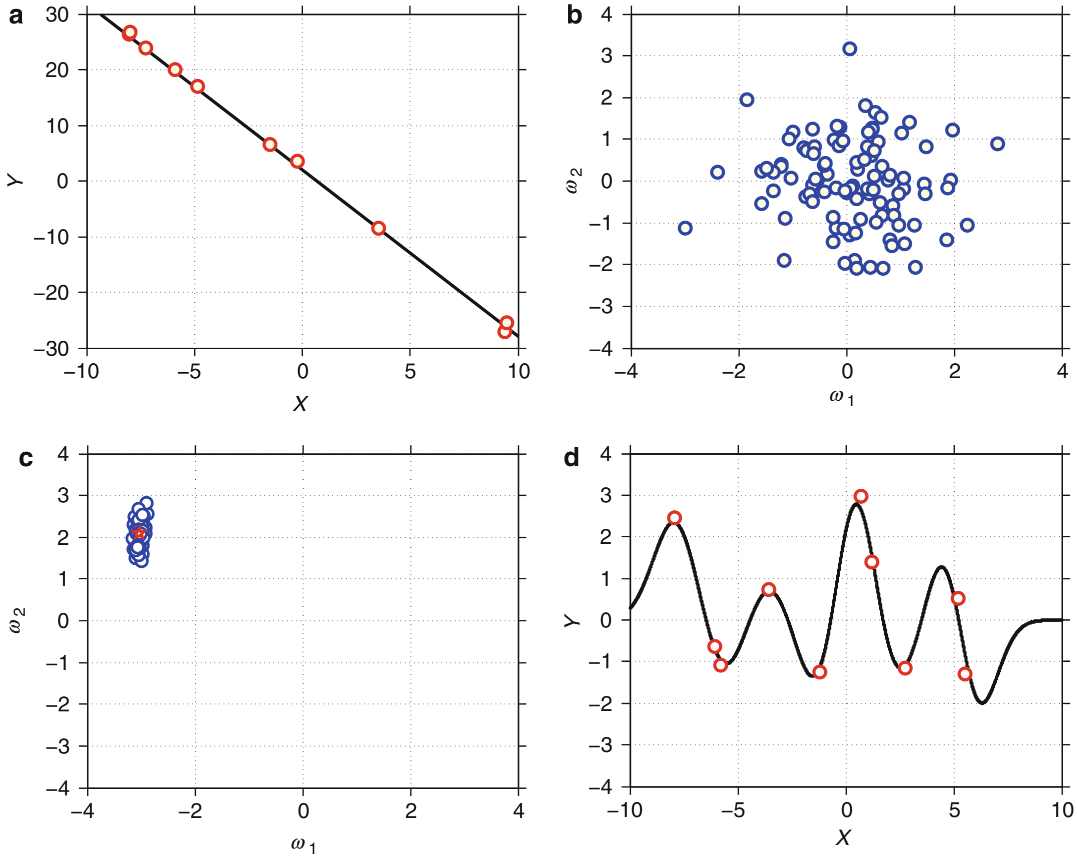
Expectation propagation; Kernels; Laplace estimate; Nonparametric Bayesian

Definition

Gaussian processes generalize multivariate Gaussian distributions over finite-dimensional vectors to infinite dimensionality. Specifically, a Gaussian process is a stochastic process that has Gaussian-distributed finite-dimensional marginal distributions, hence the name. In doing so, it defines a distribution over functions, i.e., each draw from a Gaussian process is a function. Gaussian processes provide a principled, practical, and probabilistic approach to inference and learning in kernel machines.

Motivation and Background

Bayesian probabilistic approaches have many virtues, including their ability to incorporate prior knowledge and their ability to link related



Gaussian Process, Fig. 1 (**a**) Ten observations (one-dimensional input x and output y variables) generated from a ▶ Linear Regression model $y = -3x + 2 + \epsilon$ with Gaussian noise ϵ. The task is to learn the functional relationship between x and y. Assuming the parametric model $y = \omega_1 x + \omega_2 + \epsilon$, i.e., $\omega = (\omega_1, \omega_2)$, is the vector of parameters, and the prior distribution over ω is a two-dimensional Gaussian as shown in (**b**), the posterior distribution over ω can be estimated as shown in (**c**). Its mean $(-2.9716, 1.9981)$ is close to the true parameters $(-3, 2)$. The inference, however, was performed in an ideal situation where in the relationship between x and y was indeed linear. If the true relationship is not known in advances and/or cannot easily be described using a finite set of parameters, this approach may fail. For example, in (**d**), infinite number of parameters might be required to recover the functional relationship

sources of information. Typically, we are given a set of data points sampled from an underlying but unknown distribution, each of which includes input x and output y, such as the ones shown in Fig. 1a. The task is to learn a functional relationship between x and y. Traditionally, in a parametric approach, an assumption on the mathematical form of the relationship such as linear, polynomial, exponential, or a combination of them needs to be chosen a priori. Subsequently, weights (or parameters) are placed on each of the chosen forms, and a prior distribution is then defined over parameters. Thus, the learning task is now reduced to the Bayesian estimation over the parameters, cf. Fig. 1a–c. This approach, however, may not always be practical, as illustrated in Fig. 1d. To discover the latent input–output relationship in Fig. 1d, we might need infinitely many functional forms, and this translates to infinite number of parameters. Instead of working over a parameter space, Gaussian processes place a prior directly on the space of functions without parameterizing the function, hence nonparametric. As will be shown, the computational complexity of inference now scales as the number of data points instead of the number of parameters.

Several nonparametric Bayesian models have been developed for different tasks such as density estimation, regression, classification, survival time analysis, topic modeling, etc. Among the most popular ones are ▶ Dirichlet Processes and *Gaussian processes*. Just as the Gaussian process, a Dirichlet process has Dirichlet-distributed finite-dimensional marginal distributions, hence the name.

Gaussian processes were first formalized for machine-learning tasks by Williams and Rasmussen (1996) and Neal (1996).

Theory

Formally, a Gaussian process is a stochastic process (i.e., a collection of random variables) in which all the finite-dimensional distributions are multivariate Gaussian distributions for any finite choice of variables. In general, Gaussian processes are used to define a probability distribution over functions $f : \mathcal{X} \rightarrow \mathbb{R}$ such that the set of values of f evaluated at an arbitrary set of points $\{x_i\}_{i=1}^{N} \in \mathcal{X}$ will have an N-variate Gaussian distribution. Note that, for $x_i \in \mathbb{R}^2$, this may also be known as a Gaussian random field.

Gaussian Process

A Gaussian distribution is completely specified by its mean and covariance matrix. Similarly, a Gaussian process is characterized by its mean function $m(x) := \mathbf{E}[f(x)]$ and covariance function

$$C(x, x') := \mathbf{E}[(f(x) - m(x))(f(x') - m(x'))] \, .$$

We say a real process $f(x)$ is a Gaussian process distributed with a mean function $m(x)$ and a covariance function $C(x, x')$, written as $f \sim \mathcal{GP}(m(x), C(x, x'))$.

The mean function can be arbitrarily chosen (for convenience, it is often taken to be a zero function since we can always center our observed outputs to have a zero mean), but the covariance function must be a positive-definite function to ensure the existence of all finite-dimensional distributions. That is, the positive definiteness of $C(.,.)$ ensures the positive (semi-)definiteness of all covariance matrices, Σ, appearing in the exponent of the finite-dimensional multivariate Gaussian distribution.

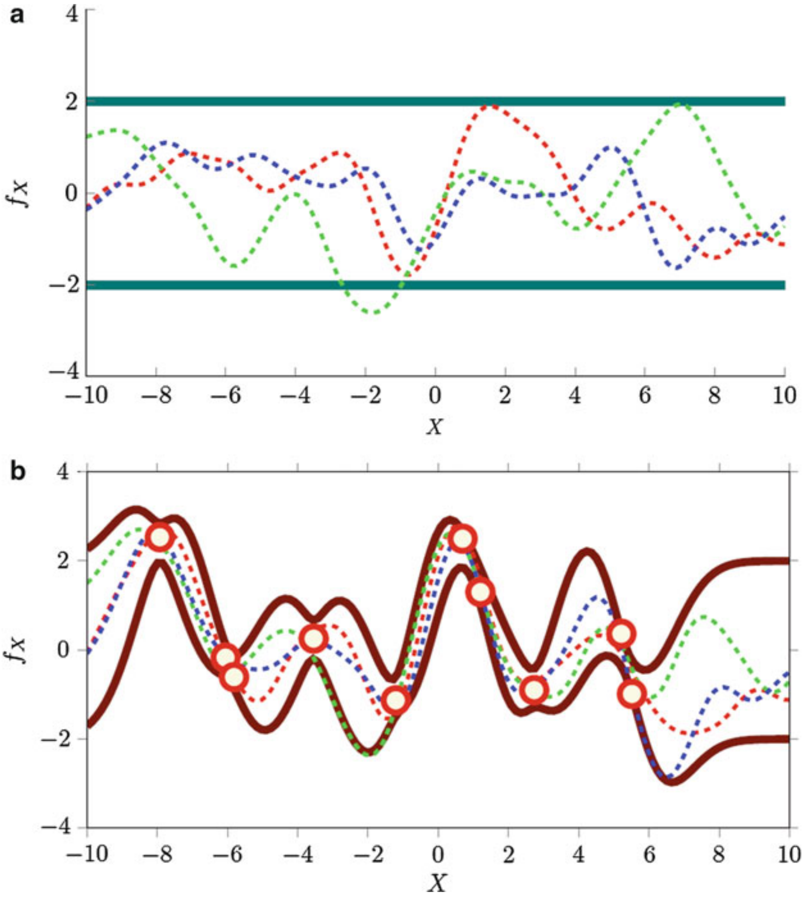
The attractiveness of Gaussian processes is that they admit the marginalization property (▶ Gaussian Distribution), i.e., if the Gaussian process specifies $(f(x_1), \; f(x_2)) \sim \mathcal{N}(\mu, \Sigma)$, then it must also specify $f(x_1) \sim \mathcal{N}(\mu_1, \Sigma_{11})$, where Σ_{11} is the relevant submatrix of Σ. This means addition of novel points will not influence the distribution of existing points. The marginalization property allows us to concentrate on distribution of only observed data points with the rest of unobserved points considered to be marginalized out; thus, a finite amount of computation for inference can be achieved.

Covariance Functions

A covariance function bears an essential role in a Gaussian process model as its continuity properties determine the continuity properties of samples (functions) from the Gaussian process. In the literature, covariance functions are also known as positive (semi-)definite kernels or Mercer's kernels.

There are generally two types of covariance functions: *stationary* and *nonstationary*. A stationary covariance function is a function that is translation invariant, i.e., $C(x, x') = D(x - x')$ for some function D. The typical examples include squared exponential, Matérn class, γ-exponential, exponential, and rational quadratic, while examples of nonstationary covariance functions are dot product and polynomial.

Squared exponential (SE) is a popular form of stationary covariance function, and it corresponds to the class of sums of infinitely many Gaussian-shaped basis functions placed everywhere, $f(x) := \lim_{n\rightarrow\infty} \frac{s}{n} \sum_i^n \gamma_i \exp\left(-((x - x_i)/2\ell)^2\right)$ with $\gamma_i \sim \mathcal{N}(0, 1) \; \forall i$. This covariance function is in the form of



Gaussian Process, Fig. 2 (**a**) Three functions drawn at random from a Gaussian process prior. (**b**) Three random functions drawn from the posterior, i.e., the distribution learned with the prior from Fig. 2a and the ten observations from Fig. 1d. In both plots, the *shaded area* within two *solid lines* shows the pointwise mean plus and minus two times the standard deviation for each input value, i.e., the 95 % confidence region. Animations, if they are visible, are generated using the method described in Hennig (2013)

$$C(x, x') = \mathbf{E}[f(x)f(x')]$$
$$= s^2 \exp\left(-\frac{1}{2\ell^2}\|x - x'\|_2^2\right).$$

Typical functions sampled from this covariance function can be seen in Fig. 2a. This covariance function has the characteristic length scale ℓ and the signal variance s^2 as free parameters (hyperparameters). The longer the characteristic length scale, the more slowly varying the typical sample function is. The signal variance defines the vertical scale of variations of a sample function. Figure 3 illustrates prediction with SE covariance function with varying characteristic length scale. Several other covariance functions are listed in Table 1.

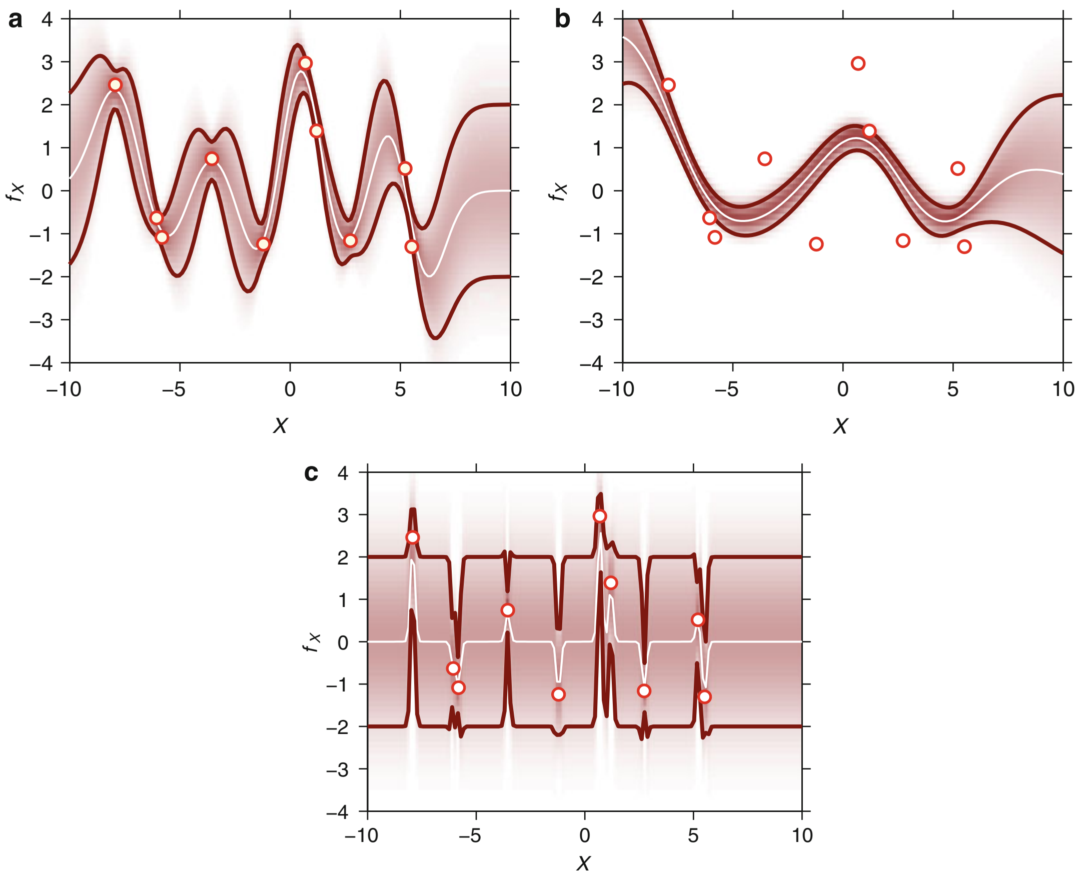
For a comprehensive review on the field of covariance functions, we refer interested readers to Abrahamsen (1992).

