear dynamic Bayesian networks (Heskes and Zoeter 2002).

Future Directions

From an application point of view, expectation propagation will probably become one of the standard techniques for approximate Bayesian machine learning, much like the Laplace approximation and Monte Carlo methods. Future research may involve questions like

- When does expectation propagation converge? Can we design variants that are guaranteed to converge for any type of model?
- What "power" to use in power expectation propagation for what kind of purposes?
- Can we adapt expectation propagation to handle approximating distributions that are not part of the exponential family? Recent progress in this direction includes Barthelme and Chopin (2014).

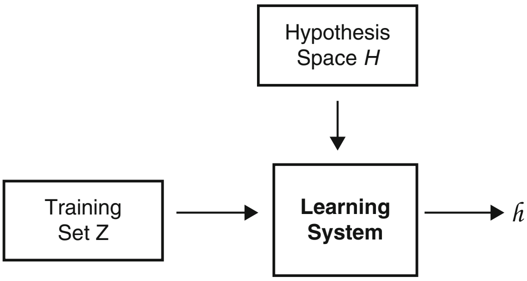
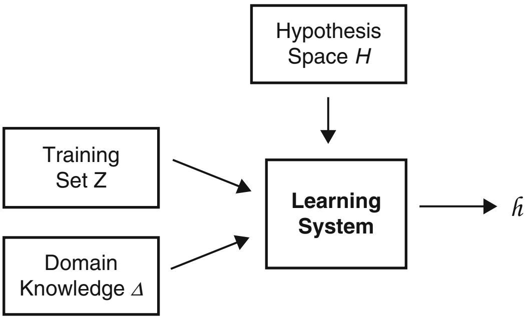
Definition

Explanation-based learning (EBL) is a principled method for exploiting available domain knowledge to improve ► supervised learning. Improvement can be in speed of learning, confidence of learning, accuracy of the learned concept, or a combination of these. In modern EBL the domain theory represents an expert's approximate knowledge of complex systematic world behavior. It may be imperfect and incomplete. Inference over the domain knowledge provides *analytic* evidence that compliments the empirical evidence of the training data. By contrast, in original EBL, the domain theory is required to be much stronger; inferred properties are guaranteed. Another important aspect of modern EBL is the interaction between domain knowledge and labeled training examples afforded by explanations. Interaction allows the nonlinear combination of evidence so that the resulting information about the target concept can be much greater than the sum of the information from each evidence source taken independently.



Explanation-Based Learning, Fig. 1 Conventional learner



Explanation-Based Learning, Fig. 2 EBL learner

Motivation and Background

A conventional machine learning system is illustrated in Fig. 1. A hypothesis $\hat{h}$ is selected from a space of candidates H using a training set of labeled examples Z as evidence. It is common to assume that the examples are drawn from some space of well-formed inputs X according to some fixed but unknown distribution $\mathcal{D}$. The quality of $\hat{h}$ is to be judged against different examples similarly selected and labeled. The correct label for an example is specified by some ideal *target concept*, c^*. This is typically some complex world process whose outcome is of interest. The target concept, c^*, will generally not be a member of space of acceptable candidates, H. Rather, the learner tries to find some $\hat{h}$ which is acceptably similar to c^* over $X_{\mathcal{D}}$ and can serve as a computationally tractable stand-in.

Of course, good performance of $\hat{h}$ on Z (its training performance) alone is insufficient. The learner must achieve some statistical guarantee of good performance on the underlying distribution (test performance). If H is too rich and diverse or if Z is too impoverished, a learner is likely to ▸ overfit the data; it may find a pattern in the training data that does not hold in the underlying distribution $X_{\mathcal{D}}$. Test performance will be poor despite good training performance.

An explanation-based learner employs its domain theory, Δ (Fig. 2), as an additional source of information. This domain theory must not be confused with ▸ learning bias, which is present in all learners. Determinations (Russell and Grosof 1987) provide an extreme illustration. These are logical expressions that make strong claims about the world but only after seeing a training example. EBL domain theories are used only to explain. An inferred expression is not guaranteed to hold but only provides analytic evidence.

An explanation for some $z \in Z$ is immediately and easily generalized: The structure of the explanation accounts for why zs assigned classification label should follow from its features. All other examples that meet these conditions are assigned the same classification by the generalized explanation for the same reasons.

Early approaches to EBL (e.g., DeJong and Mooney 1986; Mitchell et al. 1986; Mitchell 1997; Russell and Norvig 2003) were undone by two difficult problems: (1) unavoidable imperfections in the domain theory and (2) the utility problem. The former stems from assuming a conventional semantics for the domain theory. It results in a brittleness and an under-reliance on the training data. Modern EBL is largely a reaction to this difficulty. The utility problem is a consequence of an ill-defined hypothesis space and, as will be discussed later, can be avoided in a straightforward manner.

Structure of Learning System

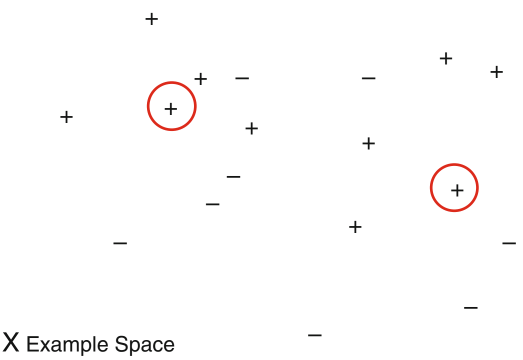
Explanations and Their Generalization

An *explanation* for a training example is any causal structure, derivable from Δ, which justifies why this training example might merit its teacher-assigned classification label. A *generalized explanation* is the structure of an explanation without the commitment to any particular example. The explanation and generalization processes are relatively straightforward and not significantly different from the original EBL algorithms.

The weakness of early EBL is in viewing the components of Δ as constraints. This leads to a view of explanations and their generalizations as *proofs*. Real-world brittleness due to the qualification problem (McCarthy 1980) follows inevitably. In modern EBL, Δ is seen as approximating the underlying world constraints (DeJong 2006; Kimmig et al. 2007). The domain theory is fundamentally a statistical device. Its analytic evidence and the empirical evidence of the training examples both provide a bridge to the real world.

The domain theory introduces new predicates and specifies their significant potential interactions. From a statistical point of view, these are named latent (hidden) features together with a kind of grammar for constructing alternative estimators for them. In short, the domain theory compactly specifies a large set of conceptual structures that an expert believes may be useful in making sense of the domain. If the expert is correct, then patterns of interest will become computationally much more accessible via analytic inference.

One flexible and useful form of a domain theory is sound inference over a set of first-order symbolic logic sentences. In such domain theories, the explanation mechanism can be identical to logical deduction although using a paraconsistent inference mechanism; inference must be well behaved despite inconsistencies in the theory. Generalized explanations are simply "theorems" of Δ that relate a classification label to the values of observable example features. But since the sentences of the theory only approximate world constraints, derivation alone, even via sound inference, is not sufficient evidence to believe a conclusion. Thus, a generalized explanation is only a conjecture. Additional training examples beyond those used to generate each explanation help to estimate the utility of these generalizations.



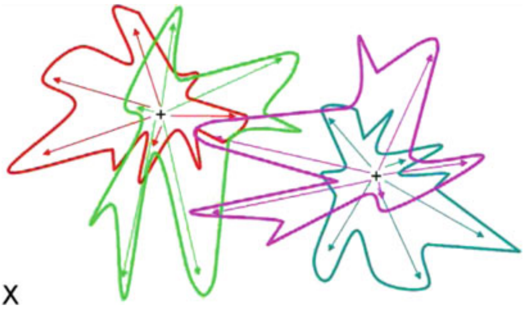
Explanation-Based Learning, Fig. 3 An example space with two designated positive training items

But analytic mechanisms need not be limited to symbolic logic-like inference. For example, one EBL approach is to distinguish handwritten Chinese characters (Lim et al. 2007) employing a Hough transform as a component of the domain theory. There, an explanation conjectures (hidden) glyph "strokes" to explain how the observed pixels of the training images may realize the image's character label.

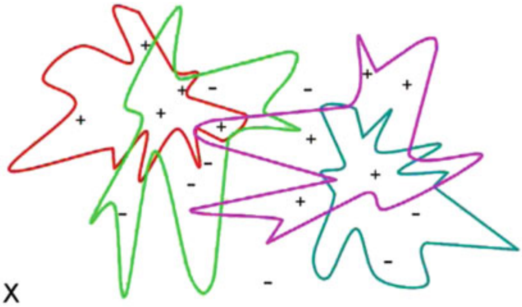
Whatever the form of the analytic inferential mechanism, multiple, quite incompatible explanations can be generated; the same training label can be explained using different input features and postulating different interactions. Such explanations will generalize to cover quite different subsets of X. Figure 3 shows a small training set with two positive examples highlighted. While the explanation process can be applied to all examples both positive and negative, these two will be used to illustrate. In this illustration, just two explanations are constructed for each of the highlighted training examples. Figure 4 shows the generalized extensions of these four explanations in the example space. The region enclosed by each contour is meant to denote the subset of X conjectured to merit the same classification as the explained example. Explanations make no claim about the labels for examples outside their extension.

Evaluation and Hypothesis Selection

Additional training examples that fall within the extension of a generalized explanation help to evaluate it empirically. This is shown in Fig. 5. The estimated utility of a generalized explanation



Explanation-Based Learning, Fig. 4 Four constructed explanations are sufficient to cover the positive examples



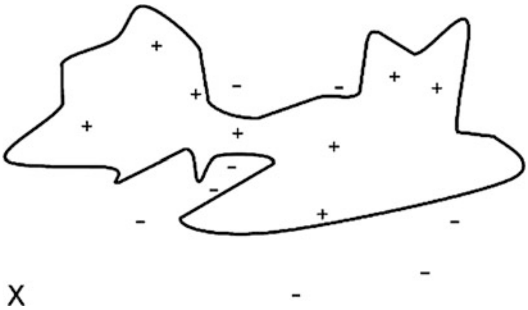
Explanation-Based Learning, Fig. 5 Explanations are evaluated with other training examples

reflects (1) the generalized explanation's empirical accuracy on these training examples, (2) the inferential effort required to derive the explanation (see DeJong 2006), and (3) the redundancies and interactions with other generalized explanations (higher utility is estimated if its correct predictions are less commonly shared by other generalized explanations).

The estimated utilities define an EBL classifier as a mixture of the generalized explanations each weighted by its estimated utility:

$$\hat{c}_{\mathrm{EBL}}(x) = \sum_{g \in \mathrm{GE}(Z,\Delta)} u_g \cdot g(x),$$

where $\mathrm{GE}(Z, \Delta)$ denotes the generalized explanations for Z from Δ and u_g is the estimated utility for g. This corresponds to a voting scheme where each generalized explanation that claims to apply to an example casts a vote in proportion to its estimated utility. The votes are normalized



Explanation-Based Learning, Fig. 6 An element from H that approximates the weighted explanations

over the utilities of voting generalized explanations. The mixture scheme is similar to that of sleeping experts (Freund et al. 1997). This EBL classifier approximates the target concept c^*. But unlike the approximation chosen by a conventional learner, $\hat{c}_{\mathrm{EBL}}$ reflects the information of Δ in addition to Z.

The final step is to select a hypothesis $\hat{h}$ from H. The EBL concept $\hat{c}_{\mathrm{EBL}}$ is used to guide this choice. Figure 6 illustrates the selection of a $\hat{h} \in H$, which is a good approximation to a utility-blended mixture of Fig. 5. This final step, selecting a hypothesis from H, is important but was omitted in original EBL. These systems employed generalized explanations directly. Unfortunately, such classifiers suffer from a difficulty known as the *utility problem* (Minton 1990). Note this is a slightly different use of the term *utility*, referring to the performance of an application system. This system can be harmed more than helped by concepts such as $\hat{c}_{\mathrm{EBL}}$, even if these concepts provide highly accurate classification. Essentially, the average cost of evaluating an EBL concept may outweigh the average benefit that it provides to the application system. It is now clear that this utility problem is simply the manifestation of a poorly structured hypothesis space. Note that, in general, an EBL classifier itself will not be an element of the space of acceptable hypotheses H. Previous approaches to the utility problem (Minton 1990; Gratch and DeJong 1992; Greiner and Jurisica 1992; Etzioni 1993) identify and disallow offending EBL concepts. However, the root cause is addressed by employing the EBL concept as a guidance in selecting a $\hat{h} \in H$

rather than using $\hat{c}_{\mathrm{EBL}}$ directly. Without this last step, H is completely ignored. But H embodies all of the information in the learning problem about what makes an acceptable hypothesis. The "utility problem" is simply the manifestation of leaving out this important information.

Literature

The roots and motivation for EBL extend at least to the MACROPs of STRIPS (Fikes et al. 1972). The importance of explanations of training examples was first suggested in DeJong (1981). The standard references for the early EBL work are Mitchell et al. (1986) and DeJong and Mooney (1986). When covering EBL, current textbooks give somewhat refined versions of this early approach (Mitchell 1997; Russell and Norvig 2003). Important related ideas include determinations (Russell and Grosof 1987), chunking (Laird et al. 1986), and knowledge compilation (Anderson 1986). EBL's ability to employ first-order theories make it an attractive compliment to learning Horn theories with ▶ Inductive Logic Programming (Hirsh 1987; Bruynooghe et al. 1989; Pazzani and Kibler 1992; Zelle and Mooney 1993). The problem of imperfect domain theories was recognized early, and there have been many approaches (Flann and Dietterich 1989; Genest et al. 1990; Towell et al. 1991; Cohen 1992; Thrun and Mitchell 1993; Ourston and Mooney 1994). But with modern statistical learning ascending to the dominant paradigm of the field, interest in analytic approaches waned. The current resurgence of interest is largely driven by placing EBL in a modern statistically sophisticated framework that nonetheless is still able to exploit a first-order expressiveness (DeJong 2006; Kimmig et al. 2007; Lim et al. 2007; Sun and DeJong 2005).

Explanation-based generalization for planning; Speedup learning for planning

Definition

▸ Explanation-based learning (EBL) involves using prior knowledge to explain ("prove") why the training example has the label it is given and using this explanation to guide the learning. Since the explanations are often able to pinpoint the features of the example that justify its label, EBL techniques are able to get by with much fewer number of training examples. On the flip side, unlike general classification learners, EBL requires prior knowledge (aka "domain theory/model") in addition to labeled training examples – a requirement that is not easily met in some scenarios. Since many planning and problem-solving agents do start with declarative domain theories (consisting at least of descriptions of actions along with their preconditions and effects), EBL has been a popular learning technique for planning.

Dimensions of Variation

The application of EBL in planning varies along several dimensions: whether the learning was for improving the speed and quality of the underlying planner (Etzioni 1993; Kambhampati 1994; Kambhampati et al. 1996; Minton et al. 1989; Yoon et al. 2008) or acquire the domain model (Levine and DeJong 2006), whether it was done from successes (Kambhampati 1994; Yoon et al. 2008) or failures (Minton et al. 1989; Ihrig and Kambhampati 1997), whether the explanations were based on complete/correct (Minton et al. 1989; Kambhampati et al. 1996) or partial domain theories (Yoon et al.), whether learning is based on single (Kambhampati 1994; Kambhampati et al. 1996; Minton et al. 1989) or multiple examples (Flann and Dietterich 1989; Estlin and Mooney 1997) (where, in the latter case, inductive learning is used in conjunction with EBL), and finally whether the planner whose performance EBL aims to improve is a means-ends analysis one (Minton et al. 1989), partial-order planner (Estlin and Mooney 1997), or a heuristic search planner (Yoon et al.).

EBL techniques have been used in planning both to improve search and to reduce domain modeling burden (although the former has received more attention by far). In the former case, EBL is used to learn "control knowledge" to speed up the search process (Minton et al. 1989; Kambhampati et al. 1996) or to improve the quality of the solutions found by the search process (Estlin and Mooney 1997). In the latter case, EBL is used to develop domain models (e.g., action models) (Levine and DeJong 2006).

EBL for search improvement involves either remembering and reusing successful plans or learning search control rules to avoid failing search branches. Other variations include learning effective indexing of stored cases from retrieval failures (Ihrig and Kambhampati 1997) and learning "adjustments" to the default heuristic used by the underlying search.

Another important issue is the degree of completeness/correctness of the underlying background theory used to explain examples. If the theory is complete and correct, then learning is possible from a single example. This type of EBL has been called "analytical learning." When the theory is partial, EBL still is effective in narrowing down the set of potentially relevant features of the training example. These features can then be used within an inductive learner. Within planning, EBL has been used in the context of complete/correct as well as partial domain models.

A final dimension of variation that differentiated a large number of research efforts is the type of underlying planner. Initially, EBL was used on top of means-ends analysis planners (cf. PRODIGY, Minton et al. 1989). Later work focused on partial-order planners (e.g., Kambhampati et al. 1996; Estlin and Mooney 1997). More recently, the focus has been on forward search state-space planners (Yoon et al. 2008).

Learning from Success: Explanation-Based Generalization

When learning from successful cases (plans), the training examples comprise of successful plans, and the explanations involve proofs showing that the plan, as it is given, is able to support the goals. Only the parts of the plan that take part in this proof are relevant for justifying the success of the plan. The plan is thus "generalized" by removing extraneous actions that do not take part in the proof. Object identifiers and action orderings are also generalized as long as the generalization does not affect the proof of correctness (Kambhampati 1994). The output of the learning phase is thus a variablized plan containing a subset of the constraints (actions, orderings, object identity constraints) of the original plan. This is then typically indexed and used as a macro-operator to speed up later search.