Applications

For Gaussian processes, there are two main classes of applications: regression and classification. We will discuss each of them in turn.

Regression

In a ▶ Regression problem, we are interested to recover a functional dependency $y_i = f(x_i) + \epsilon_i$ from N observed training data points $\{(x_i, y_i)\}_{i=1}^N$, where $y_i \in \mathbb{R}$ is the noisy observed output at input location $x_i \in \mathbb{R}^d$. Traditionally, in the Bayesian ▶ Linear Regression model, this regression problem is tackled by requiring us to parameterize the latent function f by a parameter $w \in \mathbb{R}^H$, $f(x) := \langle \phi(x), w \rangle$ for H fixed basis functions $\{\phi_h(x)\}_{h=1}^H$. A prior distribution is then defined over parameter w. The idea of the Gaussian process regression (in the



Gaussian Process, Fig. 3 The Gaussian process prediction with the SE kernel. (**a**) Mean of the prediction distribution with length scale 1.0 and signal variance 1.0 (the hyperparameters of the original process used to generate the data in Fig. 1). The other two plots show the prediction setting of the length scale: **(b)** longer (3.0) and **(c)** shorter (0.1). In all plots, the 95 % confidence region is shown

Gaussian Process, Table 1 Examples of covariance functions. θ_{cov} denotes the set of hyperparameters

Name	$C(x,x')$	θ_{cov}	Remark
Squared exp. (SE)	$s^2 \exp\left(-\frac{1}{2\ell^2}\,\\|x-x'\\|_2^2\right)$	$\{s,\ell\}$	Strong smoothness assumption
Matérn class	$\frac{2^{1-\nu}}{\Gamma(\nu)}\left(\frac{\sqrt{2\nu}\lvert x-x'\rvert}{\ell}\right)^{\nu} K_\nu(\frac{\sqrt{2\nu r}}{\ell})$	$\{\nu,\ell\}$	Less smooth than SE
γ-exponential	$\exp(-(\lvert x-x'\rvert/\ell)^{\gamma}),\ \text{with } 0<\gamma<=2$	$\{\ell\}$	Includes both Exp. and SE
Exponential	$\exp\left(\frac{-\lvert x-x'\rvert}{\ell}\right)$	$\{\ell\}$	$\nu = 1/2$ in the Matérn class
Rational quadratic	$\left(1+\frac{\\|x-x'\\|_2^2}{2\alpha\ell^2}\right)^{-\alpha}$	$\{\alpha,\ell\}$	An infinite sum of SE
Dot product	$\sigma_w^2\,\langle x,x'\rangle+\sigma_c^2$	$\{\sigma_w,\sigma_c\}$	
Polynomial	$(\langle x,x'\rangle+\sigma_c^2)^p$	$\{\sigma_c\}$	Effective for high-dimensional classification with binary or grayscale input

geostatistical literature, this is also called *kriging*; see, e.g., Krige 1951; Matheron 1963) is to place a prior directly on the space of functions without parameterizing the function (vide Motivation and Background).

Likelihood Function and Posterior Distribution

Assuming independent and normally distributed noise terms, $\epsilon_i \overset{i.i.d.}{\sim} \mathcal{N}(0, \sigma^2_{\text{noise}})$, the likelihood model on an output vector $Y \in \mathbb{R}^N$ and an input matrix $X \in \mathbb{R}^{N \times d}$ will be

$$\begin{aligned} p(Y \mid f_X) &= \prod_{i=1}^{N} p(y_i | x_i, f) \\ &= \mathcal{N}(Y \mid f_X, \sigma^2_{\text{noise}} I), \end{aligned}$$

with $f_X = (f(x_1), \ldots, f(x_N))^\top$ be an N-dimensional vector of function values at N input locations x_i. That is, the data likelihood is distributed according to a Gaussian distribution with the function values evaluated at training input locations as its mean and the variance of the noise terms as its variance.

Placing a (zero mean) Gaussian process prior over functions

$$f \sim \mathcal{GP}(m(x) \equiv 0, k(x, x')), \tag{1}$$

will lead us to a Gaussian process posterior (this form of posterior process is described in the next section):

$$\begin{aligned} &f | X, Y \sim \mathcal{GP}(m_{\text{post}}(x) \\ &= k(x, X)[K + \sigma^2_{\text{noise}} I]^{-1} Y, k_{\text{post}}(x, x') \\ &= k(x, x') - k(x, X)[K + \sigma^2_{\text{noise}} I]^{-1} k(x', X)). \end{aligned} \tag{2}$$

In the above equations, $K \in \mathbb{R}^{N \times N}$ denotes the Gram matrix with elements $K_{ij} = k(x_i, x_j)$, and $k(x, x')$ is the kernel function. The term $k(x, X)$ denotes a kernel function with one of the inputs fixed at training points.

Predictive Distribution

The final goal in regression is to make an output prediction for a novel input x_*, given a set of input–output training points. By the marginalization property, instead of working with a prior over infinite-dimensional function spaces as in (1), we can concentrate on the marginal distribution over the training inputs:

$$f_X \sim \mathcal{N}(0, K). \tag{3}$$

Subsequently, the marginal distribution over training outputs (conditioned on inputs) can be computed via

$$\begin{aligned} p(Y | X) &= \int p(Y \mid f_X) p(f_X) \mathrm{d} f_X \\ &= \mathcal{N}(0, K + \sigma^2_{\text{noise}} I). \end{aligned} \tag{4}$$

The above integration is computed by using the standard result for the convolution of two Gaussian distributions (▶ Gaussian Distribution).

Therefore, given inputs X, the joint distribution over outputs Y and the latent function f_X is given by

$$p(Y, f_X | X) = \mathcal{N}(0, C), \tag{5}$$

where $C \in \mathbb{R}^{(2N) \times (2N)}$ is the joint covariance matrix. We can partition this joint covariance matrix as follows:

$$C = \begin{bmatrix} K + \sigma^2_{\text{noise}} I & K \\ K & K \end{bmatrix},$$

The noise variance appears only at the diagonal elements of the covariance matrix C; this is due to the independence assumption about the noise. Using a standard Gaussian property on computing conditional distribution from a joint Gaussian distribution (▶ Gaussian Distribution), the Gaussian posterior distribution can be seen to admit the following form: $p(f_X | X, Y) = \mathcal{N}(\mu_{f_X}, \Sigma_{f_X})$ with the mean $\mu_{f_X} = K(K + \sigma^2_{\text{noise}} I)^{-1} Y$ and the covariance $\Sigma_{f_X} = K - K(K + \sigma^2_{\text{noise}} I)^{-1} K$.

From the posterior distribution, we can compute the predictive distribution on the new output

y^* at an input location x^*, as follows:

$$p(y_*|x_*,X,Y) = \int p(y_*|f_*,x_*)$$
$$\times \int p(f_*|f_X)p(f_X|X,Y)\mathrm{d}f_X\mathrm{d}f_*. \qquad (6)$$

The $p(f_*|f_X)$ is a conditional multivariate Gaussian with mean $\mu_{f_*|f_X} = k_{X,x_*}^\top K^{-1} f_X$ and variance $\sigma^2_{f_*|f_X} = k(x_*,x_*) - k_{X,x_*}^\top K^{-1} k_{X,x_*}$ due to the GP marginalization property, where the vector $k_{X,x_*} \in \mathbb{R}^N$ has elements $k(x_i,x_*)$ for $i = 1,\ldots,N$ and $\top$ denotes a transpose operation. Equation (6) is a general equation for computing the predictive distribution in a Gaussian process framework and is applicable, among others, for both regression and classification settings. For regression, since all the terms are Gaussians, the inner integration $\int p(f_*|f_X)p(f_X|X,Y)\mathrm{d}f_X$ is a Gaussian with mean $\mu_{f_*} = k_{X,x_*}^\top K^{-1}\mu_{f_X}$ and variance $\sigma^2_{f_*} = k(x_*,x_*) - k_{X,x_*}^\top K^{-1} k_{X,x_*} + k_{X,x_*}^\top K^{-1} \Sigma_{f_X} K^{-1} k_{X,x_*}$. Subsequently, the outer integration $\int \mathcal{N}(f_*,\sigma^2_{\text{noise}})\mathcal{N}(\mu_{f_*},\sigma^2_{f_*})\mathrm{d}f_*$ is also a Gaussian, and therefore the above $p(y_*|x_*,X,Y)$ is a Gaussian distribution, and it is in the form of

$$p(y_*|x_*,X,Y) = \mathcal{N}(\mu_*,\sigma^2_*), \qquad (7)$$

with

$$\mu_* = k_{X,x_*}^\top (K + \sigma^2_{\text{noise}} I)^{-1} Y, \qquad (8)$$
$$\sigma^2_* = k(x_*,x_*)$$
$$- k_{X,x_*}^\top (K + \sigma^2_{\text{noise}} I)^{-1} k_{X,x_*} + \sigma^2_{\text{noise}}. \qquad (9)$$

Note that (8) and (9) are the mean function and the covariance function of the posterior process in (2) for any novel inputs. The only difference is the additional term σ^2_{noise}, since there exists observation noise ϵ_* such that $y_* = f_* + \epsilon_*$.

Point Prediction

The previous section has shown how to compute a predictive distribution for outputs y_* associated with the novel test inputs x_*. To convert this predictive distribution into a point prediction, we need the notion of a loss function, $\mathcal{L}(y_{\text{true}}, y_{\text{prediction}})$. This function specifies the loss incurred for predicting the value $y_{\text{prediction}}$, while the true value is y_{true}. Thus, the optimal point prediction can be computed by minimizing the expected loss as follows:

$$y_{\text{optimal}}|x_* = \underset{y_{\text{prediction}} \in \mathbb{R}}{\operatorname{argmin}} \int \mathcal{L}(y_*, y_{\text{prediction}})$$
$$\times p(y_*|x_*,X,Y)\mathrm{d}y_*. \qquad (10)$$

For a squared loss function (or any other symmetric loss functions) and predictive distribution (7), the solution to the above equation is the mean of the predictive distribution, i.e.,

$$y_{\text{optimal}}|x_* = \mathbf{E}_{y_* \sim p(y_*|x_*,X,Y)}[y_*] = \mu_*.$$

The above Gaussian process regression description is known as a function space view in the literature (Rasmussen and Williams 2006). Equivalently, a Gaussian process regression can also be viewed from the traditional Bayesian linear regression with a possibly infinite number of basis functions $\phi(x)$ and with a zero mean and arbitrary positive-definite covariance matrix Gaussian prior on the parameter w; see, e.g., Rasmussen and Williams (2006).

Classification

Gaussian process models can also be applied to classification problems. In a probabilistic approach to classification, the goal is to model posterior probabilities of an input point x_i belonging to one of Ω classes, $y_i \in \{1,\ldots,\Omega\}$. These probabilities must lie in the interval [0, 1]; however, a Gaussian process model draws functions that lie on $(-\infty,\infty)$. For the binary classification ($\Omega = 2$), we can turn the output of a Gaussian process into a class probability using an appropriate nonlinear activation function. In the following, we will show this for the case of binary classification. For the more general cases, see, e.g., Rasmussen and Williams (2006).

Likelihood Function and Posterior Distribution

In a regression problem, a Gaussian likelihood is chosen and combined with a Gaussian process prior, which leads to a Gaussian posterior process over functions where in all required integrations remain analytically tractable. For classification, however, Gaussian likelihood is not the most suitable owing to the discreteness nature of the class labels. The most commonly used likelihood functions are

$$\begin{aligned} p(y_i \,|\, f, x_i) &= \frac{1}{1+\exp(-y_i f_{x_i})} \quad \text{or} \\ p(y_i \,|\, f, x_i) &= \int_{-\infty}^{y_i f_{x_i}} \mathcal{N}(0,1)\mathrm{d}t \\ &= \Phi_{0,1}(y_i f_{x_i}), \end{aligned} \tag{11}$$

known as logistic and cumulative Gaussian likelihood functions, respectively. Assuming that the class labels (conditioned on f) are generated independent and identically distributed, the joint likelihood over N data points can be expressed as $p(Y \,|\, f_X) = \prod_{i=1}^{N} p(y_i \,|\, f, x_i)$. By Bayes' rule, the posterior distribution over latent functions is given by $p(f_X|X,Y) = \frac{p(Y \,|\, f_X)p(f_X)}{\int p(Y \,|\, f_X)p(f_X)\mathrm{d}f_X}$. This posterior is no longer analytically tractable (due to intractable integration in the denominator), and an approximation is needed.

There are several approximation methods to handle intractability of the inference stage in the Gaussian process classification such as Laplace approximation, expectation propagation, variational bounding, and MCMC, among others (see Nickisch and Rasmussen (2008) for a comprehensive overview of approximate inference in binary Gaussian process classification). Most of the methods (if not all) approximate the non-Gaussian posterior with a tractable Gaussian distribution. We describe in detail the straightforward Laplace approximation method, but note that the more complicated expectation propagation (▶ Expectation Propagation) is almost always the method of choice unless the computational budget is very tight (Nickisch and Rasmussen 2008).

Laplace method approximates the non-Gaussian posterior with a Gaussian one by performing a second-order Taylor expansion of the log posterior, $\log p(f_X|X,Y)$ at the maximum point of the posterior

$$p(f_X|X,Y) \approx \hat{p}(f_X|X,Y) = \mathcal{N}(\hat{f}_X, H^{-1}), \tag{12}$$

where $\hat{f}_X = \operatorname{argmax}_{f_X} \log p(f_X|X,Y)$ and $H := -\nabla\nabla \log p\ (f_X|X,Y)|_{f_X=\hat{f}_X}$ is the Hessian of the negative log posterior at the maxima. Since the denominator of the Bayes' theorem is independent of the latent function, the mode of the posterior can be computed instead from the log un-normalized posterior:

$$\Psi(f_X) := \log p(Y \,|\, f_X) + \log p(f_X), \tag{13}$$

with the expression for $p(f_X)$ given in (3). Computation of the mode requires us to evaluate the gradient of $\Psi(f_X)$ which is given as

$$\nabla\Psi(f_X) = \nabla \log p(Y \,|\, f_X) - K^{-1} f_X. \tag{14}$$

To find the stationary point, however, we cannot simply set this gradient to zero as $\nabla \log p(Y \,|\, f)$ depends nonlinearly on f_X. We need to resort to an iterative scheme based on the Newton–Raphson's method with the updated equation given by

$$f_X^{\text{new}} \leftarrow f_X^{\text{old}} - (\nabla\nabla\Psi(f_X))^{-1}\nabla\Psi(f_X), \tag{15}$$

and the Hessian given by

$$\nabla\nabla\Psi(f_X) = -W - K^{-1}, \tag{16}$$

and $W := -\nabla\nabla \log p(Y \,|\, f_X)$ is a diagonal matrix. It is important to note that if the likelihood function $p(Y|f_X)$ is log-concave, the diagonal elements of W are nonnegative, and the Hessian in (16) is negative definite (since $-K$ and its inverse are negative definite by construction and the sum of two negative-definite matrices is also negative definite). Thus, $\Psi(f_X)$ is concave and has a unique maxima point.

Predictive Distribution

The latent function f_X plays the role of a nuisance function, i.e., we do not observe values of f_X itself, and more importantly, we are not particularly interested in the values of f_X. What we are interested in is a class conditional posterior probability, $p(y_* = +1|x_*, X, Y)$, for a novel input x_*. We note that a class conditional probability of a class label of not 1 is $p(y_* = -1|x_*, X, Y) = 1 - p(y_* = +1|x_*, X, Y)$.

We use Equation (6) to compute the predictive distribution on the new output y^* at an input location x^*, restated here for the sake of readability:

$$p(y_*|x_*, X, Y) = \int p(y_*|f_*, x_*) \times \int p(f_*|f_X) p(f_X|X, Y) \mathrm{d} f_X \mathrm{d} f_*.$$

As in regression, the term $p(f_*|f_X)$ is a conditional multivariate Gaussian with the assumption that the underlying Gaussian process model is a noise-free process. Another approach would be assuming an independent Gaussian noise in combination with a step function likelihood function. However, this is equivalent to the noise-free latent process with a cumulative Gaussian likelihood function (Rasmussen and Williams 2006). With Laplace approximation of posterior distribution $p(f_X|X, Y) \approx \mathcal{N}(\hat{f}_X, (K^{-1} + W)^{-1})$, we can now compute the inner integration of the predictive distribution, $\int \mathcal{N}(\mu_{f_*|f_X}, \sigma^2_{f*|f_X}) \mathcal{N}(\hat{f}_X, (K^{-1} + W)^{-1}) \mathrm{d} f_X$, by using the standard result for the convolution of two Gaussian distributions. It is again a Gaussian with mean $\mu_{f_*} = k^{\top}_{X,x_*} K^{-1} \hat{f}_X$ and variance $\sigma^2_{f_*} = k(x_*, x_*) - k^{\top}_{X,x_*}(K + W^{-1})^{-1} k_{X,x_*}$.

The predictive distribution can now be computed as follows:

$$\pi_* := p(y_* = +1|x_*, X, Y) = \int p(y_* = +1|f_*, x_*) \mathcal{N}(\mu_{f_*}, \sigma^2_{f_*}) \mathrm{d} f_*.$$

The above integral can be solved analytically for a cumulative Gaussian likelihood function,

$$\pi_* = \int_{-\infty}^{\frac{\mu_{f_*}}{(y_*^{-2}+\sigma^2_{f_*})^{1/2}}} \mathcal{N}(t|0, 1) \mathrm{d}t = \Phi_{0,1}\left(\frac{\mu_{f_*}}{(y_*^{-2} + \sigma^2_{f_*})^{1/2}}\right),$$

and can be approximated for a logistic likelihood function (MacKay 1992),

$$\pi_* = \frac{1}{1 + \exp(-\mu_{f_*} \kappa(\sigma^2_{f_*}))},$$

with $\kappa(c) = (1 + c\pi/8)^{-1/2}$.

Point Prediction

Similar to the regression case, we might need to make a point prediction from the predictive distribution described in the section above. For a zero-one loss function, i.e., a loss of one unit is suffered for a wrong classification and 0 for not making a classification mistake, the optimal point prediction (in the sense of expected loss) is

$$y_{\text{optimal}}|x^* = \operatorname*{argmax}_{y_* \in \{1,\ldots,\Omega\}} \; p(y_*|x_*, X, Y). \quad (17)$$

It is worth noting that the probabilistic approach to classification allows the same inference stage to be reused with different loss functions. In some situations, a cost-sensitive loss function, i.e., different classification mistakes incur different losses, is more desirable. The optimal point prediction is now taken by minimizing expected cost-sensitive loss with respect to the same $p(y_*|x_*, X, Y)$.

Extension of binary classification to multiclass Gaussian process classification ($\Omega > 2$) can be achieved via the softmax activation function, i.e., a generalization of logistic activation function (refer to Williams and Barber (1998) for the Laplace approximation of the posterior distribution). Recently, Bratières, Quadrianto, and Ghahramani (to appear) propose a Gaussian process classification approach to structured output problems ($\Omega \gg 2$) using a generalization of softmax function called a structured softmax function. Examples of structured outputs are a tree, a grid, or a sequence, where the output consists of interdependent categorical atoms.

Practical Issues

We have seen how to do regression and classification using Gaussian processes. Like other kernel-based methods such as support vector machines, they are very flexible in that all operations are kernelized, i.e., the operations are performed in the (possibly infinite dimensional) feature space. However, this feature space is only defined implicitly via positive-definite kernels (covariance functions), which only require computation in the (lower dimensional) input space. Compared to other non-Bayesian kernel approaches, Gaussian processes provide an explicit probabilistic formulation of the model. This directly provides us with confidence intervals (for regression) or posterior class probabilities (for classification).

So far, however, we have assumed a covariance function with the known functional form and hyperparameters. In many practical applications, it may not be easy to specify all aspects of the covariance function by hand. Furthermore, inverting the corresponding $N \times N$ Gram matrix is the main computational cost, and it may be prohibitive as it scales as $\mathcal{O}(N^3)$. We will now discuss approaches to overcome both limitations in turn.

Model Selection

In many practical applications, the functional form of the covariance function needs to be chosen, and any values of hyperparameters associated with the chosen covariance function and possible free parameters of the likelihood function need to be optimally determined. This is called model selection.

Ideally, we would like to define a prior distribution over the hyperparameters θ, and predictions are made by integrating over different possible choices of hyperparameters. More formally,

$$\begin{aligned} & p(y_*|x_*, X, Y) \\ & = \int p(y_*|x_*, X, Y, \theta) p(\theta|X, Y) \mathrm{d}\theta. \end{aligned} \quad (18)$$

The evaluation of the above integral, however, may be difficult, and an approximation is needed either by using the most likely value of hyperparameters, $p(y_*|x_*, X, Y) \approx p(y_*|x_*, X, Y, \theta_{\mathrm{ML}})$, or by performing the integration numerically via Monte Carlo methods. We will focus here on the approximation approach and show how to use it for regression and classification problems.

Marginal Likelihood for Regression

The posterior probability of the hyperparameters θ in (18) is

$$p(\theta|X, Y) \propto p(Y|X, \theta) p(\theta), \quad (19)$$

where the first term is known as marginal likelihood or evidence for the hyperparameters and it is in the form of (as in (4) but with an explicit conditioning on θ)

$$\begin{aligned} p(Y|X, \theta) &= \int p(Y|\, f_X, \theta) p(f_X|\theta) \mathrm{d} f_X \\ &= \mathcal{N}(0, K + \sigma^2_{\text{noise}} I), \end{aligned}$$

where the set of free parameters θ includes both parameters of the kernel function and the noise term σ^2_{noise}. We can then set the hyperparameters by maximizing the logarithm of this marginal likelihood, and its partial derivative with respect to hyperparameters is

$$\begin{aligned} & \frac{\partial}{\partial \theta_j} \log p(Y|X, \theta) \\ & = \frac{1}{2} Y^\top \bar{K}^{-1} \frac{\partial \bar{K}}{\partial \theta_j} \bar{K}^{-1} Y - \frac{1}{2} \mathrm{tr} \left(\bar{K}^{-1} \frac{\partial \bar{K}}{\partial \theta_j} \right), \end{aligned}$$

with $\bar{K} := K + \sigma^2_{\text{noise}} I$. This is known as a type II maximum likelihood approximation, ML-II. We can also maximize the un-normalized posterior instead, assuming finding the derivatives of the priors is straightforward.

Marginal Likelihood for Classification

The Laplace approximation of the marginal likelihood, $p(Y|X, \theta) \approx \hat{p}(Y|X, \theta)$

$$= \int \exp(\Psi(f_X))\mathrm{d}f_X$$
$$= \exp(\Psi(\hat{f}_X)) \int \exp(-\frac{1}{2}(f_X - \hat{f}_X)^\top H(f_X - \hat{f}_X))\mathrm{d}f_X,$$

which is achieved via a Taylor expansion of (13) locally around $\hat{f}_X$ to obtain $\Psi(f_X) \approx \Psi(\hat{f}_X) - \frac{1}{2}(f_X - \hat{f}_X)^\top H(f_X - \hat{f}_X)$. Computing the integral analytically gives us the approximate marginal likelihood

$$\log \hat{p}(Y|X,\theta) \propto -\frac{1}{2}\hat{f}_X K^{-1}\hat{f}_X - \frac{1}{2}\log|K| + \log p(Y|\hat{f}_X) - \frac{1}{2}\log|K^{-1}+W|.$$

Subsequently, the partial derivatives with respect to hyperparameters is given by

$$\frac{\partial}{\partial\theta_j}\log \hat{p}(Y|X,\theta) = \frac{1}{2}\hat{f}_X^\top K^{-1}\frac{\partial K}{\partial\theta_j}K^{-1}\hat{f}_X - \frac{1}{2}\mathrm{tr}\left((K+W^{-1})^{-1}\frac{\partial K}{\partial\theta_j}\right) + \sum_{i=1}^{N}\frac{\partial\log\hat{p}(Y|X,\theta)}{\partial\hat{f}_{x_i}}\frac{\partial\hat{f}_{x_i}}{\partial\theta_j}.$$

The familiar multiple local optima problem is also present in the marginal likelihood maximization. However, practical experiences suggest that local optima are not a devastating problem especially with simple functional forms of covariance function.

Sparse Approximation

A significant problem with the Gaussian process model is associated with the computation cost of inverting the $N \times N$ Gram matrix. A number of sparse approximation methods have been proposed to overcome this high computational demand. Common to all these methods is that only a subset of the latent function values of size $M < N$ are treated exactly, and the remaining latent values are approximated with cheaper computational demand. Quiñonero-Candela and Rasmussen (2005) describe a unifying view of sparse approximation. Several existing sparse methods are shown to be an instance of it. The framework is described for regression problems; however, it should also be applicable for classification learning settings, albeit with complicacy associated with the non-Gaussian likelihood.

In this unifying treatment, an additional set of M latent variables $f_U \in \mathbb{R}^M$, called inducing variables, is introduced. These latent variables are latent function values corresponding to a set of input locations $X_U \in \mathbb{R}^{M\times d}$, called inducing inputs. The choice of inducing inputs is not restricted to only form the training or test inputs. Due to the marginalization property, introducing more latent variables will not change the distribution of the original variables. Consider (5) but as a joint distribution over latent training and test function values, $p(f_X, f_*|X, x_*)$

$$= \int p(f_X, f_*, f_U|X, X_U, x_*)\mathrm{d}f_U$$
$$= \int p(f_X, f_*|X, x_*, f_U)p(f_U)\mathrm{d}f_U, \quad (20)$$

with $p(f_U) = \mathcal{N}(0, K_{X_U,X_U})$. So far, no approximations have been introduced. Introducing the key assumption which is f_X is conditionally independent of f_* given f_U, $f_* \perp\!\!\!\perp f_X \mid f_U$, allow us to approximate (20) as

$$p(f_X, f_*|X, x_*) \approx \int p(f_*|x_*, f_U)p(f_X|X, f_U)p(f_U)\mathrm{d}f_U, \quad (21)$$

where $p(f_*|x_*, f_U)$ and $p(f_X|X, f_U)$ are again conditional multivariate Gaussians due to the GP marginalization property. Different computationally efficient algorithms in the literature correspond to different assumptions made on those two conditional distributions. Table 2 shows various sparse approximation methods with their corresponding approximated conditional distributions. For all sparse approximation methods, the com-

putational complexity is reduced from $\mathcal{O}(N^3)$ to $\mathcal{O}(NM^2)$.