For example, given a planning problem of starting with an initial state where five blocks, A, B, C, D, and E, are on the table, and the problem requires that in the goal state A must be on B and C must be on D and a plan P that is a sequence of actions *pickup A, stack A on B, pickup E, putdown E, Pickup C, stack C on D*, the explanation-based learner might output the generalization *do in any order* {*pickup x, stack x on y*} {*pick up z, stack z on w*} for the generalized goals *on* (x, y) *and on* (w, z), starting from a state where x, y, z, and w are all on the table and clear, and each of them denotes a distinct block.

One general class of such proof schema involves showing that every top-level goal of the planning problem as well as the precondition of every action is established and protected. Establishment requires that there is an action in the plan that gives that condition, and protection requires that once established, the condition is not deleted by any intervening action.

A crucial point is that the extent of generalization depends on the flexibility of the proof strategy used. Kambhampati and Kedar (1994) discuss a spectrum of generalization strategies associated with a spectrum of proof strategies, while Shavlik (1990) discusses how the number of actions in the plan can also be generalized.

Learning from Failure

When learning from the failure of a search branch, EBL starts by analyzing the plans at the failing nodes and constructing an explanation of failure. The failure explanation is just a subset of constraints in the plan at the current search node, which, in conjunction with domain theory, ensures that no successful solution can be reached by further refining this plan. The explanations can range from direct constraint inconsistencies (e.g., ordering cycles) to indirect violation of domain axioms (e.g., the plan requiring both clear(B) and On(A,B) to be satisfied at the same time point). The explanations at the leaf nodes are "regressed" over the decisions in the search tree to higher-level nodes to get explanations of (implicit) failures in these higher-level nodes. The search control rules can then essentially recommend pruning any search node which satisfies a failure explanation.

The deep affinity between EBL from search failures and the idea of ▶ nogood learning and dependency-directed backtracking in CSP is explored in Kambhampati (1998). As in dependency-directed backtracking, the more succinct the explanation, the higher the chance of learning effective control rules. Note that effectiveness here is defined in terms of the match costs involved in checking whether the rule is applicable and the search reductions provided when it is applicable. Significant work has been done to identify classes of failure explanation that are expected to lead to ineffective rules (Etzioni 1993). In contrast to CSP that has a finite depth search tree, one challenge in planning is that often an unpromising search node might not exhibit any direct failure with a succinct explanation and is abandoned by the search for heuristic reasons (such as the fact that the node crosses a depth limit threshold). Strategies for finding implicit explanations of failure (using domain axioms), as well as getting by with incomplete explanations of failure, are discussed in Kambhampati et al. (1996). EBL from failures has also been applied to retrieval (rather than search) failures. In this case, the failure of extending a plan retrieved from the library to solve a new problem is used to learn new indexing schemes that inhibit that case from being retrieved in such situations (Ihrig and Kambhampati 1997).

Learning Adjustments to Heuristics

Most recent work in planning has been in the context of heuristic search planners, where learning from failures does not work as well (since the heuristic search may change directions much before a given search branch ends in an explainable failure). One way of helping such planners is to improve their default heuristic (Yoon et al. 2008). Given a heuristic $h(s)$ that gives the heuristic estimate of state s, the aim in Yoon et al. is to learn an adjustment $\delta(s)$ that is added to $h(s)$ to get a better estimate of $h^*(s)$ – the true cost of state s. The system has access to actual plan traces (which can be obtained by having the underlying planner solve some problems from scratch). For each state s on the trace, we know the true distance of state s from the goal state, and we can also compute the $h(s)$ value with respect to the default heuristic. This gives the learner a set of training examples which are pairs of states and the adjustments they needed to make the default heuristic meet the true distance. In order to learn the $\delta(s)$ from this training data, we need to enumerate the features of state s that are relevant to it needing the specific adjustment. This is where EBL comes in. Specifically, one way of enumerating the relevant features is to explain why s has the default heuristic value. This, in turn, is done by taking the features of the relaxed plan for state s. Since the relaxed plan is a plan that assumes away all negative interactions between the actions, relaxed plan features can be seen as features of the explanation of the label for state s in terms of a *partial domain theory* (one which ignores all the deletes of all actions).

EBL from Incomplete Domain Theories

While most early efforts for speedup focused on complete and correct theories, several efforts also looked at speedup learning from incomplete theories. The so-called Lazy EBL approaches (Tadepalli 1989; Chien 1989) work by first constructing partial explanations and subsequently refining the over-general rules learned. Other approaches that use similar ideas outside planning include Flann and Dietterich (1989) and Cohen (1992). As we noted above, the work by Yoon et al. (2008) can also be seen as basing learning (in their case of adjustments to a default heuristic function) w.r.t. a partial domain theory.

EBL to Learn Domain Knowledge

Although most work in EBL for planning has been focused on speedup, there has also been some work aimed at learning domain knowledge (rather than control knowledge). Of particular interest is "operationalizing" a complex, if opaque, domain model by learning from it a simplified domain model that is adequate to efficiently solve an expected distribution of problems. The recent work by Levine and DeJong (2006) is an example of such an effort.

EBL and Knowledge-Level Learning

Although the focus of this article is on EBL as applied to planning, we need to foreground one general issue: whether EBL is capable of knowledge-level learning or not. A popular misconception of EBL is that since it depends on a complete and correct domain theory, no knowledge-level learning is possible, and speedup learning is the only possibility. (The origins of this misconception can be traced back to the very beginning. The two seminal articles on EBL in the very first issue of the Machine Learning journal differed profoundly in their interpretations of EBL. While Mitchell et al. (1986) assumed that EBL by default works with complete and correct theories (thus precluding any knowledge-level learning), Levine and DeJong (2006) provides a more general view of EBL that uses background knowledge – whether or not it is complete – to focus the generalization (and as such can be seen as a knowledge-based feature-selection step for a subsequent inductive learner).) As we noted at the outset however, EBL is not required to depend on complete and correct domain theories, and when it does not, knowledge-level learning is indeed possible.

Utility Problem and Its Nonexclusive Relation to EBL

As we saw above, much early work in EBL for planning focused on speedup for the underlying planner. Some of the knowledge learned for speedup – especially control rules and macro-operators – can also adversely affect the search by increasing either the search space size (macros) or per-node cost (matching control rules). Clearly, in order for the net effect to be positive, care needs to be exercised as to which control rules and/or macros are stored. This has been called the "utility problem" (Minton 1990), and significant attention has been paid to develop strategies that either dynamically evaluate the utility of the learned control knowledge (and forget useless rules) (Markovitch and Scott 1988; Minton 1990) or select the set of rules that best serve a given distribution of problem instances (Gratch et al. 1994).

Despite the prominent attention given to the utility problem, it is important to note the nonexclusive connection between EBL and utility problem. We note that *any* strategy that aims to provide/acquire control knowledge will suffer from the utility problem. For example, utility problem also holds for inductive learning techniques that were used to learn control knowledge (cf. Leckie and Zukerman 1993). In other words, it is not special to EBL but rather to the specific application task. We note that it is both possible to do speedup learning that is less susceptible to the utility problem (e.g., learn adjustments to heuristics, Yoon et al. 2008) and possible to use EBL for knowledge-level learning (Levine and DeJong 2006).

Current Status

EBL for planning was very much in vogue in the late 1980s and early 1990s. However, as the speed of the underlying planners increased drastically, the need for learning as a crutch to improve search efficiency reduced. There has however been a recent resurgence of interest, both in further speeding up the planners and in learning domain models. Starting 2008, there is a new track in the International Planning Competition devoted to learning methods for planning. In the first year, the emphasis was on speedup learning. ObtuseWedge, a system that uses EBL analysis to learn adjustments to the default heuristic, was among the winners of the track. The DARPA integrated learning initiative, and interest in model-lite planning have also brought focus back to EBL for planning – this time with partial domain theories.

Additional Reading

The tutorial (Yoon and Kambhampati 2007) provides an up-to-date and broader overview of learning techniques applied to planning and contains significant discussion of EBL techniques. The paper Zimmerman and Kambhampati (2003) provides a survey of machine learning techniques used in planning and includes a more comprehensive listing of research efforts that applied EBL in planning.

F

F_1-Measure

The F_1-measure is used to evaluate the accuracy of predictions in two-class (binary) ▶ classification problems. It originates in the field of information retrieval and is often used to evaluate ▶ document classification models and algorithms. It is defined as the harmonic mean of ▶ precision (i.e., the ratio of ▶ true positives to all instances predicted as positive) and ▶ recall (i.e., the ratio of true positives to all instances that are actually positive). As such, it lies between precision and recall, but is closer to the smaller of these two values. Therefore a system with high F_1 has both good precision and good recall. The F_1-measure is a special case of the more general family of evaluation measures:

$$F_\beta = (\beta^2 + 1)\mathit{precisionrecall} / (\beta^2 \mathit{precision} + \mathit{recall})$$

Thus using $\beta >$ increases the influence of precision on the overall measure, while using $\beta < 1$ increases the influence of recall. Some authors use an alternative parameterization,

$$F_\alpha = 1/(\alpha/\mathit{precision} + (1t\alpha)/\mathit{recall})$$

which, however, leads to the same family of measures; conversion is possible via the relationship $\alpha = 1/(\beta^2 + 1)$.

False Negative

In a two-class problem, a ▶ classification model makes two types of error: ▶ false positives and false negatives. A **false negative** is an example of positive class that has been incorrectly classified as negative. See ▶ confusion matrix for a complete range of related terms.

False Positive

In a two-class problem, a ▶ classification model makes two types of error: false positives and ▶ false negatives. A **false positive** is an example of a negative class that has been incorrectly classified as positive. See ▶ confusion matrix for a complete range of related terms.

Feature generation in text mining

Definition

Feature construction in text mining consists of various techniques and approaches which convert textual data into a feature-based representation. Since traditional machine learning and data mining techniques are generally not designed to deal directly with textual data, feature construction is an important preliminary step in text mining, converting source documents into a representation that a data mining algorithm can then work with. Various kinds of feature construction approaches are used in text mining depending on the task that is being addressed, the data mining algorithms used, and the nature of the dataset in question.

Motivation and Background

Text mining is the use of machine learning and data mining techniques on textual data. This data consists of natural language documents that can be more or less structured, ranging from completely unstructured plain text to documents with various kinds of tags containing machine-readable semantic information. Furthermore, documents may sometimes contain hyperlinks that connect them into a graph. Since most traditional machine learning and data mining techniques are not directly equipped to deal with this kind of data, an important first step in text mining is to extract or construct features from the input documents, thereby obtaining a feature-based representation which is suitable for handling with machine learning and data mining algorithms. Thus, the task of feature construction in text mining is inextricably connected with text mining itself and has evolved alongside it. An important trend over the years has been the development of techniques that do not process each document in isolation but make use of a corpus of documents as a whole, possibly even involving external data or background knowledge in the process.

Documents and text data provide for valuable sources of information, and their growing availability in electronic form naturally led to application of different analytic methods. One of the common ways is to take a whole vocabulary of the natural language in which the text is written as a feature set, resulting in several tens of thousands of features. In a simple setting, each feature gives a count of the word occurrences in a document. In this way text of a document is represented as a vector of numbers. The representation of a particular document contains many zeros, as most of the words from the vocabulary do not occur in a particular document. In addition to the already mentioned two common specifics of text data, having a large number of features and a sparse data representation, it was observed that frequency of words in text in general follows Zipf's law – a small subset of words occur very frequently in texts, while a large number of words occur only rarely. Document classification takes these and some other data specifics into account when developing the appropriate classification methods.

Structure of Learning System

In a learning or mining system that deals with textual data, feature construction is usually one of the first steps that is often performed alongside typical preprocessing tasks such as data cleaning. A typical output of feature construction is feature vector representing the input documents; these vectors themselves then form the input for a machine learning or data mining algorithm. On the other hand, sometimes feature construction is more closely integrated into the learning algorithm itself, and sometimes it can be argued that the features themselves are the desired output that is the goal of the text mining task.

Solutions

At the lowest level, text is represented as a sequence of bytes or other elementary units of information. How these bytes are to be converted into a sequence of characters depends on the *character encoding* of the text. Many standard encodings exist, such as UTF-8, the ISO-8859 family, and so on. Often, all the texts that appear as input for a specific text mining task are in the same encoding, or if various encodings are used, they are specified clearly and explicitly (e.g., via the Content-Type header in the HTTP protocol), in which case the problem of conversion is straightforward. In the case of missing or faulty encoding information, various heuristics can be used to detect the encoding and convert the data to characters; it is best to think of this as a data cleaning and preprocessing step.

Word-Based Features

When we have our text represented as a sequence of characters, the usual next step is to convert it into a sequence of words. This is usually performed with heuristics which depend to some extent on the language and underlying character set; for the purposes of segmentation of text into words, a word is thought of as a sequence of alphabetic characters delimited by whitespace and/or punctuation. Some efforts to standardize word boundary detection in a way that would work reasonably well with a large set of natural languages have also been made (see, e.g., the Unicode Standard Annex #29, *Unicode Text Segmentation*). For many (but not all) text mining tasks, the distinction between upper- and lowercase (if it is present in the underlying natural language) is largely or entirely irrelevant; hence, all texts are often converted into lowercase at this point. Another frequently used preprocessing step is *stemming*, whereby each word is replaced by its stem (e.g., *walking* → *walk*). The details of stemming depend on the natural language involved; for English, a relatively simple set of heuristics such as Porter's stemmer is sufficient. Instead of stemming, where the ending is chopped off the word, one can apply a more sophisticated transformation referred to as lemmatization that replaces the word by its normalized form (lemma). Lemmatization is especially relevant for natural languages that have many different forms of the same word (e.g., several cases, gender influence on verb form, etc.). Efforts have also been made to discover stemming rules or lemmatization rules automatically using machine learning techniques (Plisson et al. 2008).

The individual words can themselves be thought of as features of the document. In the feature vector representation of a document d, the feature corresponding to the word w would tell something about the presence of the word w in this document: either the frequency (number of occurrences) of w in d, or a simple binary value (1 if present, 0 if absent), or it can further be modified by, e.g., the TF-IDF weighting. In this kind of representation, all information about the word order in the original document is lost; hence, it is referred to as the "bag-of-words" model. For many tasks, the loss of word order information is not critical, and the bag-of-words model is a staple of information retrieval, document classification, and many other text-related tasks. A downside of this approach (and many other word-based feature construction techniques) is that the resulting number of features can be very large (there are easily tens of thousands of different words in a mid-sized document corpus); see Feature Selection in Text Mining.

Clearly, ignoring the word order completely can sometimes lead to the loss of valuable information. Multi-word phrases sometimes have a meaning that is not adequately covered by the individual words of the phrase (e.g., proper names, technical terms, etc.). Various ways of creating multi-word features have been considered. Let d be a document consisting of the sequence of words $(w_1, w_2, \ldots, w_m)$ (note that this sequence might already be an output of some preprocessing operations, e.g., the removal of stopwords and of very infrequent words). Then an *n-gram* is defined as a sequence of n adjacent words from the document, i.e., $(w_i, w_{i+1}, \ldots, w_{i+n-1})$. We can use n-grams as features in the same way as individual words, and indeed a typical approach is to use n-grams for all values of n from 1 to a certain upper limit (e.g., 5). Many of the resulting n-grams will be incidental and irrelevant, but some of them may be valuable and informative phrases; whether the text mining algorithm will be able to profit from them depends a lot on the algorithm used, and feature selection might be even more necessary than in the case of individual words. A related problem is the explosion of the number of features; if the number of different words in a corpus grows approximately with the square root of the length of the corpus (Heaps' law), the number of different n-grams is more likely to grow nearly linearly with the length of the corpus. The use of n-grams as features has been found to be beneficial, e.g., for the classification of very short documents (Mladenić and Grobelnik 2003).

Further generalization of n-grams is possible by removing the requirement that the words of the n-gram must appear adjacently; we can allow them to be separated by other words. The weight of an occurrence of the n-gram is often defined as decreasing exponentially with the number of intervening separator words. Another direction of generalizing n-gram is to ignore the order of words within the n-gram; in effect one treats n-grams as bags (multisets) instead of sequences. This results in features sometimes called *loose phrases* or *proximity features* (i.e., every bag of words up to a certain size, occurring in sufficiently close proximity to each other, is considered to be a feature). These generalizations greatly increase the feature space as well as the number of features present in any individual document, so the risk of computational intractability is greatly increased; this can sometimes be alleviated through the use of kernels (see below).

Character-Based Features

Instead of treating the text as a sequences of words, we might choose to treat it as a sequence of characters. A sequence of n characters is also known as an n-graph. We can use n-graphs as features in the representation of text in a way analogous to the use of n-grams in the previous subsection. The weight of the feature corresponding to a particular n-graph in the feature vector of a particular document d will typically depend on the number of occurrences of that n-graph in the text of d. Sometimes noncontiguous occurrences of the n-graph are also counted (i.e., occurrences where characters from the n-graph are separated by one or more other characters), although with a lower weight; this is can be done very elegantly with kernel methods (see below). Feature selection and TF-IDF style weighting schemes can also be used as in the case of n-grams. Whether an n-graph-based representation offers any benefits compared to an n-gram-based one depends largely on the dataset and task in question. For example, the classification of English documents and the usefulness of n-graphs have been found to be dubious, but they can be beneficial in highly agglutinative languages where an individual word can consist of many morphemes, and it is not really useful to treat a whole word as an individual unit of information (as would be the case in a word-based feature representation). In effect, the use of n-graphs provides the learner with cheap access to the sort of information that would otherwise require more sophisticated NLP technologies (stemming, parsing, morpheme analysis, etc.); the downside is that a lot of the n-graph features are merely noise (Lodhi et al. 2002). For some application, word suffixes can be particularly useful features, e.g., to learn lemmatization rules (Mladenić 2002; Plisson et al. 2008).

Kernel Methods

Let φ be a function which assigns, to a given document d, a feature vector $\varphi(d)$ from some feature space F. Assume furthermore that a dot product (a.k.a. inner product) is defined over F, denoted by $\langle \cdot, \cdot \rangle_F$. Then the function K defined by $K(d_1, d_2) = \langle \varphi(d_1), \varphi(d_2) \rangle_F$ is called a kernel function. It turns out that many machine learning and data mining methods can be described in a way such that the only operation they need to do with the data is to compute dot products of their feature vectors; in other words, they only require us to be able to compute the kernel function over our documents. These approaches are collectively known as *kernel methods*; a well-known example of this is the support vector machine (SVM) method for supervised learning, but the same principle can be used in clustering as well. An important advantage of this approach is that it is often possible to compute the kernel function K directly from the documents $d_{1,2}$ without explicitly generating the feature vectors $\varphi(d_{1,2})$. This is especially valuable if the feature space is untractably large. Several families of kernel functions for textual data have been described in the literature, corresponding to various kinds of n-graph and n-gram-based features (Brank 2006; Lodhi et al. 2002).

Linear Algebra Methods

Assume that a corpus of n documents have already been represented by d-dimensional real feature vectors $\mathbf{x}_1, \ldots, \mathbf{x}_n \in R^d$. If we select some direction $\mathbf{y} \in R^d$ and project a vector $\mathbf{x}_i$ in this direction, the resulting value $\mathbf{y}^T \mathbf{x}_i / ||\mathbf{y}||$ is in effect a new feature describing the document i. In other words, we have constructed a new feature as a linear combination of the existing features. This leads to the question of how to select one or more suitable directions $\mathbf{y}$; various techniques from linear algebra and statistics have been proposed for this.

A well-known example of this is principal component analysis (PCA) in which one or more new coordinate axes $\mathbf{y}$ are selected in such a way that the variance of the original vectors $\mathbf{x}_1, \ldots, \mathbf{x}_n$ in the directions of the new coordinate axes is maximized. As it turns out, this problem is equivalent to computing the principal eigenvectors of the covariance matrix of the original dataset.

Another technique of this sort is latent semantic indexing (LSI) (Deerwester et al. 1990). Let X be a $d \times n$ matrix with $\mathbf{x}_1, \ldots, \mathbf{x}_n$ as its columns (a.k.a. the *term-document matrix*). LSI uses singular value decomposition (SVD) to express X as the product of three matrices, $T \cdot S \cdot D$, where T is a $d \times r$ orthonormal matrix, D is a $r \times n$ orthonormal matrix, and S is a $r \times r$ diagonal matrix containing the singular values of X. Here, r denotes the rank of the original matrix X. Let $T^{(m)}$ be the matrix consisting of the left m columns of T, let $D^{(m)}$ be the matrix consisting of the top m rows of D, and let $S^{(m)}$ be the top left $m \times m$ submatrix of S. Then it turns out that $X^{(m)} = T^{(m)} S^{(m)} D^{(m)}$ is the best rank-m approximation of the original X (best in the sense of minimizing the Frobenius norm of $X - X^{(m)}$). Thus, the i-th column of $D^{(m)}$ can be seen as a vector of m new features representing the i-th document of our original dataset, and the product $T^{(m)} S^{(m)}$ can be seen as a set of m new coordinate axes. The new feature vectors (columns of $D^{(m)}$) can be used instead of the original vectors $\mathbf{x}_i$.

Canonical correlation analysis (CCA): Sometimes several vector representations are available for the same document d_i, for example, we might have the same text in two different languages, giving rise to two feature vectors, e.g., $\mathbf{x}_i \in R^d$ and $\mathbf{y}_i \in R^{d'}$. Given such a "parallel corpus" of pairs $(\mathbf{x}_i, \mathbf{y}_i), i = 1 \ldots n$, it is sometimes desirable to convert both types of representations to a "common denominator." In other words, we want to find a set of r new coordinate axes in $\mathbf{x}$-space (say the columns of $U \in R^{d \times r}$) and a set of r new coordinate axes in $\mathbf{y}$-space (say the columns of $V \in R^{d\prime \times r}$) such that the j-th column of U has a similar role in $\mathbf{x}$-space as the j-th column of V has in $\mathbf{y}$-space, for all j. This can be formulated as an optimization problem: find U and V such that the correlation between U^T $\mathbf{x}_i$ and $V^T \mathbf{y}_i$ (i.e., the projections of $\mathbf{x}_i$ and $\mathbf{y}_i$ onto the new sets of axes) is maximized. Once we have suitable matrices U and V , we can convert any feature vector from the original $\mathbf{x}$-space or $\mathbf{y}$-space into a common new r-dimensional space. This makes it easier to deal with multilingual corpora, allowing us, e.g., to retrieve documents in language $\mathbf{x}$ as a response to a query in language $\mathbf{y}$ or vice versa. The same techniques are applicable in multimodal scenarios (i.e., $\mathbf{x}_i$ and $\mathbf{y}_i$ can be any two representations of the same instance d_i from two substantially different perspectives, not necessarily textual). This method is often used in combination with kernels, in which case it is known as *kernel* canonical correlation analysis (KCCA) (Hardoon et al. 2004).

Nonlinear Methods

Powerful feature representations can also be obtained by statistical methods. For example, probabilistic latent semantic analysis (PLSA) (Hoffmann 1999) is an unsupervised approach that models a corpus of documents as if it was generated by a mixture of latent topics, with each topic being represented as a probability distribution over words. The model consists of topic probabilities $P(z|d)$ for each latent topic z and each document d and of word probabilities $P(w|z)$ for each word and topic. One of the downsides of PLSA is that it cannot be readily extended to model probabilities of documents that were not seen during training; this problem is addressed by approaches such as latent Dirichlet allocation (LDA) (Blei et al. 2003), in which the mixture of topics in each document is modeled as a random variable sampled from a Dirichlet distribution. In both cases, the mixture of topics $\langle P(z|d)\rangle_z$ can be interpreted as a new feature vector representation of the document d, and likewise the conditional probabilities $.\langle P(w|z)\rangle_z$ can be interpreted as a new feature vector representation of the term w.

Another important family of nonlinear feature construction methods are *deep learning methods*, which are based on training a multilevel neural network model that includes at least one hidden layer. Traditionally one would be interested in the outputs of the final output layer of the network, which is supposed to be solving whatever learning task the network was originally trained for. However, in deep learning, one discards the output layers and instead uses the outputs of the hidden layer as a new feature vector representation of the input document (or a word, n-gram, etc.). A recent example of such a representation is *word2vec* (Mikolov et al. 2013).

Miscellaneous

There are many other ways to extract or construct features from text, depending on the use that the features are intended for. For example, a *dual representation* of a corpus may be considered, in which features are used to represent terms and not documents. The feature vector for a term t contains one feature for each document, and its value is related to the frequency of t in that document. This representation can be used to analyze which words co-occur frequently and may therefore be related in meaning. Feature construction can also utilize methods from *information extraction*, such as identifying various kinds of named entities (names of persons, places, organizations, etc.) or other interesting bits of information and introducing features which indicate the presence of particular names or other tagged entities in the document.

Abstract

Data dimensionality is growing rapidly, which poses challenges to the vast majority of existing mining and learning algorithms, such as the curse of dimensionality, large storage requirement, and high computational cost. Feature selection has been proven to be an effective and efficient way to prepare high-dimensional data for data mining and machine learning. The recent emergence of novel techniques and new types of data and features not only advances existing feature selection research but also evolves feature selection continually, becoming applicable to a broader range of applications. In this entry, we aim to provide a basic introduction to feature selection including basic concepts, classifications of existing systems, recent development, and applications.

Synonyms

Attribute selection; Feature subset selection; Feature weighting

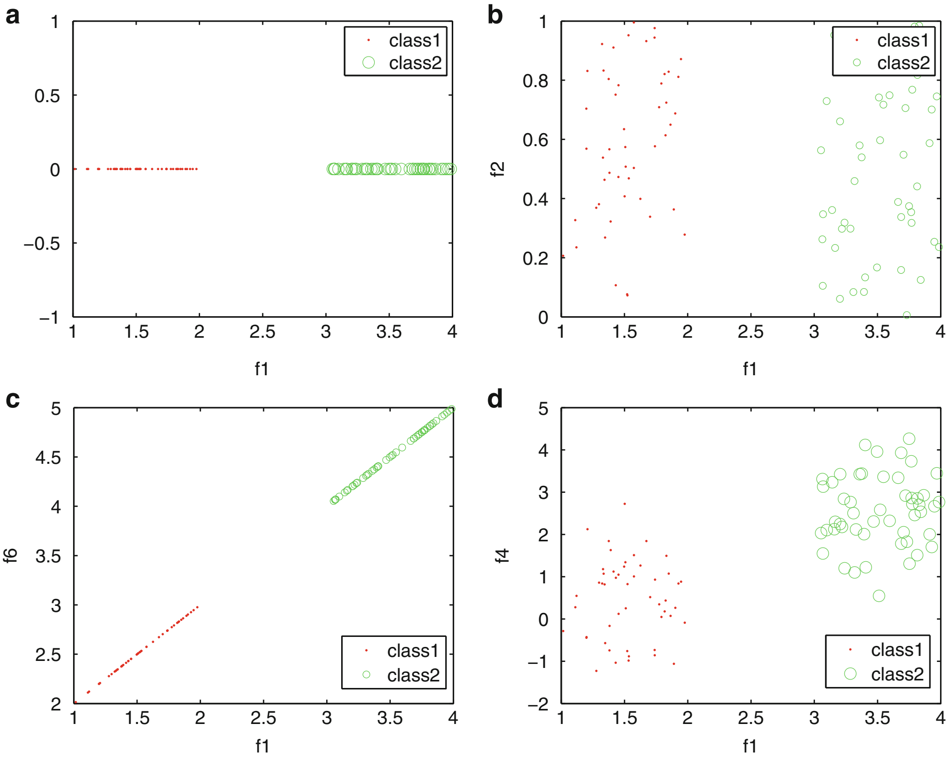
Definition (or Synopsis)

Feature selection, as a dimensionality reduction technique, aims to choose a small subset of the relevant features from the original ones by removing irrelevant, redundant, or noisy features. Feature selection usually leads to better learning performance, i.e., higher learning accuracy, lower computational cost, and better model interpretability.

Generally speaking, irrelevant features are features that cannot help discriminate samples from different classes(supervised) or clusters(unsupervised). Removing irrelevant features will not affect learning performance. In fact, the removal of irrelevant features may help learn a better model, as irrelevant features may confuse the learning system and cause memory and computation inefficiency. For example, in Fig. 1a, f_1 is a relevant feature because f_1 can discriminate class1 and class2. In Fig. 1b, f_2 is a redundant feature because f_2 cannot distinguish points from class1 and class2. Removal of f_2 doesn't affect the ability of f_1 to distinguish samples from class1 and class2.

A redundant feature is a feature that implies the copresence of another feature. Individually, each redundant feature is relevant, but removal of one of them will not affect the learning performance. For example, in Fig. 1c, f_1 and f_6 are strongly correlated. f_6 is a relevant feature itself. However, when f_1 is selected first, the later appearance of f_6 doesn't provide additional information. Instead, it adds more memory and computational requirement to learn the classification model.

A noisy feature is a type of relevant feature. However, due to the noise introduced during the data collection process or because of the nature of this feature, a noisy feature may not be so relevant to the learning or mining task. As shown in Fig. 1d, f_4 is a noisy feature. It can



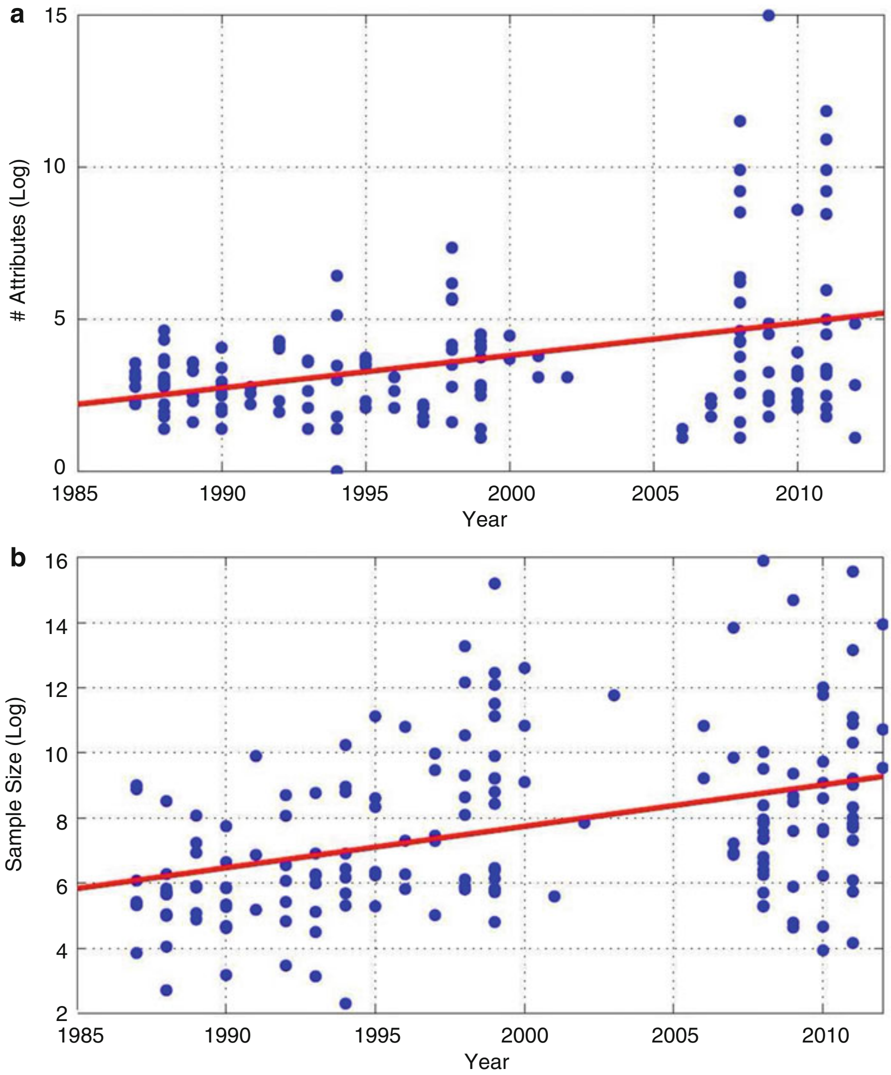
Feature Selection, Fig. 1 A toy example to illustrate the concept of irrelevant, redundant, and noisy features. $f1$ is a relevant feature and can discriminate class1 and class2. $f2$ is an irrelevant feature. Removal of $f2$ will not affect the learning performance. $f4$ is a noisy feature. The presence of noisy features may degenerate the learning performance. $f6$ is a redundant feature when $f1$ is present. If $f1$ is selected, removal of $f6$ will not affect the learning performance. (**a**) Relevant feature. (**b**) Irrelevant feature. (**c**) Redundant feature. (**d**) Noisy feature

discriminate a part of the points from the two classes and may confuse the learning model for the overlapping points (Noisy features are very subtle. One feature may be a noisy feature itself. However, in some cases, when two or more noisy features can complement each other to distinguish samples from different classes, they may be selected together to benefit the learning model.)

Motivation and Background

In many real-world applications, such as data mining, machine learning, computer vision, and bioinformatics, we need to deal with high-dimensional data. In the past 30 years, the dimensionality of the data involved in these areas has increased explosively. The growth of the number of attributes in the UCI machine learning repository is shown in Fig. 2a. In addition, the number of samples also increases explosively. The growth of the number of samples in the UCI machine learning repository is shown in Fig. 2b. The huge number of high-dimensional data has presented serious challenges to existing learning methods. First, due to the large number of features and relatively small number of training samples, a learning model tends to overfit, and their learning performance degenerates. Data with high dimensionality not only degenerates many algorithms' performance due to the curse of dimensionality and the existence of irrelevant, redundant, and noisy dimensions, it also significantly increases the time and memory requirement of the algorithms. Second, storing and processing such amounts of high-dimensional data become a challenge.

Dimensionality reduction is one of the most popular techniques to reduce dimensionality



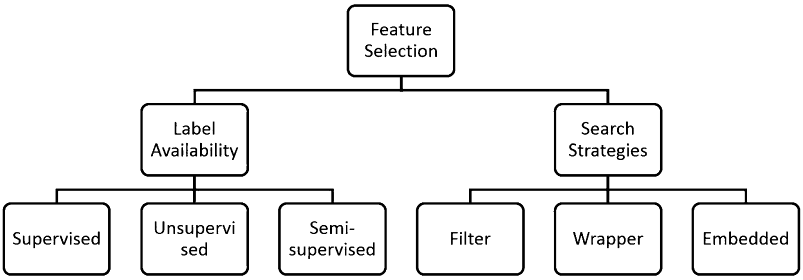
Feature Selection, Fig. 2 Growth of the number of features and the number of samples in the UCI ML repository. (**a**) UCI ML repository number of attribute growth. (**b**) UCI ML repository number of sample growth

and can be categorized into feature extraction and feature selection. Both feature extraction and feature selection are capable of improving performance, lowering computational complexity, building better generalization models, and decreasing required storage. Feature extraction maps the original feature space to a new feature space with lower dimensionality by combining the original feature space. Therefore, further analysis of new features is problematic since there is no physical meaning for the transformed features obtained from feature extraction. In contrast, feature selection selects a subset of features from the original feature set. Therefore, feature selection keeps the actual meaning of each selected feature, which makes it superior in terms of feature readability and interpretability.