Current and Future Directions

Gaussian processes are an active area of research both within the machine learning and the Bayesian statistics community. First, there is the issue of efficient inference and learning as already discussed in the text above. Some of the recent approaches include converting Gaussian processes with stationary covariance functions to state-space models (Särkkä et al. 2013) and using stochastic variational inference (Hensman et al. 2013). Second, there is interest in adapting Gaussian processes to other learning settings. They have been used for ordinal regression (Chu and Ghahramani 2005a; Yu et al. 2006b), preference learning (Chu and Ghahramani 2005b), ranking (Guiver and Snelson 2008), mixtures of experts (Tresp 2000b), transductive learning (Schwaighofer and Tresp 2003), multitask learning (Yu et al. 2005), dimensionality reduction (Lawrence 2005), matrix factorization (Lawrence and Urtasun 2009), and reinforcement learning (Engel et al. 2005; Deisenroth and Rasmussen 2009), among other settings. They have also been extended to handle relational data (Chu et al. 2006; Yu et al. 2006a; Silva et al. 2007; Xu et al. 2009; Kersting and Xu 2009). Standard Gaussian processes only exploit the available information about attributes of instances and typically ignore any relations among the instances. Intuitively, however, we would like to use our information about one instance to help us reach conclusions about other related instances.

There is the issue of relaxing the assumption of the standard Gaussian process model that the noise on the output is uniform throughout the domain. If we assume that the noise is a smooth function of the inputs, the noise variance can be modeled using a second Gaussian process, in addition to the process governing the noise-free output values. The resulting heteroscedastic, i.e., input-dependent noise regression model, has been shown to outperform state-of-the-art methods for mobile robot localization (Plagemann et al. 2007). Heteroscedastic classification has also been explored by Hernández-Lobato et al. (2014) in the context of ▶ Learning Using Privileged Information.

Finally, Gaussian processes are also of great interest for practical applications because they naturally deal with noisy measurements, unevenly distributed observations, and fill small gaps in the data with high confidence while assigning higher predictive uncertainty in sparsely sampled areas. Two recent applications areas are Bayesian optimization for automatically tuning hyperparameters of machine-learning models (see, e.g., Snoek et al. 2012) and an automated Bayesian statistician for automating the process of statistical modeling (see, e.g., Lloyd et al. 2014).

In addition to the references embedded in the text above, we also recommend http://www.gaussian-process.org/. A highly recommended textbook is Rasmussen and Williams (2006).

Gaussian Process Reinforcement Learning

Yaakov Engel
University of Alberta, Edmonton, AB, Canada

Definition

Gaussian process reinforcement learning generically refers to a class of ▶ reinforcement learning (RL) algorithms that use Gaussian processes (GPs) to model and learn some aspect of the problem.

Such methods may be divided roughly into two groups:

1. *Model-based methods*: Here, GPs are used to learn the transition and reward model of the ▶ Markov decision process (MDP) underlying the RL problem. The estimated MDP model is then used to compute an approximate solution to the true MDP.
2. *Model-free methods*: Here, no explicit representation of the MDP is maintained. Rather, GPs are used to learn either the MDP's value function, state–action value function, or some other quantity that may be used to solve the MDP.

This entry is concerned with the latter class of methods, as these constitute the majority of published research in this area.

Motivation and Background

▶ Reinforcement learning is a class of learning problems concerned with achieving long-term goals in unfamiliar, uncertain, and dynamic environments. Such tasks are conventionally formulated by modeling the environment as ▶ MDPs (or more generally as partially observable MDPs (▶ POMDPs)) and modeling the agent as an adaptive controller implementing an action-selection policy.

Markov Decision Processes

Let us denote by $\mathcal{P}(\mathcal{S})$ the set of probability distributions over (Borel) subsets of a set $\mathcal{S}$. A discrete time MDP is a tuple $(\mathcal{X}, \mathcal{U}, p_0, p, q, \gamma)$, where $\mathcal{X}$ and $\mathcal{U}$ are the state and action spaces, respectively; $p_0(\cdot) \in \mathcal{P}(\mathcal{X})$ is a probability density over initial states; $p(\cdot|\mathbf{x}, \mathbf{u}) \in \mathcal{P}(\mathcal{X})$ is a probability density over successor states, conditioned on the current state $\mathbf{x}$ and action $\mathbf{u}$; $q(\cdot|\mathbf{x}, \mathbf{u}) \in \mathcal{P}(\mathbb{R})$ is a probability distribution over immediate single-step rewards, conditioned on the current state and action. We denote by $R(\mathbf{x}, \mathbf{u})$ the random variable distributed according to $q(\cdot|\mathbf{x}, \mathbf{u})$. Finally, $\gamma \in [0, 1]$ is a discount factor. We assume that both p and q are stationary, that is, they do not depend explicitly on time. To maintain generality, we use $\mathbf{z}$ to denote either a state $\mathbf{x}$ or a state–action pair $(\mathbf{x}, \mathbf{u})$. This overloaded notation will allow us to present models and algorithms in a concise and unified form.

In the context of control, it is useful to make several additional definitions. A *stationary policy* $\mu(\cdot|\mathbf{x}) \in \mathcal{P}(\mathcal{U})$ is a time-independent mapping from states to action-selection probabilities. A stationary policy μ induces a Markov reward process (MRP) (Puterman 1994) via *policy-dependent* state-transition probability density, defined as (Here and in the sequel, whenever integration is performed over a finite or discrete space, the integral should be understood as a summation.)

$$p_{\mathbf{x}}^{\mu}(\mathbf{x}'|\mathbf{x}) = \int_{\mathcal{U}} d\mathbf{u}\, \mu(\mathbf{u}|\mathbf{x})\, p(\mathbf{x}'|\mathbf{u},\mathbf{x}).$$

Similarly, the policy μ may also be used to define a state–action transition probability density, defined as

$$p_{\mathbf{x},\mathbf{u}}^{\mu}(\mathbf{x}',\mathbf{u}'|\mathbf{x},\mathbf{u}) = p(\mathbf{x}'|\mathbf{u},\mathbf{x})\mu(\mathbf{u}'|\mathbf{x}').$$

Using our overloaded notational convention, we refer to either of these as $p_{\mathbf{z}}^{\mu}$. Let us denote by $\boldsymbol{\xi}(\mathbf{z})$ a path that starts at $\mathbf{z}$. Hence, for a fixed policy μ and a fixed initial state or state–action pair $\mathbf{z}_0$, the probability (density) of observing the path $\boldsymbol{\xi}(\mathbf{z}_0) = (\mathbf{z}_0, \mathbf{z}_1, \ldots, \mathbf{z}_t)$ of length t is (we take $\mathbf{z}_0$ as given) $\mathbb{P}(\boldsymbol{\xi}(\mathbf{z}_0)) = \prod_{i=1}^{t} p_{\mathbf{z}}^{\mu}(\mathbf{z}_i|\mathbf{z}_{i-1})$. The *discounted return* $D^{\mu}(\boldsymbol{\xi}(\mathbf{z}))$ of a path $\boldsymbol{\xi}(\mathbf{z})$ is a random process, defined (with some abuse of notation) as

$$D^{\mu}(\mathbf{z}) = D^{\mu}(\boldsymbol{\xi}(\mathbf{z})) = \sum_{i=0}^{\infty} \gamma^{i} R(\mathbf{z}_i)|(\mathbf{z}_0 = \mathbf{z}), \tag{1}$$

where $\gamma \in [0, 1]$ is the discount factor. (When $\gamma = 1$, the policy must be proper; see Bertsekas and Tsitsiklis (1996).) The randomness in $D^{\mu}(\mathbf{z})$, for any given $\mathbf{z}$, is due both to $\boldsymbol{\xi}(\mathbf{z})$ being a random process and to the randomness, or noise, in the rewards $R(\mathbf{z}_0), R(\mathbf{z}_1), \ldots$, etc., both of which jointly constitute the *intrinsic* randomness of the MDP. Equation (1) together with the stationarity of the MDP yields the recursive formula

$$D^{\mu}(\mathbf{z}) = R(\mathbf{z}) + \gamma D^{\mu}(\mathbf{z}') \quad \text{where } \mathbf{z}' \sim p_{\mathbf{z}}^{\mu}(\cdot|\mathbf{z}). \tag{2}$$

Let us define the expectation operator $\mathbf{E}_{\xi}$ as the expectation over all possible trajectories and all possible rewards collected in them. This allows us to define the *value function* $V^{\mu}(\mathbf{z})$ as the result of applying this expectation operator to the discounted return $D^{\mu}(\mathbf{z})$, i.e.,

$$V^{\mu}(\mathbf{z}) = \mathbf{E}_{\xi} D^{\mu}(\mathbf{z}). \tag{3}$$

Applying the law of total expectation to this equation results in the MRP (fixed policy) version of the Bellman equation:

$$V^{\mu}(\mathbf{z}) = R(\mathbf{z}) + \gamma \mathbf{E}_{\mathbf{z}'|\mathbf{z}}[V^{\mu}(\mathbf{z}')]. \tag{4}$$

A policy that maximizes the expected discounted return from each state is called an optimal policy and is denoted by μ^*. In the case of stationary MDPs, there exists a *deterministic* optimal policy (this is no longer the case for POMDPs and Markov games; see Kaelbling et al. (1998) and Littman (1994)). The value function corresponding to an optimal policy is called the optimal value and is denoted by $V^* = V^{\mu^*}$. While there may exist more than one optimal policy, the optimal value function is unique (Bertsekas 1995).

Reinforcement Learning

Many of the algorithms developed for solving RL problems may be traced back to the ▸ dynamic programming *value iteration* and *policy iteration* algorithms (Bellman 1957; Bertsekas 1995; Bertsekas and Tsitsiklis 1996; Howard 1960). However, there are two major features distinguishing RL from the traditional planning framework. First, while in planning it is assumed that the environment is fully known, in RL no such assumption is made. Second, the learning process in RL is usually assumed to take place *online*, namely, concurrently with the acquirement of data by the learning agent as it interacts with its environment. These two features make solving RL problems a significantly more challenging undertaking.

An important algorithmic component of policy iteration-based RL algorithms is the estimation of either state or state–action values of a fixed policy controlling an MDP, a task known as *policy evaluation*. Sutton's TD(λ) algorithm (Sutton 1984) is an early RL algorithm that performs policy evaluation based on observed sample trajectories from the MDP, while it is being controlled by the policy being evaluated (see ► Temporal Difference Learning). In its original formulation, TD(λ) as well as many other algorithms (e.g., Watkins' ► Q-Learning 1989) employs a lookup table to store values corresponding to the MDP's states or state–action pairs. This approach clearly becomes infeasible when the size of the MDP's joint state–action space exceeds the memory capacity of modern workstations. One solution to this problem is to represent the value function using a parametric function approximation architecture and allow these algorithms to estimate the parameters of approximate value functions. Unfortunately, with few exceptions, this seemingly benign modification turns out to have ruinous consequences to the convergence properties of these algorithms. One notable exception is TD(λ), when it is used in conjunction with a function approximator $\hat{V}(\mathbf{z}) = \sum_{i=1}^{N} w_i \phi_i(\mathbf{z})$, which is linear in its tunable parameters $\mathbf{w} = (w_1, \ldots, w_N)^\top$. Under certain technical conditions, it has been shown that in this case, TD(λ) converges almost surely, and the limit of convergence is "close" (in a well-defined manner) to a projection ΠV^μ of the true value function V^μ onto the finite-dimensional space $\mathcal{H}_\phi$ of functions spanned by $\{\phi_i | i = 1, \ldots, N\}$ (Tsitsiklis and Van Roy 1996). Note that this projection is the best one may hope for, as long as one is restricted to a fixed function approximation architecture. In fact, when $\lambda = 1$, the bound of Tsitsiklis and Van Roy (1996) implies that TD(1) converges to ΠV^μ (assuming it is unique). However, as λ is reduced toward 0, the quality of TD(λ)'s solution may deteriorate significantly. If V^μ happens to belong to $\mathcal{H}_\phi$, then $V^\mu = \Pi V^\mu$ and TD(λ) converges almost surely to V^μ, for any $\lambda \in [0, 1]$.

As noted in Bertsekas and Tsitsiklis (1996), TD(λ) is a stochastic approximation algorithm (Kushner and Yin 1997). As such, to ensure convergence to a meaningful result, it relies on making small and diminishing updates to its value function estimates. Moreover, in the typical online mode of operation of TD(λ), a sample is observed, is acted upon (by updating the parameters of $\hat{V}$), and is then discarded, never to be seen again. A negative consequence of these two properties is that online TD(λ) is inherently wasteful in its use of the observed data. The least-squares TD(λ), or LSTD(λ) algorithm (Boyan 1999; Bradtke and Barto 1996), was put forward as an alternative to TD(λ) that makes better use of data, by directly solving a set of equations characterizing the fixed point of the TD(λ) updates. LSTD(λ) is amenable to a recursive implementation, at a time and memory cost of $O(N^2)$ per sample. A more fundamental shortcoming, shared by both TD(λ) and LSTD(λ), is that they do not supply the user with a measure of the accuracy of their value predictions.

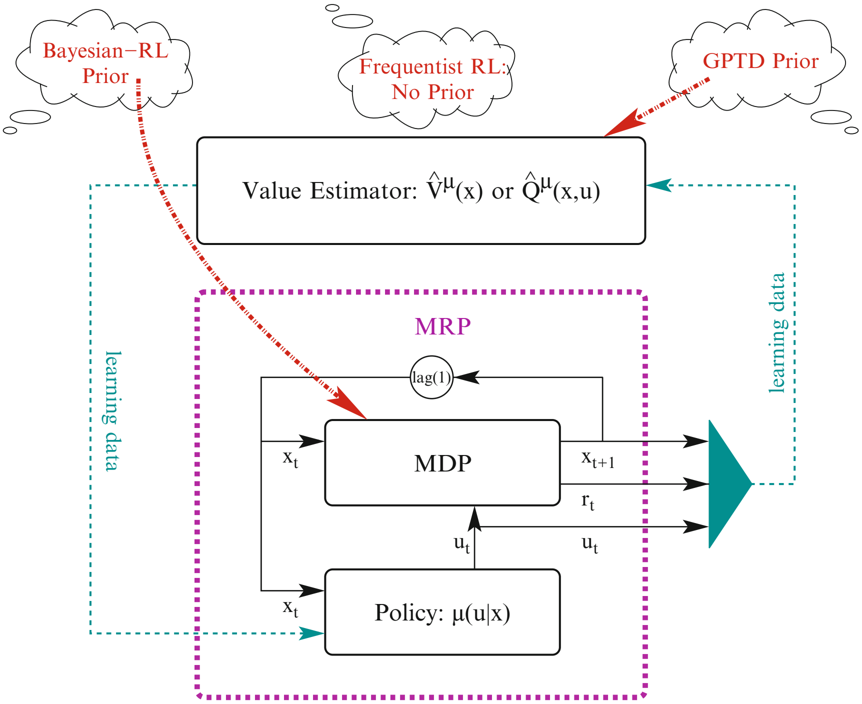
The discussion above motivates the search for:

1. Nonparametric estimators for V^μ, since these are not generally restricted to searching in any finite-dimensional hypothesis space, such as $\mathcal{H}_\phi$.
2. Estimators that make efficient use of the data.
3. Estimators that, in addition to value predictions, deliver a measure of the uncertainty in their predictions.