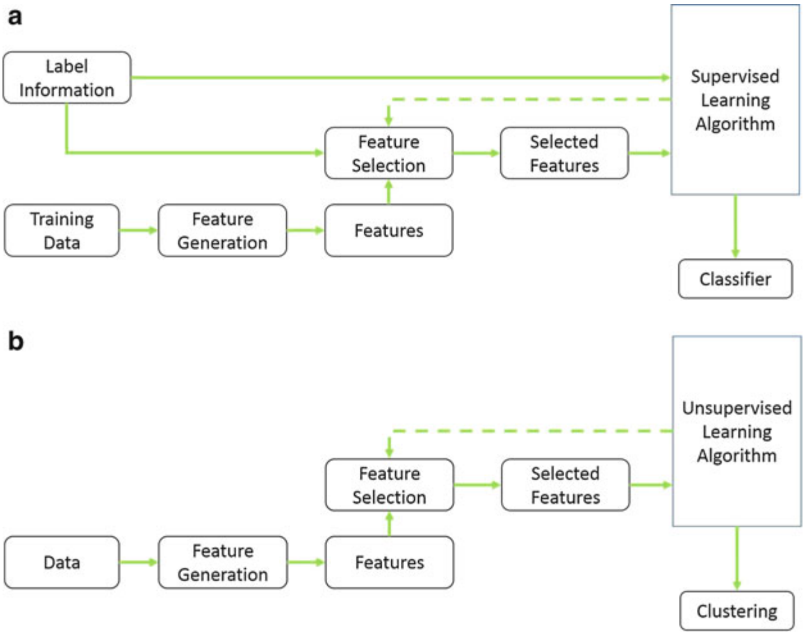
Structure of the Learning System

From the perspective of label availability, feature selection methods can be broadly classified into supervised, unsupervised, and semi-supervised

Feature Selection, Fig. 3 Feature selection categories



Feature Selection, Fig. 4 General frameworks of supervised and unsupervised feature selection. (**a**) A general framework of supervised feature selection. (**b**) A general framework of unsupervised feature selection



methods. In terms of different selection strategies, feature selection can be categorized as filter, wrapper, and embedded models. Figure 3 shows the classification of feature selection methods.

Supervised feature selection is usually used for classification tasks. The availability of the class labels allows supervised feature selection algorithms to effectively select discriminative features to distinguish samples from different classes. A general framework of supervised feature selection is shown in Fig. 4a. Features are first generated from training data. Instead of using all the data to train the supervised learning model, supervised feature selection will first select a subset of features and then process the data with the selected features to the learning model. The feature selection phase will use the label information and the characteristics of the data, such as information gain or Gini index, to select relevant features. The final selected features, as well as with the label information, are used to train a classifier, which can be used for prediction.

Unsupervised feature selection is usually used for clustering tasks. A general framework of unsupervised feature selection is described in Fig. 4b, which is very similar to supervised feature selection, except that there's no label information involved in the feature selection phase and the model learning phase. Without label information to define feature relevance, unsupervised feature selection relies on another alternative criterion during the feature selection phase. One commonly used criterion chooses features that can best preserve the manifold structure of the original data. Another frequently used method is to seek cluster indicators through clustering algorithms and then transform the unsupervised feature selection into a supervised framework. There are two different ways to use this method. One way is to seek cluster indicators and simultaneously perform the supervised feature selection within one unified framework. The other way is to first seek cluster indicators, then to perform feature selection to remove or select certain features, and finally to repeat these two steps iteratively until certain criterion is met. In addition, certain supervised feature selection criterion can still be used with some modification.

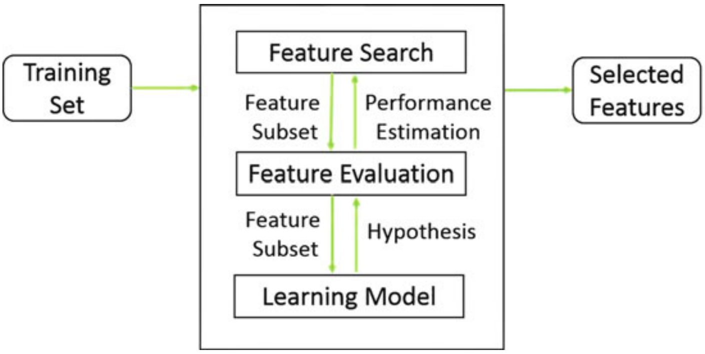
Semi-supervised feature selection is usually used when a small portion of the data is labeled. When such data is given to perform feature selection, both supervised and unsupervised feature selection might not be the best choice. Supervised feature selection might not be able to select relevant features because the labeled data is insufficient to represent the distribution of the features. Unsupervised feature selection will not use the label information, while label information can give some discriminative information to select relevant features. Semi-supervised feature selection, which takes advantage of both labeled data and unlabeled data, is a better choice to handle partially labeled data. The general framework of semi-supervised feature selection is the same as that of supervised feature selection, except that data is partially labeled. Most of the existing semi-supervised feature selection algorithms rely on the construction of the similarity matrix and select features that best fit the similarity matrix. Both the label information and the similarity measure of the labeled and unlabeled data are used to construct the similarity matrix so that label information can provide discriminative information to select relevant features, while unlabeled data provide complementary information.

Filter Models For filter models, features are selected based on the characteristics of the data without utilizing learning algorithms. This approach is very efficient. However, it doesn't consider the bias and heuristics of the learning algorithms. Thus, it may miss features that are relevant for the target learning algorithm. A filter algorithm usually consists of two steps. In the first step, features are ranked based on certain criterion. In the second step, features with the highest rankings are chosen. A lot of ranking criteria, which measures different characteristics of the features, are proposed: the ability to effectively separate samples from different classes by considering between class variance and within class variance, the dependence between the feature and the class label, the correlation between feature-class and feature-feature, the ability to preserve the manifold structure, the mutual information between the features, and so on.

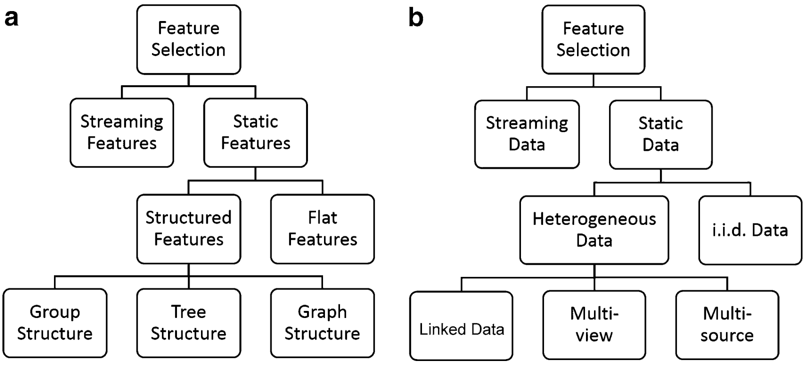
Wrapper Models The major disadvantage of the filter approach is that it totally ignores the effects of the selected feature subset on the performance of the clustering or classification algorithm. The optimal feature subset should depend on the specific biases and heuristics of the learning algorithms. Based on this assumption, wrapper models use a specific learning algorithm to evaluate the quality of the selected features. Given a predefined learning algorithm, a general framework of the wrapper model is shown in Fig. 5. The feature search component will produce a set of features based on certain search strategies. The feature evaluation component will then use the predefined learning algorithm to evaluate the performance, which will be returned to the feature search component for the next iteration of feature subset selection. The feature set with the best performance will be chosen as the final set. The search space for m features is $O(2^m)$. To avoid exhaustive search, a wide range of search strategies can be used, including hill-climbing, best-first, branch-and-bound, and genetic algorithms.

Embedded Models Filter models are computationally efficient, but totally ignore the biases of the learning algorithm. Compared with filter models, wrapper models obtain better predictive accuracy estimates, since they take into account the biases of the learning algorithms. However, wrapper models are very computationally expensive. Embedded models are a tradeoff between the two models by embedding the feature selection into the model construction. Thus, embedded models take advantage of both filter models and wrapper models: (1) they are

Feature Selection, Fig. 5 A general framework of wrapper models



Feature Selection, Fig. 6 Classification of recent development of feature selection from feature perspective and data perspective



far less computationally intensive than wrapper methods, since they don't need to run the learning models many times to evaluate the features, and (2) they include the interaction with the learning model. The biggest difference between wrapper models and embedded models is that wrapper models first train learning models using the candidate features and then perform feature selection by evaluating features using the learning model, while embedded models select features during the process of model construction to perform feature selection without further evaluation of the features.

Recent Developments

The recent emergence of new machine learning algorithms, such as sparse learning, and new types of data, such as social media data, has accelerated the evolution of feature selection. In this section, we will discuss recent developments of feature selection from both feature and data perspectives.

From the feature perspective, features can be categorized as static and streaming features, as shown in Fig. 6a. Static features can be further categorized as flat features and structured features. The recent development of feature selection from the feature perspective mainly focuses on streaming and structure features.

Usually we assume that all features are known in advance. These features are designated as static features. In some scenarios, new features are sequentially presented to the learning algorithm. For example, Twitter produces more than 250 millions tweets per day, and many new words (features) are generated, such as abbreviations. In these scenarios, the candidate features are generated dynamically, and the size of features is unknown. These features are usually named as streaming features, and feature selection for streaming features is called streaming feature selection. For flat features, we assume that features are independent. However, in many real-world applications, features may exhibit certain intrinsic structures, such as overlapping groups, trees, and graph structures. For example, in speed and signal processing, different frequency bands can be represented by groups. Figure 6a shows the classification of structured features. Incorporating knowledge about feature structures may significantly improve the performance of learning models and help select important features. Feature selection algorithms for the structured features usually use the recently developed sparse learning techniques such as group lasso and tree-guided lasso.

From the data perspective, data can be categorized as streaming data and static data as shown in Fig. 6b. Static data can be further categorized as independent identically distributed (i.i.d.) data and heterogeneous data. The recent development of feature selection from the data perspective is mainly concentrated on streaming and heterogeneous data.

Similar to streaming features, streaming data comes sequentially. Online streaming feature selection is proposed to deal with streaming data. When new data instances come, an online feature selection algorithm needs to determine (1) whether adding the newly generated features from the coming data to the currently selected features and (2) whether removing features from the set of currently selected features ID. Traditional data is usually assumed to be i.i.d. data, such as text and gene data. However, heterogeneous data, such as linked data, apparently contradicts this assumption. For example, linked data is inherently not i.i.d., since instances are linked and correlated. New types of data cultivate new types of feature selection algorithms correspondingly, such as feature selection for linked data and multi-view and multisource feature selection.

Applications

High-dimensional data is very ubiquitous in the real world, which makes feature selection a very popular and practical preprocessing technique for various real-world applications, such as text categorization, remote sensing, image retrieval, microarray analysis, mass spectrum analysis, sequence analysis, and so on.

Text Clustering The task of text clustering is to group similar documents together. In text clustering, a text or document is always represented as a bag of words, which causes high-dimensional feature space and sparse representation. Obviously, a single document has a sparse vector over the set of all terms. The performance of clustering algorithms degrades dramatically due to high dimensionality and data sparseness. Therefore, in practice, feature selection is a very important step to reduce the feature space in text clustering.

Genomic Microarray Data Microarray data is usually short and fat data – high dimensionality with a small sample size, which poses a great challenge for computational techniques. Their dimensionality can be up to tens of thousands of genes, while their sample sizes can only be several hundreds. Furthermore, additional experimental complications like noise and variability render the analysis of microarray data an exciting domain. Because of these issues, various feature selection algorithms are adopted to reduce the dimensionality and remove noise in microarray data analysis.

Hyperspectral Image Classification Hyperspectral sensors record the reflectance from the Earth's surface over the full range of solar wavelengths with high spectral resolution, which results in high-dimensional data that contains rich information for a wide range of applications. However, this high-dimensional data contains many irrelevant, noisy, and redundant features that are not important, useful, or desirable for specific tasks. Feature selection is a critical preprocessing step to reduce computational cost for hyperspectral data classification by selecting relevant features.

Sequence Analysis In bioinformatics, sequence analysis is a very important process to understand a sequence's features, functions, structure, or evolution. In addition to basic features that represent nucleotide or amino acids at each position in a sequence, many other features, such as k-mer patterns, can be derived. By varying the pattern length k, the number of features grows exponentially. However, many of these features are irrelevant or redundant; thus, feature selection techniques are applied to select a relevant feature subset and essential for sequence analysis.

Open Problems

Scalability With the rapid growth of dataset size, the scalability of current feature selection algorithms may be a big issue, especially for online classifiers. Large data cannot be loaded to the memory with a single scan. However, full dimensionality data must be scanned for some feature selection. Usually, they require a sufficient number of samples to obtain statistically significant result. It is very difficult to observe the feature relevance score without considering the density around each sample. Therefore, scalability is a big issue.

Stability Feature selection algorithms are often evaluated through classification accuracy or clustering accuracy. However, the stability of algorithms is also an important consideration when developing feature selection methods. For example, when feature selection is applied on gene data, the domain experts would like to see the same or at least similar sets of genes selected after each time they obtain new samples with a small amount of perturbation. Otherwise, they will not trust the algorithm. However, well-known feature selection methods, especially unsupervised feature selection algorithms, can select features with low stability after perturbation is introduced to the training data. Developing algorithms of feature selection with high accuracy and stability is still an open problem.

Parameter Selection In feature selection, we usually need to specify the number of features to select. However, the optimal number of features for the dataset is unknown. If the number of selected features is too few, the performance will be degenerated, since some relevant features are eliminated. If the number of selected features is too large, the performance may also not be very good since some noisy, irrelevant, or redundant features are selected to confuse the learning model. In practice, we would grid search the number of features in a range and pick the one that has relatively better performance on learning models, which is computationally expensive. In particular, for supervised feature selection, cross validation can be used to search the number of features to select. How to automatically determine the best number of selected features remains an open problem.

For many unsupervised feature selection methods, in addition to choosing the optimal number of features, we also need to specify the number of clusters. Since there is no label information and we have limited knowledge about each domain, the actual number of clusters in the data is usually unknown and not well defined. The number of clusters specified by users will result in selecting different feature subsets by the unsupervised feature selection algorithm. How to choose the number of clusters for unsupervised feature selection is an open problem.

Feature Selection in Text Mining

Dunja Mladenić
Artificial Intelligence Laboratory, Jožef Stefan Insitute, Ljubljana, Slovenia

Abstract

Feature selection is commonly used when we are dealing with a large number of features or potentially noisy or redundant features. By selecting only some of the available features we hope to simplify the data representation, reduce the needed time and/or space for data processing, in some cases decrease the cost of collecting the feature values and, in some situations also to improve performance of the data modeling. Even though some approaches to feature selection are commonly applicable also in text mining, there are some specifics worth checking in tuning the existing methods or proposing some new methods for feature selection.

Synonyms

Dimensionality reduction on text via feature selection

Definition

The term *feature selection* is used in machine learning for the process of selecting a subset of features (dimensions) used to represent the data (see ▸ Feature Selection and ▸ Dimensionality Reduction). Feature selection can be seen as a part of data pre-processing potentially followed or coupled with ▸ feature construction (see ▸ Feature Construction in Text Mining), but can also be coupled with the learning phase if embedded in the learning algorithm. An assumption of feature selection is that we have defined an original feature space that can be used to represent the data, and our goal is to reduce its dimensionality by selecting a subset of original features. The original feature space of the data is then mapped onto a new feature space. *Feature selection in text mining* is addressed here separately due to the specificity of textual data compared to the data commonly addressed in machine learning.

Motivation and Background

Tasks addressed in machine learning on text are often characterized by a high number of features used to represent the data. However, these features are not necessarily all relevant and pbeneficial for the task and may slow down the applied methods giving similar results as a much smaller feature set. The main reasons for using feature selection in machine learning are Mladenić (2006) to improve performance, to improve learning efficiency, to provide faster models possibly requesting less information on the original data, and to reduce the complexity of the learned results and enable better understanding of the underlying process.

Feature selection in text mining was applied in a simple form from the start of applying machine learning methods on text data, for instance, feature selection by keeping the most frequent features and learning decision rules ▶ Rule Learning proposed in Apte et al. (1994) or keeping the most informative features for learning decision trees ▶ Decision Trees or ▶ naïve Bayes Bayes Rule proposed in Lewis and Ringuette (1994). The reason is that the number of features used to represent text data for machine learning tasks is high, as the basic approach of learning on text defines a feature for each word that occurs in the given text. This can easily result in several tens of thousands of features, compared to several tens or hundreds of features, as commonly observed on most machine learning tasks at the time.

Most methods for ▶ feature subset selection that are used on text are very simple compared to the feature selection methods developed in machine learning (Liu et al. 2010). They perform a filtering of features assuming feature independence, so that a score is assigned to each feature independently, and the features with high scores are selected. However, there are also more sophisticated methods for feature selection on text data that take into account interactions between the features. Embedded feature selection methods were successfully used on text data, either by applying a learning algorithm that has feature selection embedded (pre-processing step) or by inspecting a model generated by such an algorithm to extract feature scores. On the other hand, approaches to feature selection that search a space of all possible feature subsets can be rather time-consuming when dealing with a high number of features and are rarely used on text data.

Structure of Learning System

Feature selection in text mining is mainly used in connection with applying known machine learning and statistical methods on text when addressing tasks such as ▶ Document Clustering or ▶ Document Classification. This is also the focus of this chapter. However, we may need to perform some kind of feature selection on different text mining tasks where features are not necessary words or phrases, in which case we should reconsider the appropriate feature selection methods in the light of the task properties, including the number and type of features.

As already pointed out, the common way of document text representation is by defining a feature for each word in the document collection and feature selection by assuming feature independence, assigning score to the features, and selecting features with high scores. Scoring of individual features is performed either in an unsupervised way, ignoring the class information, or in a supervised way, taking into account the class information. Surprisingly both kind of approaches have been shown to perform comparably on ▶ document classification tasks, even though supervised scoring uses more information. Here we discuss several feature scoring measures and their performance on document classification, as reported in different researcher papers.

One of the first scoring measures used on text data is scoring by the number of documents that contain a particular word. This was applied after removing very frequent words, as given in a standard "stop-list" for English. An alternative is scoring by frequency – that is, by the number of times a feature occurs in a document collection. Both were shown to work well in document classification (Mladenić and Grobelnik 2003; Yang and Pedersen 1997).

▶ Information gain is commonly used in decision tree induction (Quinlan 1993). It was reported to work well as a feature scoring measure on text data (Yang and Pedersen 1997) in some domains (news articles of in a collection named Reuters-22173, abstracts of medical articles in a subset of the ▶ MEDLINE collection), where a multiclass problem was addressed using the nearest neighbor algorithm ▶ Nearest Neighbor. The same feature scoring almost completely failed when using ▶ naïve Bayes ▶ Bayes Rule on a binary classification problem on a hierarchical topic taxonomy of Web pages (Mladenić and Grobelnik 2003). This difference in performance can be partially attributed to the classification algorithm and domain characteristics.

It is interesting to notice that information gain takes into account all values for each feature. In the case of document classification, these are two values: occurs or does not occur in a document. On the other hand, expected cross entropy as used on text data (Koller and Sahami 1997; Mladenić and Grobelnik 2003) is similar in nature to information gain, but only uses the situation when the feature occurred in a document. Experiments on classifying document into a hierarchical topic taxonomy (Mladenić and Grobelnik 2003) have shown that this significantly improves performance. Expected cross entropy is related to information gain as follows: InfGain(F) = CrossEntropyTxt(F) + CrossEntropy Txt(F), where F is a binary feature (usually representing a word's occurrence).

The ▸ odds ratio was reported to outperform many other measures (Mladenić and Grobelnik 2003) in combination with naïve Bayes, used for document classification on data with highly imbalanced class distribution. A characteristic of naïve Bayes used for ▸ text classification is that, once the model has been generated, the classification is based on the features that occur in a document to be classified. This means that an empty document will be classified into the majority class. Consequently, having a highly imbalanced class distribution, if we want to identify documents from the underrepresented class value, we need to have a model sensitive to the features that occur in such documents. If most of the selected features are representative for the majority class value, the documents from other classes will be almost empty when represented using the selected features.

Experimental comparison of different feature selection measures in combination with the ▸ support vector machines ▸ Support Vector Machines classification algorithm ▸ (SVM) on news articles from the Reuters-2000 collection (Brank et al. 2002) has shown that using all or almost all the features yields the best performance. The same finding was confirmed in experimental evaluation of different feature selection measures on a number of text classification problems (Forman 2003). In addition, in Forman (2003) a new feature selection measure was introduced: binormal separation, which was reported to improve the performance of SVM, especially with problems where the class distribution is highly imbalanced. Interestingly, they also report that information gain is outperforming the other tested measures in the situation when using only a small number of selected features (20–50 features).

Another feature scoring measure for text data, called the Fisher index, was proposed as part of a ▸ document retrieval system based on organizing large text databases into hierarchical topic ▸ taxonomies (Chakrabarti et al. 1998). Similar to Mladenić (1998), for each internal node in the topic taxonomy, a separate feature subset is used to build a ▸ naïve Bayes model for that node. This is sometimes referred to as ▸ local feature selection or, alternatively, context-sensitive feature selection. The feature set used in each node is relatively small and tuned to the node context.

What follows are formulas of the described scoring measures as given in Mladenić and Grobelnik (2003).

$$\begin{aligned}\mathrm{InfGain}(F) &= P(F)\sum\nolimits_i P(C_i|F)\\ &\quad\times\log(P(C_i|F)/P(C_i)) + P(\bar{F})\sum\nolimits_i P(C_i|\bar{F})\\ &\quad\times\log P(C_i|\bar{F})/P(C_i))\end{aligned}$$

$$\mathrm{CrossEntropyTxt}(F) = P(F)\sum\nolimits_i P(C_i|F)\quad \log(P(C_i|F)/P(C_i))$$

$$\mathrm{MutualInfoTxt}(F) = \sum\nolimits_i P(C_i)\log(P(F|C_i)/P(F))$$

$$\begin{aligned}\mathrm{OddsRatio}(F) &= \log(P(F|C_{\mathrm{pos}})(1-P(F|C_{\mathrm{neg}})))\\ &\quad-\log((1-P(F|C_{\mathrm{pos}}))P(F|C_{\mathrm{neg}}))\end{aligned}$$

$$\begin{aligned}\mathrm{Bi\text{-}NormalSeparation}(F) &= Z^{-1}(P(F|C_{\mathrm{pos}}))\\ &\quad - Z^{-1}(P(F|C_{\mathrm{neg}}))\end{aligned}$$

$$\begin{aligned}\mathrm{FisherIndexTxt}(F) &= \left(\sum\nolimits_{\mathrm{pos,neg}}(P(F|C_{\mathrm{pos}}\right)\\ &\quad - P(F|C_{\mathrm{neg}}))^2)/\sum\nolimits_{\mathrm{Ci\varepsilon pos,neg}}|C_i|^{-1}\\ &\quad\times\sum\nolimits_{\mathrm{d\varepsilon Ci}}(n(F,d)-P(F|C_i))2\end{aligned}$$

where $P(F)$ is the probability that feature F occurred, $\bar{F}$ means that the feature does not occur, $P(C_i)$ is the probability of the ith class value, $P(C_i|F)$ is the conditional probability of the ith class value given that feature F occurred, $P(F|C_i)$ is the conditional probability of feature occurrence given the ith class value, $P(F|C_{\text{pos}})$ is the conditional probability of feature F occurring given the class value "positive," $P(F|C_{\text{neg}})$ is the conditional probability of feature F occurring given the class value "negative," $Z^{-1}(x)$ is the standard normal distribution's inverse ▶ cumulative probability function (z-score), $|C_i|$ is the number of documents in class C_i , and $n(F, d)$ is 1 if the document d contains feature F and 0 otherwise.

As already highlighted in ▶ text classification, most of the feature selection methods evaluate each feature independently. A more sophisticated approach is proposed in Brank et al. (2002), where a linear SVM is first trained using all the features, and the induced model is then used to score the features (weight assigned to each feature in the normal to the induced hyperplane is used as a feature score). Experimental evaluation using that feature selection in combination with ▶ SVM, Perceptron, and naïve Bayes has shown that the best performance is achieved by SVM when using almost all the features. The experiments have confirmed the previous findings on ▶ feature subset selection improving the performance of naïve Bayes, but the overall performance is lower than using SVM on all the features.

Much the same as in Brank et al. (2002), feature selection was performed using a linear SVM to rank the features in Bi et al. (2003). However, the experiments in Bi et al. (2003) were performed on a regression problem, and the final model was induced using a nonlinear SVM. The feature selection was shown to improve performance. Feature selection on text was also performed in a two-stage way, first using information gain to score the features and then applying genetic algorithms and principal component analysis (Uguz 2011) .

Distributional clustering of words with an agglomerative approach (words are viewed as distributions over document categories) is used for dimensionality reduction via ▶ feature construction (Bekkerman et al. 2003) that preserves the mutual information between the features as much as possible. This representation was shown to achieve comparable or better results than the bag-of-words document representation using feature selection based on mutual information for text; a linear SVM was used as the classifier. A related approach, also based on preserving the mutual information between the features (Globerson and Tishby 2003), finds new dimensions by using an iterative projection algorithm instead of clustering. It was shown to achieve performance comparable to the bag-of-words representation with all the original features, using significantly less features (e.g., on one dataset, four constructed features achieved 98 % of performance of 500 original features) using the linear SVM classifier.

Divisive clustering for feature construction (Dhillon et al. 2003) was shown to outperform distributional clustering when used for dimensionality reduction on text data. The approach uses the Kullback-Leibler divergence as a distance function and minimizes within-cluster divergence while maximizing between-cluster divergence. Experiments on two datasets have shown that this dimensionality reduction slightly improves the performance of ▶ naïve Bayes (compared to using all the original features), outperforming the agglomerative clustering of words combined with naïve Bayes and achieving considerably higher classification accuracy for the same number of features than feature subset selection using information gain or mutual information (in combination with naïve Bayes or SVM).

First-Order Logic

Peter A. Flach
Department of Computer Science, University of Bristol, Bristol, UK

Synonyms

Predicate logic; Predicate calculus; First-order predicate logic; First-order predicate calculus

Definition

First-order predicate logic – first-order logic for short – is the logic of properties of, and relations between, objects and their parts. Like any logic, it consists of three parts: *syntax* governs the formation of *well-formed formulae*, *semantics* ascribes meaning to well-formed formulae and formalizes the notion of *deductive consequence*, and *proof procedures* allow the inference of deductive consequences by syntactic means. A number of variants of first-order logic exist, mainly differing in their syntax and proof systems. In machine learning, the main use of first-order logic is in ▸ Learning from Structured Data, ▸ Inductive Logic Programming, and ▸ Relational Data Mining.

Motivation and Background

The interest in logic arises from a desire to formalize human, mathematical, and scientific reasoning and goes back to at least the Greek philosophers. Aristotle devised a form of propositional reasoning called *syllogisms* in the fourth century BC. Aristotle was held in very high esteem by medieval scholars, and so further significant advances were not made until after the Middle Ages. Leibniz wrote of an "algebra of thought" and linked reasoning to calculation in the late seventeenth century. Boole and De Morgan developed the algebraic point of view in the mid-nineteenth century.

Universally quantified variables, which form the main innovation in first-order logic as compared to ▸ Propositional Logic, were invented by Gottlob Frege in his *Begriffsschrift* ("concept notation") from 1879 and independently by Charles Sanders Peirce in 1885, who introduced the notation $\prod_x$ and $\sum_x$ for universal and existential quantification. Frege's work went largely unnoticed until it was developed further by Alfred North Whitehead and Bertrand Russell in their *Principia Mathematica* (1903). Seminal contributions were made, among many others: by Giuseppe Peano, who axiomatized number theory and introduced the notation (x) and $\exists x$; by Kurt Gödel, who established the completeness of first-order logic as well as the incompleteness of any system incorporating Peano arithmetic; by Alonzo Church, who proved that first-order logic is undecidable and who introduced λ-calculus, a form of ▸ Higher-Order Logic that allows quantification over predicates and functions (as opposed to first-order logic, which only allows quantification over objects); and by Alfred Tarski, who pioneered logical semantics through model theory and the notion of logical consequence. The now universally accepted notation $\forall x$ was introduced by Gerhard Gentzen.

Logic plays an important role in any approach to symbolic AI that employs a formal language for knowledge representation and inference. A significant, relatively recent development was the introduction of logic programming languages such as ▸ Prolog, which turn logical inference into computation. In machine learning, the use of a first-order language is essential in order to handle domains in which objects have inherent structure; the availability of Prolog as a common language and programming platform gave rise to the field of ▸ Inductive Logic Programming.

Theory

Syntax

A first-order logical language is built from *constant symbols*, *variable symbols*, *predicate symbols*, and *function symbols*; the latter two kinds of symbols have an associated *arity*, which is the number of arguments they take. *Terms* are either constant symbols, variable symbols, or of the form $f(t_1, \ldots, t_n)$ where f is a function symbol with arity n and $t_1, \ldots, t_n$ is a sequence of n terms. Using the logical connectives $\neg$ (negation), $\wedge$ (conjunction), $\vee$ (disjunction), and $\rightarrow$ (material implication) and the quantifiers $\forall$ (universal quantifier) and $\exists$ (existential quantifier), well-formed formulae or *wffs* are defined recursively as follows: (1) if P is a predicate symbol with arity n, and $t_1, \ldots, t_n$ is a sequence of n terms, then $P(t_1, \ldots, t_n)$ is a wff, also referred to as an atomic formula or *atom*; (2) if ϕ_1 and ϕ_2 are wffs, then $(\neg\phi_1)$, $(\phi_1 \wedge \phi_2)$, $(\phi_1 \vee \phi_2)$, and $(\phi_1 \rightarrow \phi_2)$ are wffs; (3) if x is a variable and ϕ is a wff, then $(\forall x : \phi)$ and $(\exists x : \phi)$ are wffs; (4) and nothing else is a wff. Brackets are usually dropped as much as it is possible without causing confusion.

Example 1 Let "*man*," "*single*," and "*partner*" be two unary and one binary predicate symbol, respectively, and let "x" and "y" be variable symbols, then the following is a wff ϕ expressing that men who are not single have a partner:

$$(\forall x : (man(x) \wedge (\neg single(x))) \\ \rightarrow (\exists y : partner(x, y)))$$

Assuming that $\neg$ binds strongest, then $\wedge$, then $\rightarrow$, the brackets can be dropped:

$$\forall x : man(x) \wedge \neg single(x) \\ \rightarrow \exists y : partner(x, y)$$

A *propositional language* is a special case of a predicate-logical language, built only from predicate symbols with arity 0, referred to as *proposition symbols* or propositional atoms, and connectives. So, for instance, assuming the proposition symbols "*man*," "*single*," and "*has_partner*," the following is a propositional wff: $man \wedge \neg single \rightarrow has\_partner$. The main difference is that in propositional logic, references to objects cannot be expressed and therefore have to be understood implicitly.

Semantics

First-order wffs express statements that can be true or false, and so a first-order semantics consists in constructing a mapping from wffs to truth values, given an interpretation, which is a possible state of affairs in the domain of discourse, mapping constant, predicate, and function symbols to elements, relations, and functions in and over the domain. To deal with variables, a valuation function is employed. Once this mapping is defined, the meaning of a wff consists in the set of interpretations in which the wff maps to true, also called its models. The intuition is that the more "knowledge" a wff contains, the fewer models it has. The key notion of logical consequence is then defined in terms of models: one wff is a logical consequence of another if the set of models of the first contains the set of models of the second; hence, the second wff contains at least the same, if not more, knowledge than the first.

Formally, a *predicate-logical interpretation*, or *interpretation* for short, is a pair (D, i), where D is a nonempty *domain* of individuals and i is a function assigning to every constant symbol an element of D, to every function symbol with arity n a mapping from D^n to D, and to every predicate symbol with arity n a subset of D^n, called the *extension* of the predicate. A *valuation* is a function v assigning to every variable symbol an element of D.

Given an interpretation $I = (D, i)$ and a valuation v, a mapping i_v from terms to individuals is defined as follows: (1) if t is a constant symbol, $i_v(t) = i(t)$; (2) if t is a variable symbol, $i_v(t) = v(t)$; (3) and if t is a term $f(t_1, \ldots, t_n)$, $i_v(t) = i(f)(i_v(t_1), \ldots, i_v(t_n))$. The mapping is extended to a mapping from wffs to truth values as follows: (4) if ϕ is an atom $P(t_1, \ldots, t_n)$, $i_v(\phi) = i(P)(i_v(t_1), \ldots, i_v(t_n))$; (5) $i_v(\neg\phi) = T$ if $i_v(\phi) = F$ and F otherwise; (6) $i_v(\phi_1 \wedge \phi_2) = T$ if $i_v(\phi_1) = T$ and $i_v(\phi_2) = T$ and F otherwise; (7) and $i_v(\forall x : \phi) = T$ if $i_{v_{x \rightarrow d}}(\phi) = T$ for all $d \in D$ and F otherwise, where $v_{x \rightarrow d}$ is v except that x is assigned d. The remaining connectives and quantifier are evaluated by rewriting: (8) $i_v(\phi_1 \vee \phi_2) = i_v(\neg(\neg\phi_1 \wedge \neg\phi_2))$; (9) $i_v(\phi_1 \rightarrow \phi_2) = i_v(\neg\phi_1 \vee \phi_2)$; (10) $i_v(\exists x : \phi) = i_v(\neg\forall x : \neg\phi)$.

An interpretation I *satisfies* a wff ϕ, notation $I \models \phi$, if $i_v(\phi) = T$ for all valuations v; we say that I is a *model* of ϕ and that ϕ is *satisfiable*. If all models of a set of wffs Σ are also models of ϕ, we say that Σ *logically entails* ϕ or ϕ is a *logical consequence* of Σ and write $\Sigma \models \phi$. If $\Sigma = \emptyset$, ϕ is called a *tautology* and we write $\models \phi$. A wff ψ is a *contradiction* if $\neg\psi$ is a tautology. Contradictions do not have any models, and consequently $\psi \models \alpha$ for any wff α. The *deduction theorem* says that $\Sigma \models \alpha \rightarrow \beta$ if and only if $\Sigma \cup \{\alpha\} \models \beta$. Another useful fact is that, if $\Sigma \cup \{\neg\gamma\}$ is a contradiction, $\Sigma \models \gamma$; this gives rise to a proof technique known as *Reductio ad absurdum* or *proof by contradiction* (see below).