Structure of Learning System

We first describe the structure and operation of the basic GP temporal difference (GPTD) algorithm for policy evaluation. We then build on this algorithm to describe policy-improving algorithms, in the spirit of Howard's policy iteration (Howard 1960).

In the preceding section, we showed that the value V is the result of taking the expectation of the discounted return D with respect to the randomness in the trajectories and in the rewards collected therein. In the classic or frequentist approach, V is no longer random, since it is the true, albeit unknown value function induced by the policy μ. Adopting the Bayesian approach, we may still view the value V as a random entity by assigning it additional randomness, that is due to our *subjective uncertainty* regarding the MDP's transition model (p, q). We do not know what the true distributions p and q are,



Gaussian Process Reinforcement Learning, Fig. 1 An illustration of the frequentist as well as the two different Bayesian approaches to value function-based reinforcement learning. In the traditional Bayesian RL approach, a prior is placed on the MDP's model, whereas in our GPTD approach, the prior is placed directly on the value function. x, $\mathbf{u}$, and r denote state, action, and reward, respectively. The data required to learn value estimators typically consists of a temporal stream of state–action–reward triplets. Another stream of data is used to update the policy based on the current estimate of the value function. An MDP and a stationary policy controlling it jointly constitute an MRP. lag(1) denotes the 1-step time-lag operator

which means that we are also uncertain about the true value function. Previous attempts to apply Bayesian reasoning to RL modeled this uncertainty by placing priors over the MDP's transition and reward model (p, q) and applying Bayes' rule to update a posterior based on observed transitions. This line of work may be traced back to the pioneering works of Bellman (1956) and Howard (1960) followed by more recent contributions in the machine learning literature (Dearden et al. 1999, 1998; Duff 2002; Mannor et al. 2004; Poupart et al. 2006; Strens 2000; Wang et al. 2005). A fundamental shortcoming of this approach is that the resulting algorithms are limited to solving MDPs with finite (and typically rather small) state and action spaces, due to the need to maintain a probability distribution over the MDP's transition model. In this work, we pursue a different path – we choose to model our uncertainty about the MDP by placing a prior (and updating a posterior) directly on V. We achieve this by modeling V as a random process or, more specifically, as a Gaussian process. This mirrors the traditional classification of classical RL algorithms to either model-based or model-free (direct) methods; see Chapter 9 in Sutton and Barto (1998). Figure 1 illustrates these different approaches.

Gaussian Process Temporal Difference Learning

GPTD should be viewed as a family of *statistical generative models* (see ▸ Generative Learning) for value functions, rather than as a family of algorithms. As such, GPTD models specify the statistical relation between the unobserved value function and the observable quantities, namely, the observed trajectories and the rewards collected in them. The set of equations prescribing the GPTD model for a path $\boldsymbol{\xi} = (\mathbf{z}_0, \mathbf{z}_1, \ldots, \mathbf{z}_t)$ is (Here and in the sequel, to simplify notation, we omit the superscript μ, with the understanding that quantities such as D, V, or $\boldsymbol{\xi}$ generally depend on the policy μ being evaluated.)

$$R(\mathbf{z}_i) = V(\mathbf{z}_i) - \gamma V(\mathbf{z}_{i+1}) + N(\mathbf{z}_i, \mathbf{z}_{i+1})$$
$$\text{for } i = 0, 1, \ldots, t-1.$$

$N(\mathbf{z}_i, \mathbf{z}_{i+1})$ is a zero-mean noise term that must account for the statistics of $R(\mathbf{z}_i) + \gamma V(\mathbf{z}_{i+1}) - V(\mathbf{z}_i)$. If V is a priori distributed according to a GP prior and the noise term $N(\mathbf{z}_i, \mathbf{z}_{i+1})$ is also normally distributed, then $R(\mathbf{z}_i)$ is also normally distributed and so is the posterior distribution of V conditioned on the observed rewards. To fully specify the GPTD model, we need to specify the GP prior over V in terms of prior mean and covariance as well as the covariance of the noise process N. In Engel et al. (2003), it was shown that modeling N as a white noise process is a suitable choice for MRPs with deterministic transition dynamics. In Engel et al. (2005a), a different, correlated noise model was shown to be useful for general MRPs. Let us define $R_t = (R(\mathbf{z}_0), \ldots, R(\mathbf{z}_t))$, $V_t = (V(\mathbf{z}_0), \ldots, V(\mathbf{z}_t))$, and $N_t = (N(\mathbf{z}_0, \mathbf{z}_1), \ldots, N(\mathbf{z}_{t-1}, \mathbf{z}_t))$ and also define the $t \times (t+1)$ matrix

$$\mathbf{H}_t = \begin{bmatrix} 1 & -\gamma & 0 & \ldots & 0 \\ 0 & 1 & -\gamma & & \vdots \\ \vdots & & \ddots & \ddots & 0 \\ 0 & \ldots & 0 & 1 & -\gamma \end{bmatrix}.$$

In the white noise and correlated noise GPTD models, the noise covariance matrices $\boldsymbol{\Sigma}_t = \mathrm{Cov}[N_t]$ are given, respectively, by

$$\begin{bmatrix} \sigma_R^2(\mathbf{z}_0) & 0 & \ldots & 0 \\ 0 & \sigma_R^2(\mathbf{z}_1) & & \vdots \\ \vdots & & \ddots & 0 \\ 0 & \ldots & 0 & \sigma_R^2(\mathbf{z}_{t-1}) \end{bmatrix}$$

$$\text{and} \quad \mathbf{H}_t \begin{bmatrix} \sigma_0^2 & 0 & \ldots & 0 \\ 0 & \sigma_1^2 & & \vdots \\ \vdots & & \ddots & 0 \\ 0 & \ldots & 0 & \sigma_t^2 \end{bmatrix} \mathbf{H}_t^\top.$$

The final component of the GPTD model remaining to be specified is the prior distribution of the GP V. This distribution is specified by prior mean and covariance functions $v_0(\mathbf{z})$ and $k(\mathbf{z}, \mathbf{z}')$, respectively.

Let us define $\boldsymbol{v}_t = (v_0(\mathbf{z}_0), \ldots, v_0(\mathbf{z}_t))^\top$. Employing ▸ Bayes' rule, the posterior distribution of $V(\mathbf{z})$ – the value function at some arbitrary query point $\mathbf{z}$ – is now given by

$$(V(\mathbf{z}) | R_{t-1} = \mathbf{r}_{t-1}) \sim \mathcal{N}\{\hat{V}_t(\mathbf{z}), P_t(\mathbf{z}, \mathbf{z}),$$

where

$$\hat{V}_t(\mathbf{z}) = v_0(\mathbf{z}) + \mathbf{k}_t(\mathbf{z})^\top \boldsymbol{\alpha}_t, \quad P_t(\mathbf{z}, \mathbf{z}')$$
$$= k(\mathbf{z}, \mathbf{z}') - \mathbf{k}_t(\mathbf{z})^\top \mathbf{C}_t \mathbf{k}_t(\mathbf{z}'),$$
$$\boldsymbol{\alpha}_t = \mathbf{H}_t^\top (\mathbf{H}_t \mathbf{K}_t \mathbf{H}_t^\top + \boldsymbol{\Sigma}_t)^{-1} (\mathbf{r}_{t-1} - \mathbf{H}_t \boldsymbol{v}_t),$$
$$\mathbf{C}_t = \mathbf{H}_t^\top (\mathbf{H}_t \mathbf{K}_t \mathbf{H}_t^\top + \boldsymbol{\Sigma}_t)^{-1} \mathbf{H}_t.$$

It is seen here that in order to compute the posterior distribution of V for arbitrary sets of query points, one only needs the vector $\boldsymbol{\alpha}_t$ and the matrix $\mathbf{C}_t$. Consequently, $\boldsymbol{\alpha}_t$ and $\mathbf{C}_t$ are sufficient statistics for the posterior of V.

Algorithms 1 and 2 provide pseudocode for recursive computations of these sufficient statistics, in the deterministic transitions and general MDP models, respectively.

It can be seen that after observing t sample transitions, both the algorithms require storage quadratic in t (due to the matrix $\mathbf{C}_t$). The updates also require time quadratic in t due to matrix-vector products involving $\mathbf{C}_t$. These properties are unsatisfying from a practical point of view, since realistic RL problems typically require large amounts of data to learn. There are two general approaches for reducing the memory and time footprints of GPTD. One approach is to define parametric counterparts of the two GPTD models described earlier and derive the corre-

Algorithm 1 Recursive nonparametric GPTD for deterministic MDPs

```
Initialize $\boldsymbol{\alpha}_0 = 0$, $\mathbf{C}_0 = 0$, $\mathcal{D}_0 = \{\mathbf{z}_0\}$
for $t = 1, 2, \ldots$
    observe $\mathbf{z}_{t-1}, r_{t-1}, \mathbf{z}_t$
    $\mathbf{h}_t = (0, \ldots, 1, -\gamma)^\top$
    $\boldsymbol{\Delta}\mathbf{k}_t = \mathbf{k}_{t-1}(\mathbf{z}_{t-1}) - \gamma \mathbf{k}_{t-1}(\mathbf{z}_t)$
    $\Delta k_{tt} = k(\mathbf{z}_{t-1}, \mathbf{z}_{t-1}) - 2\gamma k(\mathbf{z}_{t-1}, \mathbf{z}_t) + \gamma^2 k(\mathbf{z}_t, \mathbf{z}_t)$
    $\mathbf{c}_t = \mathbf{h}_t - \begin{pmatrix} \mathbf{C}_{t-1} \boldsymbol{\Delta}\mathbf{k}_t \\ 0 \end{pmatrix}$
    $d_t = r_{t-1} - \boldsymbol{\Delta}\mathbf{k}_t{}^\top \boldsymbol{\alpha}_{t-1}$
    $s_t = \sigma_{t-1}^2 + \Delta k_{tt} - \boldsymbol{\Delta}\mathbf{k}_t{}^\top \mathbf{C}_{t-1} \boldsymbol{\Delta}\mathbf{k}_t$
    $\boldsymbol{\alpha}_t = \begin{pmatrix} \boldsymbol{\alpha}_{t-1} \\ 0 \end{pmatrix} + \frac{\mathbf{c}_t}{s_t} d_t$
    $\mathbf{C}_t = \begin{bmatrix} \mathbf{C}_{t-1} & \mathbf{0} \\ \mathbf{0}^\top & 0 \end{bmatrix} + \frac{1}{s_t} \mathbf{c}_t \mathbf{c}_t^\top$
    $\mathcal{D}_t = \mathcal{D}_{t-1} \cup \{\mathbf{z}_t\}$
end for
return $\boldsymbol{\alpha}_t$, $\mathbf{C}_t$, $\mathcal{D}_t$
```

Algorithm 2 Recursive nonparametric GPTD for general MDPs

```
Initialize $\boldsymbol{\alpha}_0 = \mathbf{0}$, $\mathbf{C}_0 = 0$, $\mathcal{D}_0 = \{\mathbf{z}_0\}$, $\mathbf{c}_0 = \mathbf{0}$, $d_0 = 0$, $1/s_0 = 0$
for $t = 1, 2, \ldots$
    observe $\mathbf{z}_{t-1}, r_{t-1}, \mathbf{z}_t$
    $\mathbf{h}_t = (0, \ldots, 1, -\gamma)^\top$
    $\boldsymbol{\Delta}\mathbf{k}_t = \mathbf{k}_{t-1}(\mathbf{z}_{t-1}) - \gamma \mathbf{k}_{t-1}(\mathbf{z}_t)$
    $\Delta k_{tt} = k(\mathbf{z}_{t-1}, \mathbf{z}_{t-1}) - 2\gamma k(\mathbf{z}_{t-1}, \mathbf{z}_t) + \gamma^2 k(\mathbf{z}_t, \mathbf{z}_t)$
    $\mathbf{c}_t = \frac{\gamma \sigma_{t-1}^2}{s_{t-1}} \begin{pmatrix} \mathbf{c}_{t-1} \\ 0 \end{pmatrix} + \mathbf{h}_t - \begin{pmatrix} \mathbf{C}_{t-1} \boldsymbol{\Delta}\mathbf{k}_t \\ 0 \end{pmatrix}$
    $d_t = \frac{\gamma \sigma_{t-1}^2}{s_{t-1}} d_{t-1} + r_{t-1} - \boldsymbol{\Delta}\mathbf{k}_t{}^\top \boldsymbol{\alpha}_{t-1}$
    $s_t = \sigma_{t-1}^2 + \gamma^2 \sigma_t^2 - \frac{\gamma^2 \sigma_{t-1}^4}{s_{t-1}} + \Delta k_{tt} - \boldsymbol{\Delta}\mathbf{k}_t{}^\top \mathbf{C}_{t-1} \boldsymbol{\Delta}\mathbf{k}_t + \frac{2\gamma \sigma_{t-1}^2}{s_{t-1}} \mathbf{c}_{t-1}^\top \boldsymbol{\Delta}\mathbf{k}_t$
    $\boldsymbol{\alpha}_t = \begin{pmatrix} \boldsymbol{\alpha}_{t-1} \\ 0 \end{pmatrix} + \frac{\mathbf{c}_t}{s_t} d_t$
    $\mathbf{C}_t = \begin{bmatrix} \mathbf{C}_{t-1} & \mathbf{0} \\ \mathbf{0}^\top & 0 \end{bmatrix} + \frac{1}{s_t} \mathbf{c}_t \mathbf{c}_t^\top$
    $\mathcal{D}_t = \mathcal{D}_{t-1} \cup \{\mathbf{z}_t\}$
end for
return $\boldsymbol{\alpha}_t$, $\mathbf{C}_t$, $\mathcal{D}_t$
```

sponding recursive algorithms. If the number of independent parameters (i.e., the dimensionality of the hypothesis space $\mathcal{H}_\phi$) used to represent the value function is m, the memory and time costs of the algorithms become quadratic in m, rather than t. Another approach, which is based on an efficient sequential kernel sparsification method, allows us to selectively exclude terms from $\mathcal{D}_t$, while controlling the error incurred as a result. Here again (bounds on m in this case may be derived using arguments based on the finiteness of packing numbers of the hypothesis space; see Engel (2005) for details), if the size of $\mathcal{D}_t$ saturates at m, the memory and time costs of the resulting algorithms are quadratic in m. For the complete derivations, as well as detailed pseudocode of the corresponding algorithms, we refer the reader to Engel (2005).