Example 2 We continue the previous example. Let $D = \{Peter, Paul, Mary\}$, and let the function i be defined as follows: $i(man) = \{Peter, Paul\}$; $i(single) = \{Paul\}$; $i(partner) = \{(Peter, Mary)\}$. We then have that the interpretation $I = (D, i)$ is a model for the wff ϕ above. On the other hand, I does not satisfy $\psi = \forall x : \exists y : partner(x, y)$, and therefore $\phi \not\models \psi$. However, the reverse does hold: there is no interpretation that satisfies ψ and not ϕ, and therefore $\psi \models \phi$.

In case of a propositional logic, this semantics can be considerably simplified. Since there are no terms, the domain D plays no role, and an interpretation simply assigns truth values to proposition symbols. Wffs can then be evaluated using rules (5–6) and (8–9). For example, if $i(man) = T$, $i(single) = T$, and $i(has\_partner) = T$, then $i(man \wedge \neg single \rightarrow has\_partner) = T$. (If this seems counterintuitive, this is probably because the reader's knowledge of the domain suggests another wff $\neg(single \wedge has\_partner)$, which is false in this particular interpretation.)

Proofs

A *proof procedure* consists of a set of *axioms* and a set of *inference rules*. Given a proof procedure P, we say that ϕ is *provable* from Σ and write $\Sigma \vdash_P \phi$ if there exists a finite sequence of wffs $\phi_1, \phi_2, \ldots, \phi_{n-1}, \phi$ which is obtained by successive applications of inference rules to axioms, *premisses* in Σ, and/or previous wffs in the sequence. Such a sequence of wffs, if it exists, is called a *proof* of ϕ from Σ. A proof procedure P is *sound*, with respect to the semantics established by predicate-logical interpretations, if $\Sigma \models \phi$ whenever $\Sigma \vdash_P \phi$; it is *complete* if $\Sigma \vdash_P \phi$ whenever $\Sigma \models \phi$. For a sound and complete proof procedure for first-order predicate logic, see, e.g., Turner (1984, p.15).

A set of wffs Σ is *consistent*, with respect to a proof procedure P, if not both $\Sigma \vdash_P \phi$ and $\Sigma \vdash_P \neg\phi$ for some wff ϕ. Given a sound and complete proof procedure, the proof-theoretic notion of consistency coincides with the semantic notion of satisfiability. In particular, if we can prove that $\Sigma \cup \{\neg\gamma\}$ is inconsistent, then we know that $\Sigma \cup \{\neg\gamma\}$ is not satisfiable, hence a contradiction, and thus $\Sigma \models \gamma$. This still holds if the proof procedure is only complete in the weaker sense of being able to demonstrate the inconsistency of arbitrary sets of wffs (see the resolution inference rule, below).

Example 3 One useful inference rule for predicate logic replaces a universally quantified variable with an arbitrary term, which is called *Universal Elimination*. So, if "c" is a constant symbol in our language, then we can infer

$$man(c) \wedge \neg single(c) \rightarrow \exists y : partner(c, y)$$

from ϕ above by Universal Elimination. Another inference rule, which was called *Modus Ponens* by Aristotle, allows us to infer β from α and $\alpha \rightarrow \beta$. So, if we additionally have $man(c) \wedge \neg single(c)$, then we can conclude

$$\exists y : partner(c, y)$$

by Modus Ponens. This rule is also applicable to propositional logic. An example of an axiom is $c = c$ for any constant symbol c. (Strictly speaking this is an *axiom schema*, giving rise to an axiom for every constant symbol in the language.)

Programming in Logic

Syntax, semantics, and proof procedures for first-order logic can be simplified and made more amenable to computation if we limit the number of ways of expressing the same thing. This can be achieved by restricting wffs to a normal form called *prenex conjunctive normal form* (PCNF). This means that all quantifiers occur at the start of the wff and are followed by a conjunction of disjunctions of atoms and negated atoms, jointly called *literals*. An example of a formula in PCNF is

$$\forall x : \exists y : \neg man(x) \vee single(x) \vee partner(x, y)$$

This formula is equivalent to the wff ϕ in Example 1, in the sense that it has the same set of models, and so either one logically entails the other.

Every first-order wff can be transformed into a logically equivalent formula in PCNF, which is unique up to the order of conjuncts and disjuncts. A transformation procedure can be found in Flach (1994).

PCNF can be further simplified if we use function symbols instead of existential quantifiers. For instance, instead of $\exists y : partner(x, y)$, we can say $partner(x, partner\_of(x))$, where *partner_of* is a unary function symbol called a *Skolem function*, after the Norwegian logician Thoralf Skolem. The two statements are not logically equivalent, as the second entails the first but not vice versa, but this difference is of little practical consequence. Since all variables are now universally quantified, the quantifiers are usually omitted, leading to *clausal form*:

$$\neg man(x) \vee single(x) \\ \vee\ partner(x, partner\_of(x))$$

To sum up, a wff in clausal form is a conjunction of disjunctions of literals, of which the variables are implicitly universally quantified. The individual disjunctions are called *clauses*.

Further simplifications include dispensing with equality, which means that terms involving function symbols, such as $partner\_of(c)$, are not evaluated and in effect treated as names of objects (in this case, the function symbols are called *functors* or *data constructors*). Under this assumption each *ground term* (a term without variables) denotes a different object, which means that we can take the set of ground terms as the domain D of an interpretation; this is called a *Herbrand interpretation*, after the French logician Jacques Herbrand.

The main advantage of clausal logic is the existence of a proof procedure consisting of a single inference rule and no axioms. This inference rule, which is called *resolution*, was introduced by Alan Robinson in 1965 (Robinson 1965). In propositional logic, given two clauses $P \vee Q$ and $\neg Q \vee R$ containing *complementary* literals Q and $\neg Q$, resolution infers the *resolvent* $P \vee R$ (P and/or R may themselves contain several disjuncts). For instance, given $\neg man \vee single \vee has\_partner$ and $man \vee woman$, we can infer $woman \vee single \vee has\_partner$ by resolution. In first-order logic, Q and $\neg Q'$ are complementary if Q and Q' are *unifiable*, i.e., there exists a *substitution* θ of terms for variables such that $Q\theta = Q'\theta$, where $Q\theta$ denotes the application of substitution θ to Q; in this case, the resolvent of $P \vee Q$ and $\neg Q' \vee R$ is $P\theta \vee R\theta$. For instance, from the following two clauses:

$$\neg man(x) \vee single(x) \\ \vee\ partner(x, partner\_of(x))$$

$$\neg single(father\_of(c))$$

we can infer

$$\neg man(father\_of(c)) \vee partner(father\_of(c), \\ partner\_of(father\_of(c)))$$

The resolution inference rule is sound but not complete: for instance, it is unable to produce tautologies such as $man(c) \vee \neg man(c)$ if no clauses involving the predicate man are given. However, it is *refutation-complete*, which means it can demonstrate the unsatisfiability of any set of clauses by deriving the *empty clause*, indicated by $\square$. For instance, $man(c) \wedge \neg man(c)$ is a wff consisting of two clauses which are complementary literals, so by resolution we infer the empty clause in one step.

Refutation by resolution is the way in which queries are answered in the logic programming language ▶ Prolog. Prolog works with a subset of clausal logic called *Horn logic*, named after the logician Alfred Horn. A *Horn clause* is a disjunction of literals with at most one positive (un-negated) literal; Horn clauses can be further divided into *definite clauses*, which have one positive literal, and *goal clauses* which have none. A Prolog program consists of definite clauses, and a goal clause functions as a procedure call. Notice that resolving a goal clause with a definite clause results in another goal clause, because the positive literal in the definite clause (also called its *head*) must be one of the complementary literals. The idea is that the resolution step reformulates the original goal into a new goal that is one step closer to the solution. A refutation is then a sequence of goals $G, G_1, G_2, \ldots, G_n$ such that G is the original goal, each G_i is obtained by resolving G_{i-1} with a clause from the program P, and $G_n = \Box$. Such a refutation demonstrates that $P \cup \{G\}$ is inconsistent, and therefore $P \models \neg G$.

Finding a refutation amounts to a search problem, because there are typically several program clauses that could be resolved against the current goal. Virtually all Prolog interpreters apply a depth-first search procedure, searching the goal literals left to right and the program clauses top-down. Once a refutation is found, the substitutions collected in all resolution steps are composed to obtain an *answer substitution*. One unique feature of logic programming is that a goal may have more than one (or, indeed, less than one) refutation and answer substitution from a given program.

Example 4 Consider the following Prolog program:

```
peano_sum(0,Y,Y).
peano_sum(s(X),Y,s(Z)):
  -peano_sum(X,Y,Z).
```

This program defines addition in Peano arithmetic. We follow Prolog syntax: variables start with an uppercase letter, and `:-` stands for reversed implication ← or "if." The unary functor `s` represents the successor function. So the first rule reads "the sum of 0 and an arbitrary number y is y," and the second rule reads "the sum of $x + 1$ and y is $z + 1$ if the sum of x and y is z."

The goal `:-peano_sum(s(0),s(s(0)),Q)` states, "there are no numbers q such that $1 + 2 = q$." We first resolve this goal with the second program clause to obtain `:-peano_sum(0,s(s(0)),Z)` under the substitution {`Q / s(Z)`}. This new goal states, "there are no numbers z such that $0 + 2 = z$." It is resolved with the first clause to yield the empty clause under the substitution {`Y / s(s(0)),Z / s(s(0))`}. The resulting answer substitution is {`Q / s(s(s(0)))`}, i.e., $q = 3$.

As another example, goal `:-peano_sum(A,B,s(s(0)))` states "there are no numbers a and b such that $a + b = 2$." This goal has three refutations: one involving the first clause only, yielding the answer substitution {`A / 0, B / s(s(0))`}; one involving the second clause then the first, resulting in {`A / s(0), B / s(0)`}; and the third applying the second clause twice followed by the first, yielding {`A / s(s(0)), B / 0`}. Prolog will return these three answers in this order.

Induction in first-order logic amount to reconstructing a logical theory from some of its logical consequences. For techniques to induce a Prolog program given examples such as `peano_sum(s(0),s(0),s(s(0)))`, see ▸ Inductive Logic Programming.

First-Order Regression Tree

Synonyms

Logical regression tree; Relational regression tree

Definition

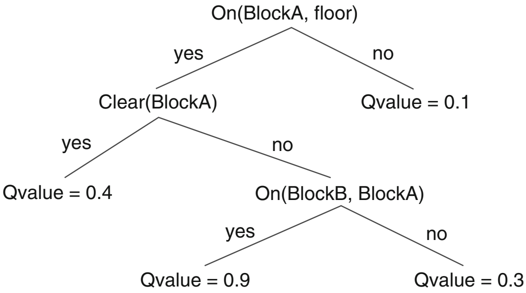
A first-order regression tree can be defined as follows:

Definition 1 (First-Order Regression Tree) A first-order regression tree is a binary tree in which

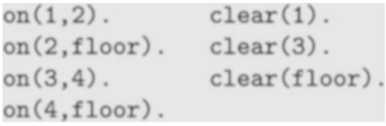
- Every internal node contains a test which is a conjunction of first-order literals.
- Every leaf (terminal node) of the tree contains a real valued prediction.

An extra constraint placed on the first-order literals that are used as tests in internal nodes is that a variable that is introduced in a node (i.e., it does not occur in higher nodes) does not occur in the right subtree of the node.

Figure 1 gives an example of a first-order regression tree. The test in a node should be read as the existentially quantified conjunction of all literals in the nodes in the path from the root of the tree to that node. In the left subtree of a node, the test of the node is added to the conjunction, for the right subtree, the negation of the test should be added. For the example state description of Fig. 2, the tree would predict a $Qvalue = 0.9$, since there exists no block that is both on the floor and clear, but there is a block which is on the floor and has another block on top of it. To see this, substitute BlockA in the tree with 2 (or 4) and BlockB with 1 (or 4).



First-Order Regression Tree, Fig. 1 A relational regression tree



```
on(1,2).          clear(1).
on(2,floor).      clear(3).
on(3,4).          clear(floor).
on(4,floor).
```

First-Order Regression Tree, Fig. 2 State description

The constraint on the use of variables stems from the fact that variables in the tests of internal nodes are existentially quantified. Suppose a node introduces a new variable X. Where the left subtree of a node corresponds to the fact that a substitution for X has been found to make the conjunction true, the right side corresponds to the situation where no substitution for X exists, i.e., there is no such X. Therefore, it makes no sense to refer to X in the right subtree.

Formal Concept Analysis

Gemma C. Garriga
Universite Pierre et Marie Curie, Paris, France

Definition

Formal concept analysis is a mathematical theory of concept hierarchies that builds on order theory; it can be seen as an unsupervised machine learning technique and is typically used as a method of knowledge representation. The approach takes an input binary relation (binary matrix) specifying a set of objects (rows) and a set of attributes for those objects (columns), finds the natural concepts described in the data, and then organizes the concepts in a partial order structure or Hasse diagram. Each concept in the final diagram is a pair of sets of objects and attributes that are maximally contained one in each other.

Theory

The above intuition can be formalized through a Galois connection as follows. Let R be the binary relation between a set of objects and a set of attributes, that is, $R \subseteq \mathcal{O} \times \mathcal{A}$. Two mappings $\alpha\colon \mathcal{O} \mapsto \mathcal{A}$ and $\beta\colon \mathcal{A} \mapsto \mathcal{O}$ are defined so that the operator $\alpha(O)$, for some $O \subseteq \mathcal{O}$, returns the maximal set of attributes common to all objects in O; dually, the operator $\beta(A)$, for some $A \subseteq \mathcal{A}$, returns the maximal set of objects containing all attributes in A. there two mappings induce a Galois connection between the powerset of objects and the powerset of attributes, that is, they satisfy $O \subseteq \beta(A) \Leftrightarrow A \subseteq \alpha(0)$ for a set of objects O and a set of attributes A.

From here, a formal concept is a pair of sets of objects and attributes (O, A) from the binary relation that satisfy $\alpha(O) = A$ and $\beta(A) = O$. Typically, O is called the extent of the concept and A the intent of the concept. Note that concepts can be interpreted from the geometrical point of view, they are maximal rectangles of ones (not necessarily consecutive) in the input binary table R. The organization of all the formal concepts in a Hasse diagram is called the concept lattice. This lattice corresponds to a partial order structure of concepts where edges between concepts correspond to the standard inclusion of the sets.

Formal Concept Analysis, Fig. 2 Concepts of the relation R organized in a Hasse diagram

A small toy example in Figs. 1 and 2 illustrates the formal concepts and their organization in a Hasse diagram.

Motivation and Background

Formal concept analysis has been applied to a variety of disciplines, from psychology, sociology, biology, medicine, linguistics, or industrial engineering, to cite some, for the interactive exploration of implicit and explicit structures in the data.

From the point of view of machine learning and data mining, the connection between the formal concepts of the lattice and the so-called, closed sets of items is remarkable. Closed sets of items appear in the context of ▸ constraint-based mining, in which the user provides restraints that guide a search of patterns in the data. They are maximal sets of attributes occuring frequently in the data; they correspond to a compacted representation of the frequent sets from frequent itemset mining. It is well known that closed sets correspond exactly to the intents of the concepts derived via formal concept analysis, and therefore, from the formal concepts it is possible to construct bases of minimal nonredundant sets of association rules from which all other rules holding in the data can be derived.

Also, formal concept analysis has been typically seen as a type of conceptual ▸ clustering. Each concept or groups of concepts form a cluster of objects sharing similar properties. The diagrams obtained from this sort of clustering can then be used in class discovery and class prediction. Although a diagram of concepts can become large and complex, different approaches have worked toward reducing the complexity of concept lattices via conceptual scaling.

We refer the reader to Ganter and Wille (1998) for a general reference on formal concept analysis, and to Davey and Priestly (2002) for the basic concepts on order theory. For more thorough descriptions of different applications of formal concept analysis in the computer science field, see Carpineto and Romano (2004).

Frequent set

Definition

Frequent itemsets (Agrawal et al. 1993, 1996) are a form of ▸ frequent pattern. Given examples that are sets of items and a minimum frequency, any set of items that occurs at least in the minimum number of examples is a frequent itemset.

For instance, customers of an on-line bookstore could be considered examples, each represented by the set of books he or she has purchased. A set of books, such as {"*Machine Learning*," "*The Elements of Statistical Learning*," "*Pattern Classification*,"} is a frequent itemset if it has been bought by sufficiently many customers. Given a frequency threshold, perhaps only 0.1 or 0.01 % for an on-line store, *all* sets of books that have been bought by at least that many customers are called frequent. Discovery of all frequent itemsets is a typical data mining task. The original use has been as part of ▸ association rule discovery. ▸ Apriori is a classical algorithm for finding frequent itemsets.

The idea generalizes far beyond examples consisting of sets. The pattern class can be re-defined, e.g., to be (frequent) subsequences rather than itemsets; or original data can often be transformed to a suitable representation, e.g., by considering each discrete attribute-value pair or an interval of a continuous attribute as an individual item. In such more general settings, the term ▸ frequent pattern is often used. Another direction to generalize frequent itemsets is to consider other conditions than frequency on the patterns to be discovered; see ▸ constraint-based mining for more details.