Theory

In this section, we derive the two GPTD models mentioned above, explicitly stating the assumptions underlying each model.

MRPs with Deterministic Transitions

In the deterministic case, the Bellman equation (4) degenerates into

$$\bar{R}(\mathbf{z}) = V(\mathbf{z}) - \gamma V(\mathbf{z}'), \qquad (5)$$

where $\mathbf{z}'$ is the state or state–action pair succeeding $\mathbf{z}$, under the deterministic policy μ. We also assume that the noise in the rewards is independent and Gaussian, but not necessarily identically distributed. We denote the reward variance by $\sigma_R^2(\mathbf{z}) = \mathrm{Var}[R(\mathbf{z})]$. Formally, this means that the reward $R(\mathbf{z})$, at some $\mathbf{z}$, satisfies $R(\mathbf{z}) = \bar{R}(\mathbf{z}) + N(\mathbf{z})$ where $\bar{R}(\mathbf{z})$ is the mean reward for that state. Assume we have a sequence of rewards sampled along a sampled path $\boldsymbol{\xi}$. Then, at the ith time step, we have $R(\mathbf{z}_i) = \bar{R}(\mathbf{z}_i) + N(\mathbf{z}_i)$. Using the random vectors R_t, V_t, and N_t defined earlier, we have $\mathcal{N}(\mathbf{0}, \boldsymbol{\Sigma}_t)$, where

$$\boldsymbol{\Sigma}_t = \mathrm{diag}(\sigma_R^2(\mathbf{z}_0), \ldots, \sigma_R^2(\mathbf{z}_{t-1})), \qquad (6)$$

and diag$(\cdot)$ denotes a diagonal matrix whose diagonal elements are the components of the argument vector. Writing the Bellman equations (5) for the points belonging to the sample path and substituting $R(\mathbf{z}_i) = \bar{R}(\mathbf{z}_i) + N(\mathbf{z}_i)$, we obtain the following set of t equations

$$R(\mathbf{z}_i) = V(\mathbf{z}_i) - \gamma V(\mathbf{z}_{i+1}) + N(\mathbf{z}_i),$$
$$i = 0, 1, \ldots, t-1.$$

This set of linear equations may be concisely written as

$$R_{t-1} = \mathbf{H}_t V_t + N_t. \tag{7}$$

General MRPs

Let us consider a decomposition of the discounted return D into its mean V and a zero-mean residual ΔV:

$$D(\mathbf{z}) = \mathbf{E}_\xi D(\mathbf{z}) + (D(\mathbf{z}) \\ -\mathbf{E}_\xi D(\mathbf{z})\big) \overset{\text{def}}{=} V(\mathbf{z}) + \Delta V(\mathbf{z}). \tag{8}$$

This decomposition is useful, since it separates the two sources of uncertainty inherent in the discounted return process D: For a known MDP model, V is a (deterministic) function, and the randomness in D is fully attributed to the intrinsic randomness in the trajectories generated by the MDP and policy pair, modeled by ΔV. On the other hand, in an MDP in which both transitions and rewards are deterministic but otherwise unknown, ΔV is deterministic (identically zero), and the randomness in D is due solely to the extrinsic Bayesian uncertainty, modeled by the random process V.

Substituting (8) into (2) and Rearranging, we get

$$R(\mathbf{z}) = V(\mathbf{z}) - \gamma V(\mathbf{z}') + N(\mathbf{z}, \mathbf{z}'),$$

where $\mathbf{z}' \sim p^{\mu}(\cdot|\mathbf{z})$ and

$$N(\mathbf{z}, \mathbf{z}') \overset{\text{def}}{=} \Delta V(\mathbf{z}) - \gamma \Delta V(\mathbf{z}'). \tag{9}$$

As before, we are provided with a sample path $\boldsymbol{\xi}$, and we may write the model Eqs. (9) for these samples, resulting in the following set of t equations:

$$R(\mathbf{z}_i) = V(\mathbf{z}_i) - \gamma V(\mathbf{z}_{i+1}) + N(\mathbf{z}_i, \mathbf{z}_{i+1}) \\ \text{for } i = 0, \dots, t-1.$$

Using our standard definitions for R_t, V_t, $\mathbf{H}_t$, and with $N_t = (N(\mathbf{z}_0, \mathbf{z}_1), \dots, N(\mathbf{z}_{t-1}, \mathbf{z}_t))^\top$, we again have

$$R_{t-1} = \mathbf{H}_t V_t + N_t. \tag{10}$$

In order to fully define a complete probabilistic generative model, we also need to specify the distribution of the noise process N_t. We model the residuals $\Delta V_t = (\Delta V(\mathbf{z}_0), \dots, \Delta V(\mathbf{z}_t))^\top$ as random Gaussian noise. (This may not be a correct assumption in general; however, in the absence of any prior information concerning the distribution of the residuals, it is the *simplest* assumption we can make, since the Gaussian distribution possesses the highest entropy among all distributions with the same covariance. It is also possible to relax the Gaussianity requirement on both the prior and the noise. The resulting estimator may then be shown to be the *linear minimum mean-squared error* estimator for the value.) In particular, this means that the distribution of the vector ΔV_t is completely specified by its mean and covariance. Another assumption we make is that each of the residuals $\Delta V(\mathbf{z}_i)$ is independently distributed. Denoting $\sigma_i^2 = \mathrm{Var}[D(\mathbf{z}_i)]$, the distribution of ΔV_t is given by

$$\Delta V_t \sim \mathcal{N}(\mathbf{0}, \mathrm{diag}(\boldsymbol{\sigma}_t)),$$

where $\boldsymbol{\sigma}_t = \left(\sigma_0^2, \sigma_1^2, \dots, \sigma_t^2\right)^\top$. Since $N_t = \mathbf{H}_t \Delta V_t$, we have $N_t \sim \mathcal{N}(\mathbf{0}, \boldsymbol{\Sigma}_t)$ with

$$\boldsymbol{\Sigma}_t = \mathbf{H}_t \mathrm{diag}(\boldsymbol{\sigma}_t) \mathbf{H}_t^\top \\ = \begin{bmatrix} \sigma_0^2 + \gamma^2\sigma_1^2 & -\gamma\sigma_1^2 & 0 & \dots & 0 & 0 \\ -\gamma\sigma_1^2 & \sigma_1^2 + \gamma^2\sigma_2^2 & -\gamma\sigma_2^2 & 0 & \dots & 0 \\ 0 & -\gamma\sigma_2^2 & \sigma_2^2 + \gamma^2\sigma_3^2 & \ddots & & \vdots \\ \vdots & 0 & \ddots & \ddots & \ddots & 0 \\ 0 & \vdots & & \ddots & \ddots & -\gamma\sigma_{t-1}^2 \\ 0 & 0 & \dots & 0 & -\gamma\sigma_{t-1}^2 & \sigma_{t-1}^2 + \gamma^2\sigma_t^2 \end{bmatrix}. \tag{11}$$

Applications

Any RL algorithm that requires policy evaluation as an algorithmic component can potentially use a GPTD algorithm for this task. In particular, this is true of algorithms based on Howard's policy iteration. In Engel et al. (2005a) and Engel (2005), it is shown how GPTD may be used to construct a SARSA-type algorithm (Rummery and Niranjan 1994; Sutton and Barto 1998), called GPSARSA. In Engel et al. (2005b), GPSARSA was used to learn control policies for a simulated Octopus arm. In Ghavamzadeh and Engel (2007), GPTD was used within a Bayesian actor–critic learning algorithm.

Future Directions

By virtue of the posterior covariance, GPTD algorithms compute a confidence measure (or, more precisely, Bayesian *credible intervals*) for their value estimates. So far, little use has been made of this additional information. Several potential uses of the posterior covariance may be envisaged:

1. It may be used to construct stopping rules for value estimation.
2. It may be used to guide exploration.
3. In the context of Bayesian actor–critic algorithms (Ghavamzadeh and Engel 2007), it may be used to control the size and direction of policy updates.

Further Reading

Yaakov Engel's doctoral thesis (Engel 2005) is currently the most complete reference to GPTD methods. Two conference papers (Engel et al. 2003, 2005a) provide a more concise view. The first of these introduces the GPTD model for deterministic MRPs, while the second introduces the general MDP model, as well as the GPSARSA algorithm. A forthcoming journal article will subsume these two papers and include some additional results, concerning the connection between GPTD and the popular TD(λ) and LSTD(λ) algorithms.

A hypothesis, h, is a predicate that maps an instance to *true* or *false*. That is, if $h(x)$ is true, then x is hypothesized to belong to the concept being learned, the *target*. Hypothesis, h_1, is more general than or equal to h_2, if h_1 covers at least as many examples as h_2 (Mitchell, 1997). That is, $h_1 \geq h_2$ if and only if

$$(\forall x)[h_1(x) \rightarrow h_2(x)]$$

A hypothesis, h_1, is strictly more general than h_2, if $h_1 \geq h_2$ and $h_2 \not\leq h_1$.

Note that the *more general than* ordering is strongly related to *subsumption*.

Definition

In the theory of statistical machine learning, a generalization bound – or, more precisely, a generalization error bound – is a statement about the predictive performance of a learning algorithm or class of algorithms. Here, a learning algorithm is viewed as a procedure that takes some finite training sample of labeled instances as input and returns a hypothesis regarding the labels of all instances, including those which may not have appeared in the training sample. Assuming labeled instances are drawn from some fixed distribution, the quality of a hypothesis can be measured in terms of its risk – its incompatibility with the distribution. The performance of a learning algorithm can then be expressed in terms of the expected risk of its hypotheses given randomly generated training samples.

Under these assumptions, a generalization bound is a theorem, which holds for any distribution and states that, with high probability, applying the learning algorithm to a randomly drawn sample will result in a hypothesis with risk no greater than some value. This bounding value typically depends on the size of the training sample, an empirical assessment of the risk of the hypothesis on the training sample as well as the "richness" or "capacity" of the class of predictors that can be output by the learning algorithm.

Motivation and Background

Suppose we have built an e-mail classifier and then collected a random sample of e-mail labeled as "spam" or "not spam" to test it on. We notice that the classifier incorrectly labels 5 % of the sample. What can be said about the accuracy of this classifier when it is applied to new, previously unseen e-mail? If we make the reasonable assumption that the mistakes made on future e-mails are independent of mistakes made on the sample, basic results from statistics tell us that the classifier's true error rate will also be around 5 %.

Now suppose that instead of building a classifier by hand we use a learning algorithm to *infer* one from the sample. What can be said about the future error rate of the inferred classifier if it also misclassifies 5 % of the training sample? In general, the answer is "nothing" since we can no longer assume future mistakes are independent of those made on the training sample. As an extreme case, consider a learning algorithm that outputs a classifier that just "memorizes" the training sample – predicts labels for e-mail in the sample according to what appears in the sample – and predicts randomly otherwise. Such a classifier will have a 0 % error rate on the sample, however, if most future e-mail does not appear in the training sample the classifier will have a true error rate around 50 %.

To avoid the problem of memorizing or overfitting the training data it is necessary to restrict the "flexibility" of the hypotheses a learning algorithm can output. Doing so forces predictions made off the training set to be related to those made on the training set so that some form of generalization takes place. However, doing this can limit the ability of the learning algorithm to output a hypothesis with small risk. Thus, there is a classic and trade-off: the bias being the limits placed on how flexible the hypotheses can be versus the variance between the training and the true error rates (see bias variance decomposition).

By quantifying the notion of hypothesis flexibility in various ways, generalization bounds provide inequalities that show how the flexibility and empirical error rate can be traded off to control the true error rate. Importantly, these statements are typically probabilistic but distribution-independent – they hold for nearly all sets of training data drawn from a fixed but unknown distribution. When such a bound holds for a learning algorithm it means that, unless the choice of training sample was very unlucky, we can be confident that some form of generalization will take place. The first results of this kind were established by Vapnik and Chervonenkis (1971) about 40 years ago and the measure of hypothesis flexibility they introduced – the ▸ VC dimension (see below) – now bears their initials. A similar style of results were obtained independently by Valiant in 1984 in the Probably Approximately Correct, or ▸ PAC learning framework (Valiant 1984). These two lines of work were drawn together by Blumer et al. (1989) and now form the basis of what is known today as statistical learning theory.

Details

For simplicity, we restrict our attention to generalization bounds for binary ▸ classification problems such as the spam classification example above. In this setting *instances* (e.g., e-mail) from a set $\mathcal{X}$ are associated with *labels* from a set $\mathcal{Y} = \{-1, 1\}$ (e.g., indicating not spam/spam) and an *example* $z = (x, y)$ is a labeled instance from $\mathcal{Z} := \mathcal{X} \times \mathcal{Y}$. The association of instances to labels is assumed to be governed by some unknown distribution P over $\mathcal{Z}$.

A *hypothesis* h is a function that assigns labels $h(x) \in \mathcal{Y}$ to instances. The quality of a hypothesis is assessed via a *loss* function $\ell : \mathcal{Y} \times \mathcal{Y} \to [0, \infty$, which assigns penalty $\ell(y, y')$ when h predicts the label $y' = h(x)$ for the example (x, y). For convenience, we will often combine the loss and hypothesis evaluation on an example $z = (x, y)$ by defining $\ell_h(z) = \ell(y, h(x))$. When examples are sampled from P the expected penalty, or *risk*

$$L_p(h) := \mathbb{E}_P[\ell_h(z)]$$

can be interpreted as a measure of how well h models the distribution P. A loss that is prevalent in classification is the *0–1 loss* $\ell^{0-1}(y, y') = [y \neq y']$ where $[p]$ is the indicator function for the predicate p. This loss simply assigns a penalty of 1 for an incorrect prediction and 0 otherwise. The associated 0–1 risk for h is the probability the prediction $h(x)$ disagrees with a randomly drawn sample (x, y) from P. Unless stated otherwise, the bounds discussed below are for the 0–1 loss only but, with care, can usually be made to hold with more general losses also.