Frequent Pattern

Hannu Toivonen
University of Helsinki, Helsinki, Finland

Definition

Given a set $\mathcal{D}$ of examples, a language $\mathcal{L}$ possible patterns, and a minimum frequency min_{-fr}, every pattern $\theta \in \mathcal{L}$ that occurs at least in the minimum number of examples, i.e., $|\{ e \in \mathcal{D} | \theta$ occurs in $e\}| \geq min_{-fr}$, is a frequent pattern. Discovery of all frequent patterns is a common data mining task. In its most typical form, the patterns are ▶ frequent itemsets. A more general formulation of the problem is ▶ constraint-based mining.

Motivation and Background

Frequent patterns can be used to characterize a given set of examples: they are the most typical feature combinations in the data.

Frequent patterns are often used as components in larger data mining or machine learning tasks. In particular, discovery of ▶ frequent itemsets was actually first introduced as an intermediate step in ▶ association rule mining (Agrawal et al. 1993) ("frequent itemsets" were then called "large"). The frequency and confidence of every valid association rule $X \rightarrow Y$ are obtained simply as the frequency of $X \cup Y$ and the ratio of frequencies of $X \cup Y$ and X, respectively.

Frequent patterns can be useful as ▶ features for further learning tasks. They may capture shared properties of examples better than individual original features, while the frequency threshold gives some guarantee that the constructed features are not so likely just noise. However, other criteria besides frequency are often used to choose a good set of candidate patterns.

Structure of Problem

A frequent pattern often is essentially a set of binary ▶ features. Given a set $\mathcal{I}$ of all available features, the pattern language $\mathcal{L}$ then is the power set of $\mathcal{I}$. An example in data $\mathcal{D}$ covers a pattern $\theta \in \mathcal{L}$ if it has all the features of θ. In such cases, the frequent pattern discovery task reduces to the task of discovering ▶ frequent itemsets. Therefore, the structure of the frequent pattern discovery problem is best described using the elementary case of frequent itemsets.

Let $\mathcal{I}$ be the set of all items (or binary features); sub-sets of $\mathcal{I}$ are called itemsets (or examples or patterns, depending on the context). The input to the frequent itemset mining problem is a multiset $\mathcal{D}$ of itemsets (examples described by their features), and a frequency threshold. The task is to output *all* frequent itemsets (patterns) and their frequencies, i.e., all subsets of $\mathcal{I}$ that exceed the given frequency threshold in the given data $\mathcal{D}$.

Example 1 Assume the following problem specification:

- Set of all items $\mathcal{I} = \{A, B, C, D\}$.
- Data $\mathcal{D} = \{\{A, B, C\}\{A, D\}, \{B, C, D\}, \{A, B, C\}, \{C, D\}, \{B, C\}\}$.
- Frequency threshold is 2.

All possible itemsets and their frequencies:

Itemset	Frequency
$\{A\}$	**3**
$\{B\}$	**4**
$\{C\}$	**5**
$\{D\}$	**3**
$\{A, B\}$	**2**
$\{A, C\}$	**2**
$\{A, D\}$	1
$\{B, C\}$	**4**

Itemset	Frequency
$\{B, D\}$	1
$\{C, D\}$	**2**
$\{A, B, C\}$	**2**
$\{A, B, D\}$	0
$\{A, C, D\}$	0
$\{B, C, D\}$	1
$\{A, B, C, D\}$	0

The frequent itemsets are $\{A\}, \{B\}, \{C\}, \{D\}$, $\{A, B\}, \{A, C\}, \{B, C\}, \{C, D\}, \{A, B, C\}$.

The ▶ hypothesis space for itemsets obviously is the power set of $\mathcal{I}$, and it has an exponential size ($2^{|\mathcal{I}|}$) in the number of items. Since all frequent itemsets are output, this is also the size of the output in the worst case (e.g., if the frequency threshold is zero, or if all examples in $\mathcal{D}$ equal $\mathcal{I}$), as well as the worst case time complexity.

In practical applications of frequent itemset mining, the size of the output as well as the running times are much smaller, but they strongly depend on the properties of the data and the frequency threshold. The useful range of thresholds varies enormously among different datasets. In many applications – such as ▶ basket analysis – the number $|\mathcal{I}|$ of different items can be in thousands, even millions, while the typical sizes of examples are at most in dozens. In such sparse datasets a relatively small number of frequent itemsets can reveal the most outstanding co-occurrences; e.g., there are not likely to be very large sets of books typically bought by the same customers. In dense datasets, in turn, the number of frequent patterns can be overwhelming and also relatively uninformative. E.g., consider the dense dataset of books that have *not* been purchased by a customer: there are a huge number of sets of books that have not been bought by the same customers.

Theory/Solutions

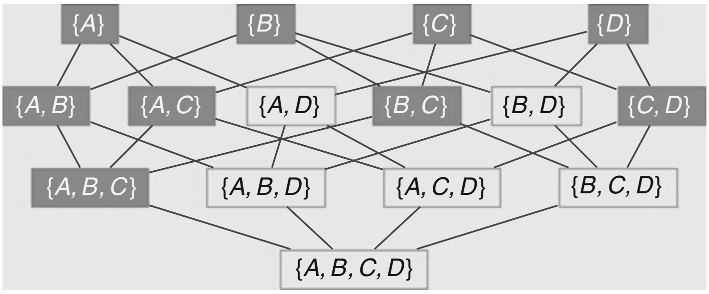
The most widely known solution for finding all frequent itemsets is the ▶ Apriori algorithm (Agrawal et al. 1996). It is based on the monotonicity of itemset frequencies (a ▶ generalization relation): the frequency of a set is at most as high as the frequency of any of its subsets. Conversely, if a set is known to be infrequent, then none of its supersets can be frequent.

Apriori views the ▶ hypothesis space of itemsets as a (refinement) lattice defined by set containment, and performs a ▶ general-to-specific search using breadth-first search. In other words, it starts with singleton itemsets, the most general and frequent sets, and proceeds to larger and less frequent sets. The search is pruned whenever a set does not reach the frequency threshold: all supersets of such sets are excluded from further search. Apriori deviates from standard breadth-first search by evaluating all sets of equal size in a single batch, i.e., it proceeds in a levelwise manner. This has no effect on the search structure or results, but can reduce disk access considerably for large databases. See the entry ▶ Apriori Algorithm for an outline of the method.

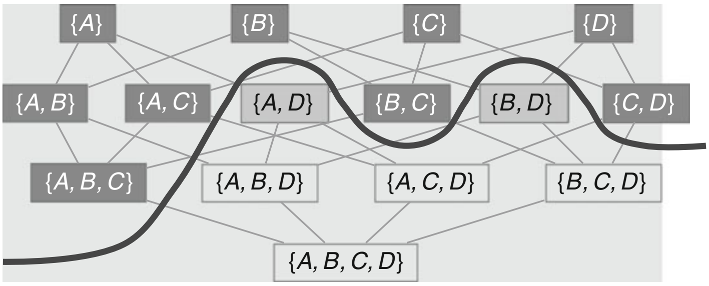
Example 2 Figure 1 illustrates the search space for the data $\mathcal{D}$ of Example 1. Dark nodes represent frequent itemsets, i.e., the answer to the frequent itemset mining problem. Apriori traverses the space a level at a time. For instance, on the second level, it finds out that $\{A, D\}$ and $\{B, D\}$ are not frequent. It therefore prunes all their supersets, i.e., does not evaluate sets $\{A, B, D\}$, $\{A, C, D\}$, and $\{B, C, D\}$ on the third level.

Other search strategies have also been applied. A depth-first search without the subset check allows faster identification of candidates, at the expense of having more candidates to evaluate and doing that without natural batches (e.g. Zaki 2000). FP-growth (Han et al. 2004) uses a tree structure to store the information in the dataset, and uses it to recursively search for frequent itemsets.

The search strategy of Apriori is optimal in a certain sense. Consider the number of sets evaluated, and assume that for any already evaluated set we know whether it was frequent or not but do not consider its frequency. Apriori evaluates the frequencies of all frequent itemsets plus a number of candidates that turn out to be infrequent. It



Frequent Pattern, Fig. 1 The search space of frequent itemsets for data D of the running example. *Dark nodes*: frequent itemsets; *white nodes*: infrequent itemsets



Frequent Pattern, Fig. 2 The positive border ($\{A, B, C\}$, $\{C, D\}$) and negative border ($\{A, D\}$, $\{B, D\}$) of frequent itemsets

turns out that every infrequent candidate must actually be evaluated under the given assumptions: knowing which other sets are frequent and which are not does not help, regardless of the search order. This observation leads to the concept of *border*: the border consists of all those itemsets whose all proper subsets are frequent and whose all proper supersets are infrequent (Gunopulos et al. 2003; Mannila and Toivonen 1997). The border can further be divided into two: the positive border contains those itemsets in the border that are frequent, the negative border contains those that are not. The positive border thus consists of the most specific patterns that are frequent, and corresponds to the "S" set of ► version spaces.

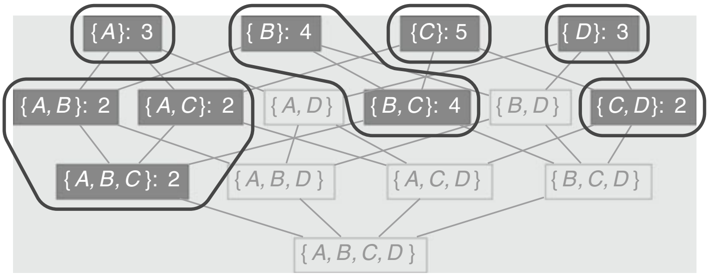
Example 3 Continuing our running example, Fig. 2 illustrates the border between the frequent and infrequent sets. Either the positive or the negative border can alone be used to specify the collection of frequent itemsets: every frequent itemset is a subset of a set in the positive border ($\{A, B, C\}$, $\{C, D\}$), while every infrequent itemset is a superset of a set in the negative border ($\{A, D\}$, $\{B, D\}$).

One variant of frequent itemset mining is to output the positive border only, i.e., to find the *maximal frequent itemsets* (Bayardo 1998). This can be implemented with search strategies that do not need to evaluate the whole space of frequent patterns. This can be useful especially if the number of frequent itemsets is very large, or if the maximal frequent itemsets are large (in which case the number of frequent itemsets is large, too, since the number of subsets is exponential in the length of the maximal set). As a trade-off, the result does not directly indicate frequencies of itemsets.

Condensed Representations: Closed Sets and Nonderivable Sets

Closed sets and nonderivable sets are a powerful concept for working with frequent itemsets, especially if the data is relatively dense or there are strong dependencies. Unlike the aforementioned simple model for borders, here also the known frequencies of sets are used to make inferences about frequencies of other sets.

As a motivation for closed sets (Pasquier et al. 1999), consider a situation where the frequency of itemset $\{i, j\}$ equals the frequency of item j. This implies that whenever j occurs, so does i. Thus, any set $A \cup \{j\}$ that contains item j also contains item i, and the frequencies of sets $A \cup \{j\}$ and $A \cup \{i, j\}$ must be equal. As a result,



Frequent Pattern, Fig. 3 Frequencies and equivalence classes of frequent itemsets in data $\mathcal{D}$ of the running example, and the corresponding closed sets and generators

it sufficies to evaluate sets $A\cup\{j\}$ to obtain the frequencies of sets $A\cup\{i, j\}$, too.

More formally, the *closure* of set A is its largest superset with identical frequency. A is *closed* iff it is its own closure, i.e., if every proper superset of A has a smaller frequency than A. The utility of closed sets comes from the fact that frequent closed sets and their frequencies are a sufficient representation of all frequent sets. Namely, if B is a frequent set then its closure is a frequent closed set in $\mathcal{C}l$, where $\mathcal{C}l$ denotes the collection of all frequent closed itemsets. B's frequency is obtained as $\mathrm{fr}(B) = \max\{\mathrm{fr}(A) | A \epsilon \mathcal{C}l \text{ and } B \subseteq A\}$. If B is not a frequent set, then it has no superset in $\mathcal{C}l$. ▶ Formal concept analysis studies and uses closed sets and other related concepts.

Generators are a complementary concept, and also constitute a sufficient representation of frequent itemsets. (To be more exact, in addition to frequent generators, generators in the border are also needed). Set A is a *generator* (also known as a key pattern or a free set) if all its proper subsets have a larger frequency than A has. Thus, in an equivalence class of itemsets, defined by the set of examples in which they occur, the maximal element is unique and is the closed set, and the minimal elements are generators. The property of being a generator is monotone in the same way that being frequent is, and generators can be found with simple modifications to the Apriori algorithm.

Example 4 Figure 3 illustrates the equivalence classes of itemsets by circles. For instance, the closure of itemset $\{A, B\}$ is $\{A, B, C\}$, i.e., whenever $\{A, B\}$ occurs in the data, C also occurs, but no other items. Given just the frequent closed sets and their frequencies, the frequency of, say, $\{B\}$ is obtained by finding its smallest frequent closed superset. It is $\{B, C\}$, with frequency 4, which is also B's frequency. Alternatively, using generators as the condensed representation, the frequency of itemset $\{B, C\}$ can be obtained by finding its maximal generator subset, i.e., $\{B\}$, with which it shares the same frequency.

Nonderivability of an itemset (Calders and Goethals 2002) is a more complex but often also a more powerful concept than closed sets. Given the frequencies of (some) subsets of itemset A, the frequency of A may actually be uniquely determined, i.e., there is only one possible consistent value. A practical method of trying to determine the frequency is based on deriving upper and lower bounds with inclusion–exclusion formula from the known frequencies of some subsets, and checking if these coincide. An itemset is derivable if this is indeed the case, otherwise it is *nonderivable*. Obviously, the collection of nonderivable frequent sets is a sufficient representation for all frequent sets.

Bounds for the absolute frequency of set I are obtained from its subsets as follows, for any $X \subseteq I$:

$$\mathrm{fr}(I) \le \sum_{J:X\subseteq J\subset I} (-1)^{|I\setminus J|+1}\mathrm{fr}(J) \qquad \text{if}|I\setminus X|\text{is odd}, \tag{1}$$

$$\mathrm{fr}(I) \ge, \sum_{J:X\subseteq J\subset I} (-1)^{|I\setminus J|+1}\,\mathrm{fr}(J) \qquad \text{if } |I\setminus X| \text{ is even}. \tag{2}$$

Using all subsets X of I, one can obtain a number of upper and lower bounds. If the least upper bound equals the greatest lower bound, then set I is derivable. The conceptual elegance of this solution lies in the fact that derivable sets follow logically from the nonderivable ones – the aforementioned formula is one way of finding (some) such situations – whereas with closed sets the user must know the closure properties.

Generalizations of Frequent Patterns

The concept of frequent patterns has been extended in two largely orthogonal directions. One is to more complex patterns and data, such as frequent sequences, trees (see ▶ tree mining), graphs (see ▶ graph mining), and first-order logic (Dehaspe and Toivonen 1999). The other direction to generalize the concept is to ▶ constraint-based mining, where other and more complex conditions are considered beyond frequency. We encourage the interested reader to continue at the entry for ▶ constraint-based mining, which also gives further insight into many of the more theoretical aspects of frequent pattern mining.

Programs and Data

Weka: http://www.cs.waikato.ac.nz/ml/weka/
Christian Borgelt's implementations: http://www.borgelt.net/software.html
Data mining template library: http://dmtl.sourceforge.net/

Applications

Frequent patterns are a general purpose tool for data exploration, with applications virtually everywhere. Market ▶ basket analysis was the first application, telecom alarm correlation and gene mapping are examples of quite different application fields.

Future Directions

Work on frequent pattern mining is being expanded in several directions. New types of pattern languages are being developed, either to meet some specific needs or to increase the expressive power. Many of these developments are motivated by different types of data and applications. Within machine learning, frequent patterns are increasingly being used as a tool for feature construction in complex domains. For an end-user application, methods for choosing and ranking the most interesting patterns among thousands or millions of them is a crucial problem, for which there are no perfect solutions (cf. Geng and Hamilton 2006). At the same time, theoretical understanding of the problem and solutions of frequent pattern discovery still has room for improvement.

Fuzzy Sets

Fuzzy sets were introduced by Lofti Zadeh as a generalization of the concept of a regular set. A fuzzy set is characterized by a membership function that assigns a degree (or grade) of membership to all the elements in the universe of discourse. The membership value is a real number in the range [0, 1], where 0 denotes no definite membership, 1 denotes definite membership, and intermediate values denote partial membership to the set. In this way, the transition from nonmembership to membership in a fuzzy set is gradual and not abrupt like in a regular set, allowing the representation of imprecise concepts like "small," "cold," "large," or "very" for example.

A variable with its values defined by fuzzy sets is called a linguistic variable. For example, a linguistic variable used to represent a temperature can be defined as taking the values "cold," "comfortable," and "warm," each one of them defined as a fuzzy set. These linguistic labels, which are imprecise by their own nature, are, however, defined very precisely by using fuzzy set concepts.

Based on the concepts of fuzzy sets and linguistic variables, it is possible to define a complete fuzzy logic, which is an extension of the classical logic but appropriate to deal with approximate knowledge, uncertainty, and imprecision.

Fuzzy Systems

A fuzzy system is a computing framework based on the concepts of the theory of ▸ fuzzy sets, fuzzy rules, and fuzzy inference. It is structured in four main components: a knowledge base, a fuzzification interface, an inference engine, and a defuzzification interface. The knowledge base consists of a rule base defined in terms of fuzzy rules, and a database that contains the definitions of the linguistic terms for each input and output linguistic variable. The fuzzification interface transforms the (crisp) input values into fuzzy values, by computing their membership to all linguistic terms defined in the corresponding input domain. The inference engine performs the fuzzy inference process, by computing the activation degree and the output of each rule. The defuzzification interface computes the (crisp) output values by combining the output of the rules and performing a specific transformation.