Once a loss is specified, the goal of a learning algorithm is to produce a low-risk hypothesis based on a finite number of examples. Formally, a *learning algorithm* $\mathcal{A}$ is a procedure that takes a *training sample* $\mathbf{z} = (z_1, \ldots, z_n) \in \mathcal{Z}^n$ as input and returns a hypothesis $h = \mathcal{A}(\mathbf{z})$ with an associated *empirical risk*

$$\hat{L}_{\mathbf{z}}(h) := \frac{1}{n} \sum_{i=1}^{n} \ell_h(z_i).$$

In order to relate the empirical and true risks, a common assumption made in statistical learning theory is that the examples are drawn independently from P. In this case, a sample $\mathbf{z} = (z_1, \ldots, z_n)$ is a random variable from the product distribution P^n over $\mathcal{Z}^n$. Since the sample can be of arbitrary but finite size a learning algorithm can be viewed as a function $\mathcal{A} : \bigcup_{n=1}^{\infty} \mathcal{Z}^n \to \mathcal{H}$ where $\mathcal{H}$ is the algorithm's ▸ hypothesis space.

A generalization bound typically comprises several quantities: an empirical estimate of a hypothesis's performance $\hat{L}_{\mathbf{z}}(h)$; the actual (and unknown) risk of the hypothesis $L_P(h)$; a confidence term $\delta \in [0, 1]$; and some measure of the flexibility or *complexity* C of the hypotheses that can be output by learning algorithm. The majority of the bounds found in the literature fit the following template.

▸ *A generic generalization bound*: Let $\mathcal{A}$ be a learning algorithm, P some unknown distribution over $\mathcal{X} \times \mathcal{Y}$, and $\delta > 0$. Then, with probability at least $1 - \delta$ over randomly drawn samples $\mathbf{z}$ from P^n, the hypothesis $h = \mathcal{A}(\mathbf{z})$ has risk $L_P(h)$ no greater than $\hat{L}_{\mathbf{z}}(h) + \epsilon(\delta, C)$.

Of course, there are many variations, refinements, and improvements of the bounds presented below and not all fit this template. The bounds discussed below are only intended to provide a survey of some of the key ideas and main results.

Basic bounds: The penalties $\ell_h(z_i) := \ell(y_i, h(x_i))$ made by a fixed hypothesis h on a sample $\mathbf{z} = (z_1, \ldots, z_n)$ drawn from P^n are independent random variables. The law of large numbers guarantees (under some mild conditions) that their mean $\hat{L}_{\mathbf{z}}(h) = \frac{1}{n}\sum_{i=1}^{n} \ell_h(z_i)$ converges to the true risk $L_P(h) = \mathbb{E}_P[\ell_h(z)]$ for h as the sample size increases and several inequalities from probability theory can be used to quantify this convergence. A key result is ▸ McDiarmid's inequality, which can be used to bound the deviation of a function of independent random variables from its mean. Since the 0–1 loss takes values in [0, 1], applying this result to the random variables $\ell_h(Z_i)$ gives

$$P^n(L_P(h) > \hat{L}_{\mathbf{z}}(h) + \varepsilon) \le \exp(-2n\varepsilon^2). \quad (1)$$

We can invert this and obtain an upper bound for the true risk that will hold on a given proportion of samples. That is, if we want $L_P(h) > \hat{L}_{\mathbf{z}}(h) + \epsilon$ to hold on at least $1 - \delta$ of the time on randomly drawn samples we can solve $\delta = \exp(-2n\varepsilon^2)$ for ε and obtain $\varepsilon = \sqrt{\frac{\ln\frac{1}{\delta}}{2n}}$ so that

$$P^n\left(L_P(h) \le \hat{L}_{\mathbf{z}}(h) + \sqrt{\frac{\ln\frac{1}{\delta}}{2n}}\right) \ge 1 - \delta. \quad (2)$$

This simple bound lays the foundation for many of the subsequent bounds discussed below and is the reason for the ubiquity of the $\sqrt{\frac{\ln\frac{1}{\delta}}{n}}$-like terms.

A crucial observation to make about the above bound is that while it holds for any hypothesis h it does *not* hold for all $h \in \mathcal{H}$ *simultaneously*. That is, the samples for which the bounds hold for h_1 may be completely different to those which make the bound hold for h_2. Since a generalization bound must hold for all possible hypotheses output by a learning algorithm we need to extend the above analysis by exploiting additional properties of the hypothesis space $\mathcal{H}$.

In the simple case when there are only finitely many hypothesis, we use the *union bound.* This states that for any distribution P and any finite or countably infinite sequence of events A_1, $A_2 \ldots$ we have $P(\bigcup_i A_i) \le \sum_i P(A_i)$. For $\mathcal{H} = \{h_1, \ldots, h_m\}$ we consider the events $Z_h = \{\mathbf{z} \in \mathcal{Z}^n : L_P(h) > \hat{L}_{\mathbf{z}}(h) + \epsilon\}$ when samples of size n give empirical risks for h that are least ε smaller than its true risk. Using the union bound and (1) on these events gives

$$P^n\left(\bigcup_{h \in \mathcal{H}} Z_h(n, \varepsilon)\right) \le \sum_{i=1}^{m} P^n(Z_h(n, \varepsilon))$$
$$= m \cdot \exp(-2n\varepsilon^2).$$

This is a bound on the probability of drawing a training sample from P^n such that *every* hypothesis has a true risk that is ε larger than its empirical risk. Inverting this inequality by setting $\delta = m\exp(-2n\varepsilon^2)$ yields the following bound.

Finite class bound: Suppose $\mathcal{A}$ has finite hypothesis class $\mathcal{H} = \{h_1, \ldots, h_m\}$. Then with probability at least $1 - \delta$ over draws of $\mathbf{z}$ from P^n the hypothesis $h = \mathcal{A}(\mathbf{z})$ satisfies

$$L_P(h) \le \hat{L}_{\mathbf{z}}(h) + \sqrt{\frac{\ln|\mathcal{H}| + \ln\frac{1}{\delta}}{2n}}. \quad (3)$$

It is instructive to compare this to the single hypothesis bound in (2) and note the bound is weakened by the additional term $|\mathcal{H}|$.

Since the union bound also holds for countable sets of events this style of bound can be extended from finite hypothesis classes to countable ones. To do this requires a slight modification of the above argument and the introduction of a distribution π over a countable hypothesis space $\mathcal{H} = \{h_1, h_2, \ldots\}$, which is chosen before any samples are seen. This distribution can be interpreted as a prior belief or preference over the hypotheses in $\mathcal{H}$. Letting $\delta(h) = \delta \cdot \pi(h)$ in the bound (2) implies that for each $\mathcal{H}$ we have

$$P^n\left(L_P(h) < \hat{L}_{\mathbf{z}}(h) + \sqrt{\frac{\ln\frac{1}{\delta \cdot \pi(h)}}{2n}}\right) < \delta \cdot \pi(h).$$

Thus, applying the countable union bound to the union of these events over all of $\mathcal{H}$, and noting that $\sum_{h \in \mathcal{H}} \delta.\ \pi(h) = \delta$ since π is a distribution over $\mathcal{H}$, gives use the following bound:

Countable class bound: Suppose μ is a probability distribution over a finite or countably infinite hypothesis space $\mathcal{H}$. Then with probability at least $1 - \delta$ over draws of $\mathbf{z}$ from P^n the following bound holds for all $h \in \mathcal{H}$

$$L_P(h) \le \hat{L}_{\mathbf{z}}(h) + \sqrt{\frac{\ln\frac{1}{\pi(h)} + \ln\frac{1}{\delta}}{2n}}. \quad (4)$$

Although the finite and countable class bounds are proved using very similar techniques (indeed, the former can be derived from the latter by choosing $\pi(h) = \frac{1}{|\mathcal{H}|}$), they differ in the type of penalty they introduce for simultaneously bounding all the hypotheses in $\mathcal{H}$. In (3), the penalty $\ln|\mathcal{H}|$ is purely a function of the size of the class whereas in (4) the penalty $\ln \frac{1}{\pi(h)}$ varies with h. These two different styles of bound can be seen as templates for the two main classes of bounds discussed below: the hypothesis-independent bounds of the next section and the hypothesis-dependent bounds in the section on PAC-Bayesian bounds. The main conceptual leap from here is the extension of the arguments above to non-countable hypothesis classes.

> *Class complexity bounds*: A key result in extending the notion of size or complexity in the above bounds to more general classes of hypotheses is the *symmetrization lemma*. Intuitively, it is based on the observation that if the empirical risks for different samples are frequently near the true risk then they will also be near each other. Formally, it states that for any $\varepsilon > 0$ such that $n\varepsilon^2 \geq 2$ we have
>
> $$P^n\left(\sup_{h\in\mathcal{H}} |L_P(h) - \hat{L}_z(h)| > \varepsilon\right)$$
>
> $$\leq 2P^{2n}\left(\sup_{h\in\mathcal{H}} |\hat{L}_{z'}(h) - \hat{L}_z(h)| > \frac{\varepsilon}{2}\right). \quad (5)$$

Thus, to obtain a bound on the difference between empirical and true risk it suffices to bound the difference in empirical risks on two independent samples $\mathbf{z}$ and $\mathbf{z}'$, both drawn from P^n. This is useful since the maximum difference $\sup_{h\in\mathcal{H}} |\hat{L}_{z'}(h) - \hat{L}_z(h)|$ is much easier to handle than the difference involving $L_P(h)$ as the former term only evaluates losses on the points in $\mathbf{z}$ and $\mathbf{z}'$ while the latter takes into account the entire space $\mathcal{Z}$.

To study these restricted evaluations, we define the restriction of a function class $\mathcal{F}$ to the sample $\mathbf{z}$ by $\mathcal{F}_z = \{(f(z_1), \ldots, f(z_n)) : f \in \mathcal{F}\}$. Since the empirical risk $\hat{L}_z(h) = \frac{1}{n}\Sigma_{i=1}^n \ell_h(z_i)$ only depends on the values of the loss functions ℓ_h on samples from $\mathbf{z}$ we define the *loss class* $\mathbb{L} = \ell_{\mathcal{H}} = \{\ell_h : h \in \mathcal{H}\}$ and consider its restriction $\mathbb{L}_{\mathbf{z}}$ as well as the restriction $\mathcal{H}_z$ of the hypothesis class it is built upon. As we will see, the measures of complexity of these two classes are closely related.

One such complexity measure is arrived at by examining the size of a restricted function class $\mathcal{F}_z$ as the size of the sample $\mathbf{z}$ increases. The *growth function* or ▶ shattering coefficient for the function class $\mathcal{F}$ is defined as the maximum number of distinct values the vectors in $\mathcal{F}_z$ can take given a sample of size n : $S_n(\mathcal{F}) = \sup_{z\in\mathcal{Z}^n} |\mathcal{F}_z|$. In the case of binary classification with a 0–1 loss, it is not hard to see that the growth functions for both $\mathbb{L}$ and $\mathcal{F}$ are equal, that is, $S_n(\mathrm{L}) = S_n(\mathcal{H})$, and so they can be used interchangeably. Applying a union bound argument to (1) as in the previous bounds guarantees that $P^n(\sup_{h\in\mathcal{H}} |L_P(h) - \hat{L}_z(h)| > \varepsilon) \leq 2S_n(\mathcal{H})\exp(-n\varepsilon^2/8)$ and by inversion we obtain the following generalization bound for arbitrary hypothesis classes $\mathcal{H}$:

> *Growth function bound*: For all $\delta > 0$, a draw of $\mathbf{z}$ from P^n will, with probability at least $1 - \delta$, satisfy for all $h \in \mathcal{H}$
>
> $$L_P(h) \leq \hat{L}_{\mathbf{z}}(h) + 2\sqrt{\frac{2\ln S_n(\mathcal{H}) + 2\ln\frac{2}{\delta}}{n}}. \quad (6)$$

One conclusion that can be immediately drawn from this bound is that the shattering coefficient must grow sub-exponentially for the bound to provide any meaningful guarantee. If the class $\mathcal{H}$ is so rich that hypotheses from it can fit all 2^n possible label combinations – if $S_n(\mathcal{H}) = 2^n$ for all n – then the term $\sqrt{2\ln S_n(\mathcal{H})/n} > 1$ and so (6) just states $L_P(h) \leq 1$. Therefore, to get nontrivial bounds from (6) there needs to exist some value d for which $S_n(\mathcal{H}) < 2^n$ whenever $n > d$.

VC dimension: This desired property of the growth function is exactly what is captured by the ▶ VC dimension $VC(\mathcal{H})$ of a hypothesis class $\mathcal{H}$. Formally, it is defined as $VC(\mathcal{H}) = \max\{n \in \mathbb{N} : S_n(\mathcal{H}) = 2^n\}$ and is infinite if no finite maximum exists. Whether or not the VC dimension is finite plays a central role in the consistency of empirical risk minimization techniques. Indeed, it is possible to show that using ERM on a hypothesis class $\mathcal{H}$ is consistent if and only if

$VC(\mathcal{H}) < \infty$. This is partly due to *Sauer's lemma*, which shows that when a hypothesis class $\mathcal{H}$ has finite VC dimension $VC(\mathcal{H}) = d_{\mathcal{H}} < \infty$ its growth function is eventually polynomial in the sample size. Specifically, for all $n \geq d_{\mathcal{H}}$ the growth function satisfies $S_n(\mathcal{H}) \leq \left(\frac{en}{d_{\mathcal{H}}}\right)^{d_{\mathcal{H}}}$. By substituting this result into the Growth Function Bound (6) we obtain the following bound, which shows how the VC dimension plays a role that is analogous to the size a hypothesis class in the finite case.

▸ *VC dimension bound*: Suppose $\mathcal{A}$ has hypothesis class $\mathcal{H}$ with finite VC dimension $d_{\mathcal{H}}$. Then with probability at least $1 - \delta$ over draws of $\mathbf{z}$ from P^n the hypothesis $h = \mathcal{A}(\mathbf{z})$ satisfies

$$L_P(h) \leq \hat{L}_z(h) + 2\sqrt{\frac{2d_{\mathcal{H}} \ln\left(\frac{2en}{d_{\mathcal{H}}}\right) + 2\ln\frac{2}{\delta}}{n}}. \tag{7}$$

There are many other bounds in the literature that are based on the VC dimension. See the Recommended Reading for pointers to these.

Rademacher averages: Rademacher averages are a second kind of measure of complexity for uncountable function classes and can be used to derive more refined bounds than those above. These averages arise naturally by treating as a random variable the sample-dependent quantity $M_{\mathcal{F}}(\mathbf{z}) = \sup_{f \in \mathcal{F}}[\mathbb{E}_P[f] - \mathbb{E}_{\mathbf{z}}[f]]$. This is just the largest difference taken over all $f \in \mathcal{F}$ between its true mean $\mathbb{E}_P[f]$ and its empirical mean $\mathbb{E}_{\mathbf{z}}[f] := \frac{1}{|\mathbf{z}|}\sum_{i=1}^{|\mathbf{z}|} f(z_i)$. For a loss class $\mathbb{L} = \ell_{\mathcal{H}}$ a bound on this maximum difference – $M_{\mathbb{L}}(\mathbf{z}) \leq B$ – immediately gives a generalization bound of the form $L_P(h) \leq \hat{L}_{\mathbf{z}}(h) + B$. Since $M_{\mathcal{F}}(\mathbf{z})$ is a random variable, McDiarmid's inequality can be used to bound its value in terms of its expected value plus the usual $\sqrt{\frac{\ln\frac{1}{\delta}}{2n}}$ term. Applying symmetrization it can then be shown that this expected value satisfies

$$\mathbb{E}_{P^n}[M_{\mathcal{F}}(\mathbf{z})] \leq \mathbb{E}\left[\sup_{f \in \mathcal{F}} \frac{1}{n}\sum_{i=1}^{n} \rho_i (f(z_i') - f(z_i))\right]$$
$$\leq 2R_n(\mathcal{F})$$

where the right-hand expectation is taken over two independent samples $\mathbf{z}, \mathbf{z}' \sim P^n$ and the *Rademacher variables* $\rho_1, \ldots, \rho_n$. These are independent random variables, each with equal probability of taking the values -1 or 1, that give their name to the *Rademacher average*

$$R_n(\mathcal{F}) = \mathrm{E}\left[\sup_{f \in \mathcal{F}} \frac{1}{n}\sum_{i=1}^{n} \rho_l f(z_i)\right].$$

Intuitively, this quantity measures how well the functions in $\mathcal{F}$ can be chosen to align with randomly chosen labels ρ_i. The Rademacher averages for the loss class $\mathbb{L}$ and the hypothesis class $\mathcal{H}$ are closely related. For 0–1 loss, it can be shown they satisfy $R_n(\mathbb{L}) = \frac{1}{2}R_n(\mathcal{H})$.

Putting all the above steps together gives the following bounds.

Rademacher bound: Suppose $\mathcal{A}$ has hypothesis class $\mathcal{H}$. Then with probability at least $1 - \delta$ over draws of $\mathbf{z}$ from P^n the hypothesis $h = \mathcal{A}(\mathbf{Z})$ satisfies

$$L_P(h) \leq \hat{L}_z(h) + R_n(\mathcal{H}) + \sqrt{\frac{\ln\frac{1}{\delta}}{2n}}. \tag{8}$$

This bound is qualitatively different to the Growth Function and VC bounds above as the Rademacher average term is *distribution-dependent* whereas the other complexity terms are purely a function of the hypothesis space. Indeed, it is possible to bound the Rademacher average in terms of the VC dimension and obtain the VC bound (7) from (8). Furthermore, the Rademacher average is closely related to the minimum empirical risk via $R_n(\mathcal{H}) = 1 - 2\mathbb{E}[\inf_{h \in \mathcal{H}} \hat{L}_{\mathbf{x},\rho}(h)]$ where $\hat{L}_{\mathbf{x},\rho}(h)$ is the empirical risk of h for the randomly labeled sample $\mathbf{z} = ((x_1, \rho_1), \ldots, (x_n, \rho_n))$. Thus, in principle, $R_n(\mathcal{H})$ could be estimated for a given learning problem using standard ERM methods.

The Rademacher bound can be further refined so that the complexity term is *data-dependent* rather than distribution-dependent. This is done by noting that the Rademacher average $R_n\mathcal{F} = \mathbb{E}[\hat{R}_{\mathbf{z}}(\mathcal{F})]$ where $\hat{R}_{\mathbf{z}}(\mathcal{F})$ is the *empirical Rademacher average* for $\mathcal{F}$ conditioned on the sample $\mathbf{z}$. Applying McDiarmid's inequality to the difference between $\hat{R}_{\mathbf{z}}(\mathcal{F})$ and its mean gives a sample-dependent bound:

> *Empirical Rademacher bound*: Under the same conditions as the Rademacher bound, the following holds with probability $1-\delta$:
>
> $$L_P(h) \leq \hat{L}_z(h) + \hat{R}_z(\mathcal{H}) + 3\sqrt{\frac{\ln\frac{2}{\delta}}{2n}}. \qquad (9)$$

PAC-Bayesian bounds: All the bounds in the previous section provide bounds on deterministic hypotheses, which include complexity terms that are functions of the entire hypothesis space. PAC-Bayesian bounds differ from these in two ways: they provide bounds on nondeterministic hypotheses – labels may be predicted for instances stochastically; and their complexity terms are *hypothesis-dependent*. The term "Bayesian" given to these bounds refers to the use of a distribution over hypotheses that is used to define the complexity term. This distribution can be interpreted as a prior belief over the efficacy of each hypothesis before any observations are made.

Nondeterministic hypotheses are modeled by assuming that a distribution μ over $\mathcal{H}$ is used to randomly draw a deterministic hypothesis $h \in \mathcal{H}$ to predict $h(x)$ each time a new instance x is seen. Such a strategy is called a *Gibbs hypothesis* for μ. Since its behavior is defined by the distribution μ, we will abuse our notation slightly and define its loss on the example z to be $\ell_\mu(z) := \mathbb{E}_{h\sim\mu}[\ell_h(z)]$. Similarly, the true risk and empirical risk for a Gibbs hypothesis are, respectively, defined to be $L_P(\mu) := \mathbb{E}_{h\sim\mu}[L_P(h)]$ and $\hat{L}_{\mathbf{z}}(\mu) := \mathbb{E}_{h\sim\mu}[\hat{L}_{\mathbf{z}}(h)]$. As with the earlier generalization bounds, the aim is to provide guarantees about the difference between $L_P(\mu)$ and $\hat{L}_{\mathbf{z}}(\mu)$. In the case of 0–1 loss, $p := L_P(\mu) \in [0,1]$ is just the probability of the Gibbs hypothesis for μ misclassifying an example and $q := \hat{L}_{\mathbf{z}}(\mu) \in [0,1]$ can be thought of as an estimate of p. However, unlike the earlier bounds on the difference between the true and estimated risk, PAC-Bayesian bounds are expressed in terms the *Kullback–Leibler (KL) divergence*. For the values $p, q \in [0, 1]$ this is defined as $kl(q\|p) := q\ln\frac{q}{p} + (1-q)\ln\frac{1-q}{1-p}$ and for distributions μ and π over the hypothesis space $\mathcal{H}$ we write $KL(\mu \parallel \pi) := \int_{\mathcal{H}} \ln\frac{d\mu}{d\pi}d\mu$. Using these definitions, the most common PAC-Bayesian bound states the following.

> *Theorem (PAC-Bayesian bound)*: For all choices of the distribution π over $\mathcal{H}$ made prior to seeing any examples, the Gibbs hypothesis defined by μ satisfies
>
> $$kl(L_P(\mu), \hat{L}_{\mathbf{z}}(\mu)) \leq \frac{KL(\mu \parallel \pi) + \ln\frac{n+1}{\delta}}{n} \qquad (10)$$
>
> with probability at least 1 – δ over draws of $\mathbf{z}$ from P^n.

This says that the difference (as measured by *kl*) between the true and empirical risk for the Gibbs hypothesis based on μ is controlled by two terms: a *complexity* term $\frac{KL(\mu\|\pi)}{n}$ and a *sampling* term $\frac{\ln\frac{n+1}{\delta}}{n}$, both of which converge to zero as n increases. To make connections with the previous bounds more apparent, we can weaken (10) using the inequality $kl(q \parallel p) \geq 2(p-q)^2$ to get the following bound that holds under the same assumptions:

$$L_P(\mu) \leq \hat{L}_{\mathbf{z}}(\mu) + \sqrt{\frac{KL(\mu \parallel \pi) + \ln\frac{n+1}{\delta}}{2n}}.$$

The sampling term is similar to the ubiquitous estimation penalty in the earlier bounds but with an additional $\ln(n+1)/n$. The complexity term is a measure of the complexity of the Gibbs hypothesis for μ *relative* to the distribution π. Intuitively, $KL(\cdot \| \pi)$ can be thought of as a parametrized family of complexity measures where hypotheses from a region where π is large are "cheap" and those where π is small are "expensive". Information theoretically, it is the expected number of extra bits required to code hypotheses drawn from μ using a code based on π instead of a code based on μ. It is for these reasons the PAC-Bayes bound is said to demonstrate the importance of choosing a good prior. If the Gibbs hypothesis μ, which minimizes $\hat{L}_z(\mu)$ is also "close" to π then the bound will be tight.

Unlike the other bounds discussed above, PAC-Bayesian bounds are in terms of the complexity of single meta-classifiers rather than the complexity of classes. Furthermore, for specific base hypothesis classes such as margin classifiers used by SVMs it is possible to get hypothesis-specific bounds via the PAC-Bayesian bounds. These are typically much tighter than the VC or Rademacher bounds.

Other bounds: While the above bounds are landmarks in statistical learning theory there is obviously much more territory that has not been covered here. For starters, the VC bounds for classification can be refined by using more sophisticated results from empirical process theory such as the Bernstein and Variance-based bounds. These are discussed in Sect. 5 of Boucheron et al. (2005). There are also other distribution- and sample-dependent complexity measures that are motivated differently to Rademacher averages. For example, the *VC entropy* (see Sect. 4.5 of Bousquet et al. 2004) is a distribution-dependent measure obtained by averaging $|\mathcal{F}_{\mathbf{z}}|$ with respect to the sample distribution rather than taking supremum in the definition of the shattering coefficient.

Moving beyond classification, bounds for regression problems have been studied in depth and have similar properties to those for classification. These bounds are obtained by essentially discretizing the function spaces. The growth function is replaced by what is known as a *covering number* but the essence of the bounds remain the same. The reader is referred to Herbrich and Williamson (2002) for a brief discussion and Anthony and Bartlett (1999) for more detail.

There are a variety of bounds that, unlike those above, are algorithm-specific. For example, the regularized empirical risk minimization performed by SVMs has been analyzed within an *algorithmic stability* framework. As discussed in Boucheron et al. (2005) and Herbrich and Williamson (2002), hypotheses are considered stable if their predictions are not varied too much when a single training example is perturbed. Two other algorithm-dependent frameworks include the *luckiness* and *compression* frameworks, both summarized in Herbrich and Williamson (2002). The former gives bounds in terms of an a priori measure of luckiness – how well a training sample aligns with biases encoded in an algorithm – while the latter considers algorithms, like SVMs, which base hypotheses on key examples within a training sample.

Recently, there has been work on a type of algorithm-dependent, relative bound called *reductions* (see Beygelzimer et al. 2008 for an overview). By transforming inputs and outputs for one type of problem (e.g., probability estimation) into a different type of problem (e.g., classification), bounds for the former can be given in terms of bounds for the latter while making very few assumptions. This opens up a variety of avenues for applying existing results to new learning tasks.

Recommended Reading

As mentioned above, the uniform convergence bounds by Vapnik and Chervonenkis (1971) and the PAC framework of Valiant (1984) were the first generalization bounds for statistical learning. Ideas from both were synthesized and extended by Blumer et al. (1989). The book by Kearns and Vazirani (1994) provides a good overview of the early PAC-style bounds while Vapnik's comprehensive book (Vapnik 1998), and Anthony and Bartlett's book (1999) cover classification and regression bounds involving the VC dimension. Rademacher averages were first considered as an alternative to VC dimension in the context of learning theory by Koltchinskii and

Panchenko (2001) and were refined and extended by Bartlett and Mendelson (2003) who provide a readable overview. Early PAC-Bayesian bounds were established by McAllester (1999) based on an earlier PAC analysis of Bayesian estimators by Shawe-Taylor and Williamson (1997). Applications of the PAC-Bayesian bound to SVMs are discussed in Langford's tutorial on prediction theory (Langford 2005) and recent paper by Banerjee (2006) provides an information theoretic motivation, a simple proof of the bound in (11), as well as connections with similar bounds in online learning.

There are several well-written surveys of generalization bounds and learning theory in general. Herbrich and Williamson (2002) present a unified view of VC, compression, luckiness, PAC-Bayesian, and stability bounds. In a very readable introduction to statistical learning theory, Bousquet et al. (2004) provide good intuition and concise proofs for all but the PAC-Bayesian bounds presented above. That introduction is a good companion for the excellent but more technical survey by Boucheron et al. (2005) based on tools from the theory of empirical processes. The latter paper also provides a wealth of further references and a concise history of the development of main techniques in statistical learning theory.

Generative and Discriminative Learning

Bin Liu[1] and Geoffrey I. Webb[2]
[1]Monash University, Clayton, VIC, Australia
[2]Faculty of Information Technology, Monash University, Victoria, Australia

Definition

Generative learning refers alternatively to any classification learning process that classifies by using an estimate of the joint probability P(y,$\mathbf{x}$) or to any classification learning process that classifies by using estimates of the ▸ prior probability P(y) and the conditional probability P($\mathbf{x}|y$) (