Fuzzy systems can be classified in different categories. The most widely used are the Mamdani and the Takagi-Sugeno models. In a Mamdani fuzzy system the output variables are defined as linguistic variables while in a Takagi-Sugeno fuzzy system they are defined as a linear combination of the input variables.

Fuzzy systems can model nonlinear functions of arbitrary complexity, however, their main strength comes from their ability to represent imprecise concepts and to establish relations between them.

Australia

Abstract
Gaussian distributions are one of the most important distributions in statistics. It is a continuous probability distribution that approximately describes some mass of objects that concentrate about their mean. The probability density function is bell shaped, peaking at the mean. Its popularity also arises partly from the central limit theorem, which says the average of a large number of independent and identically distributed random variables is approximately Gaussian distributed. Moreover, under some reasonable conditions, posterior distributions become approximately Gaussian in the large data limit. Therefore, the Gaussian distribution has been used as a simple model for many theoretical and practical problems in statistics, natural science, and social science.

Synonyms

Normal distribution

Definition

The simplest form of Gaussian distribution is the one-dimensional standard Gaussian distribution, which can be described by the probability density function (*pdf*):

$$p(x) = \phi(x) = \frac{1}{\sqrt{2\pi}} e^{-x^2/2},$$

where $\frac{1}{\sqrt{2\pi}}$ ensures the normalization, i.e., $\int_{\mathbb{R}} p(x)\mathrm{d}x = 1$. This distribution centers around $x = 0$, and the rate of decay or "width" of the curve is 1.

More generally, we can apply translation and scaling to obtain a Gaussian distribution that centers on arbitrary $\mu \in \mathbb{R}$ and with arbitrary width $\sigma > 0$. The *pdf* is

$$\begin{aligned} p(x) &= \frac{1}{\sigma}\phi\left(\frac{x-\mu}{\sigma}\right) \\ &= \frac{1}{\sqrt{2\pi}\sigma} \exp\left(-\frac{(x-\mu)^2}{2\sigma^2}\right). \end{aligned}$$

Technically, μ is called the mean and σ^2 is called the variance. Obviously, μ is the peak/mode of the density and is also the mean and median of the distribution due to the symmetry of the density around μ. If a random variable X has this density, then we write

$$X \sim \mathcal{N}(\mu, \sigma^2).$$

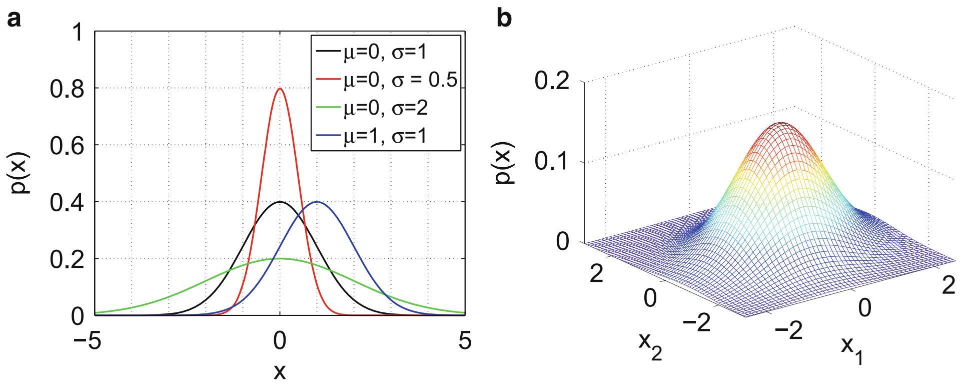
DOI 10.1007/978-1-4899-7687-1



Gaussian Distribution, Fig. 1 Gaussian probability density functions. (**a**) One dimension. (**b**) Two dimension

Example density functions are plotted in Fig. 1a.

As an extension to multivariate random variables, the multivariate Gaussian distribution is a distribution on d-dimensional column vector $\mathbf{x}$ with mean column vector $\boldsymbol{\mu}$ and positive definite variance matrix Σ. This gives

$$p(\mathbf{x}|\boldsymbol{\mu},\boldsymbol{\Sigma}) = \frac{1}{(2\pi)^{d/2}\det^{1/2}\Sigma}\exp\left(-\frac{1}{2}(\mathbf{x}-\boldsymbol{\mu})^{\top}\Sigma^{-1}(\mathbf{x}-\boldsymbol{\mu})\right),$$

and is denoted by $X \sim \mathcal{N}(\boldsymbol{\mu},\Sigma)$. An example *pdf* for the two-dimensional case is plotted in Fig. 1b.

Motivation and Background

In history, Abraham de Moivre first introduced this distribution in 1733 under the name "normal distribution" (of course, he did not call it Gaussian distribution since Gauss had not yet been born). Then Laplace used it to analyze experiment errors, based on which Legendre invented the least squares in 1805. Carl Friedrich Gauss rigorously justified it in 1809 and determined the formula of its probability density function. Finally this distribution is named the Gaussian distribution after Gauss. The name "normal distribution" is also widely used, meaning it is a typical, common, or usual distribution. It was coined by Peirce, Galton, and Lexis around 1875 and made popular by Karl Pearson near the inception of the twentieth century.

Theory/Solution

Canonical Form

The standard definition allows one to easily read off the moments from the *pdf*. Another useful parameterization is called canonical parameterization:

$$p(\mathbf{x}|\boldsymbol{\eta},\Lambda) = \exp\left(\boldsymbol{\eta}^{\top}\mathbf{x} - \frac{1}{2}\mathbf{x}^{\top}\Lambda\mathbf{x} - \frac{1}{2}\left(d\log(2\pi) - \log\det\Lambda + \boldsymbol{\eta}^{\top}\Lambda\boldsymbol{\eta}\right)\right),$$

where $\eta = \Sigma^{-1}\boldsymbol{\mu}$ and $\Lambda = \Sigma^{-1}$. Λ is often called precision. This parameterization is useful when posing the distribution as a member of the exponential family.

Cumulative Distribution Function

For one-dimensional Gaussian distribution, the cumulative distribution function (*cdf*) is defined by

$$\Phi(x) = \int_{-\infty}^{x}\phi(t)\mathrm{d}t.$$

Formally, it can be conveniently represented by the error function and its complement:

$$\mathrm{erf}(x) = \frac{2}{\sqrt{\pi}} \int_0^x e^{-t^2} \mathrm{d}t,$$

$$\mathrm{erfc}(x) = 1 - \mathrm{erf}(x) = \frac{2}{\sqrt{\pi}} \int_x^\infty e^{-t^2} \mathrm{d}t.$$

So

$$\Phi(x) = \frac{1}{2}\left(1 + \mathrm{erf}\left(\frac{x}{\sqrt{2}}\right)\right) = \frac{1}{2}\mathrm{erfc}\left(-\frac{x}{\sqrt{2}}\right).$$

The inverse of the *cdf*, called quantile function, can be written as

$$\Phi^{-1}(s) = \sqrt{2}\mathrm{erf}^{-1}(2s-1), \quad \text{for } s \in (0,1).$$

The *cdf* error function erf() and its inverse $\mathrm{erf}^{-1}()$ do not usually have a closed form and can be computed numerically by functions like `ERF` in Fortran and `double erf(double x)` in C/C++. For the multivariate case, the corresponding *cdf* is highly challenging to compute numerically.

Moments

The first order moment is $\mathbb{E}[X] = \boldsymbol{\mu}$, the variance is $\mathrm{Var}[X] = \Sigma$, and all higher order cumulants are 0. Any central moments with odd terms are 0, i.e., $\mathbb{E}[\Pi_{i=1}^d (x_i - \mu_i)^{p_i}] = 0$ when $\sum_i p_i$ is odd.

Entropy and Kullback-Leibler Divergence

The differential entropy of multivariate Gaussian is

$$h(p) = -\int_{\mathbb{R}^d} p(\mathbf{x}) \ln p(\mathbf{x}) \mathrm{d}\mathbf{x}$$
$$= \frac{1}{2} \ln\left((2\pi e)^d \det \Sigma\right).$$

The Kullback-Leibler divergence from $\mathcal{N}(\boldsymbol{\mu}_1, \Sigma_1)$ to $\mathcal{N}(\boldsymbol{\mu}_2, \Sigma_2)$ is

$$\mathrm{KL}(\mathcal{N}(\boldsymbol{\mu}_1, \Sigma_1) || \mathcal{N}(\boldsymbol{\mu}_2, \Sigma_2))$$
$$= \frac{1}{2}\left(\ln \frac{\det \Sigma_2}{\det \Sigma_1} + \mathrm{tr}\Sigma_2^{-1}\Sigma_1 \right.$$
$$\left. + (\boldsymbol{\mu}_2 - \boldsymbol{\mu}_1)^\top \Sigma_2^{-1} (\boldsymbol{\mu}_2 - \boldsymbol{\mu}_1) - d \right).$$

Properties Under Affine Transform

Let $X \sim \mathcal{N}(\boldsymbol{\mu}, \Sigma)$. Suppose A is a linear transform from $\mathbb{R}^d$ to $\mathbb{R}^s$ and $\boldsymbol{c} \in \mathbb{R}^s$, then

$$A\mathbf{x} + \boldsymbol{c} \sim \mathcal{N}(A\boldsymbol{\mu} + \boldsymbol{c}, A\Sigma A^\top)$$
$$\mathbb{E}[(\mathbf{x} - \boldsymbol{\mu})^\top A(\mathbf{x} - \boldsymbol{\mu})] = \mathrm{tr}A\Sigma$$
$$\mathrm{Var}[(\mathbf{x} - \boldsymbol{\mu})^\top A(\mathbf{x} - \boldsymbol{\mu})] = 2\mathrm{tr}A\Sigma A\Sigma$$

where the last two relations require $s = d$.

Conjugate Priors

Conjugate priors where discussed in `<the entry on Prior Probabilities>` (Springer formatters, we want to reference this entry in-line, please format appropriately.). With known variance, the conjugate prior for the mean is again a multivariate Gaussian. With known mean, the conjugate prior for the variance matrix is the Wishart distribution, while the conjugate prior for the precision matrix is the Gamma distribution.

Parameter Estimation

Given n *iid* observations $X_1, \ldots, X_n$, the maximum likelihood estimator of the mean is simply the sample mean

$$\tilde{\boldsymbol{\mu}} = \bar{X} = \frac{1}{n}\sum_{i=1}^n X_i.$$

The maximum likelihood estimator of the covariance matrix is

$$\tilde{\Sigma} = \frac{1}{n}\sum_{i=1}^n (X_i - \bar{X})(X_i - \bar{X})^\top.$$

This estimator is biased, and its expectation is $\mathbb{E}[\tilde{\Sigma}] = \frac{n-1}{n}\Sigma$. An unbiased estimator is

$$\tilde{\Sigma} = S = \frac{1}{n-1}\sum_{i=1}^n (X_i - \bar{X})(X_i - \bar{X})^\top.$$

Distributions Induced by the Gaussian

If $X \sim \mathcal{N}(0, \Sigma)$, then $X^\top \Sigma^{-1} X$ has a Gamma distribution Gamma$(d/2, 2)$.

Let $X_1, X_2 \sim \mathcal{N}(0,1)$ and they are independent. Their ratio is the standard Cauchy distribution, $X_1/X_2 \sim \text{Cauchy}(0,1)$.

Given n independent univariate random variables $X_i \sim \mathcal{N}(0,1)$, the random variable $Z := \sqrt{\sum_i X_i^2}$ has a χ distribution with degree of freedom n. And Z^2 has a χ^2 distribution with degree of freedom n.

Using Basu's theorem or Cochran's theorem, one can show that the sample mean of $X_1, \ldots, X_n$ and the sample standard deviation are independent. Their ratio

$$t := \frac{\bar{X}}{S} = \frac{\frac{1}{n}(X_1 + \ldots + X_n)}{\sqrt{\frac{1}{n-1}\left[(X_1 - \bar{X})^2 + \ldots + (X_n - \bar{X})^2\right]}}$$

has the student's t-distribution with degree of freedom $n-1$.

Applications

This section discusses some applications and properties of the Gaussian.

Central Limit Theorem

Given n independent and identically distributed observations drawn from a distribution whose variance is finite, the average of the observations is asymptotically Gaussian distributed when n tends to infinity. Under certain conditions, the requirement for identical distribution can be relaxed, and asymptotic normality still holds.

Approximate Gaussian Posterior

Consider n independent and identically distributed observations drawn from a distribution $p(X_i|\boldsymbol{\theta})$, so the data set is $\mathbf{X} = (X_1, \ldots, X_n)^\top$. Under certain conditions, saying roughly that the posterior on $\boldsymbol{\theta}$ converges in probability to a single interior point in its domain as $n \to \infty$, the posterior for $\boldsymbol{\theta}$ is approximately Gaussian for large n, $\boldsymbol{\theta}|\mathbf{X} \approx \mathcal{N}\left(\widehat{\boldsymbol{\theta}}, I\left(\widehat{\boldsymbol{\theta}}\right)\right)$, where $\widehat{\boldsymbol{\theta}}$ is the maximum likelihood or aposterior value for $\boldsymbol{\theta}$ and $I(\boldsymbol{\theta})$ is the *observed (Fisher) information*, the negative of the second derivative (Hessian) of the likelihood w.r.t. the parameters $\boldsymbol{\theta}$.

The Gaussian approximation to the posterior, while a poor approximation in many cases, serves as a useful insight into the nature of asymptotic reasoning. It is justified based on the multidimensional Taylor expansion of the log likelihood at the maximum likelihood or a posterior value, together with its asymptotic convergence property.

3-σ Rule

For standard Gaussian distribution, 99.7 % of the probability mass lie within the three standard deviations $[-3\sigma, 3\sigma]$, i.e., $\int_{-3\sigma}^{3\sigma} \phi(x)\mathrm{d}x > 0.997$. About 95 % mass lies within two standard deviations and about 68 % within one standard deviation. This empirical rule is called 3-σ rule and can be easily extended to general one-dimensional Gaussian distributions.

Combination of Random Variables

Let d-dimensional random variables $X_i \sim \mathcal{N}(\boldsymbol{\mu}_i, \Sigma_i)$. If they are independent, then for any set of linear transforms A_i from $\mathbb{R}^d$ to $\mathbb{R}^s$, we have $\sum_i A_i X_i \sim \mathcal{N}(\sum_i A_i \boldsymbol{\mu}_i, \sum_i A_i \Sigma_i A_i^\top)$. The converse is also true by the Cramer's theorem: if X_i are independent and their sum $\sum_i X_i$ is Gaussian distributed, then all X_i must be Gaussian.

Correlations and Independence

In general, independent random variables must be uncorrelated but not vice versa. However, if a multivariate random variable is jointly Gaussian, then any uncorrelated subset of the random variables *must be* independent. Notice the precondition of joint Gaussian. It is possible for two Gaussian random variables to be uncorrelated but not independent, for the reason that they are not jointly Gaussian. For example, let $X \sim \mathcal{N}(0,1)$ and $Y = -X$ if $|X| < c$, and $Y = X$ if $|X| > c$. By properly setting c, Y and X can be made uncorrelated but obviously not independent.

Marginalization, Conditioning, and Agglomeration

Suppose the vector $\mathbf{x}$ can be written as $(\mathbf{x}_1^\top, \mathbf{x}_2^\top)^\top$ and correspondingly the mean and covariance matrix can be written as

$$\boldsymbol{\mu} = \begin{pmatrix} \boldsymbol{\mu}_1 \\ \boldsymbol{\mu}_2 \end{pmatrix}, \quad \Sigma = \begin{pmatrix} \Sigma_{11} & \Sigma_{12} \\ \Sigma_{21} & \Sigma_{22} \end{pmatrix}$$

Then the marginal distribution of $\mathbf{x}_1$ is Gaussian $\mathcal{N}(\mu_1, \Sigma_{11})$, and the conditional distribution of $\mathbf{x}_1$ conditioned on $\mathbf{x}_2$ is $\mathcal{N}(\boldsymbol{\mu}_{1|2}, \Sigma_{1|2})$, where

$$\boldsymbol{\mu}_{1|2} = \boldsymbol{\mu}_1 + \Sigma_{12}\Sigma_{22}^{-1}(\mathbf{x}_2 - \boldsymbol{\mu}_2),$$
$$\Sigma_{1|2} = \Sigma_{11} - \Sigma_{12}\Sigma_{22}^{-1}\Sigma_{21}.$$

Suppose the multivariate Gaussian vector $\mathbf{x}_1 \sim \mathcal{N}(\mu_1, \Sigma_{11})$ and a vector $\mathbf{x}_2$ is a linear function of $\mathbf{x}_1$ with Gaussian noise, i.e., $\mathbf{x}_2|\mathbf{x}_1 \sim \mathcal{N}(A\mathbf{x}_1 + \boldsymbol{\mu}_{12}, \Sigma_{12})$. Then the joint distribution of $(\mathbf{x}_1^\top, \mathbf{x}_2^\top)^\top$ is also Gaussian:

$$\begin{pmatrix} \mathbf{x}_1 \\ \mathbf{x}_2 \end{pmatrix} \sim \mathcal{N}\left(\begin{pmatrix} \boldsymbol{\mu}_1 \\ A\boldsymbol{\mu}_1 + \boldsymbol{\mu}_{12} \end{pmatrix}, \begin{pmatrix} \Sigma_{11} + A^\top\Sigma_{12}A & -A^\top\Sigma_{12} \\ -\Sigma_{12}A & \Sigma_{12} \end{pmatrix}\right).$$
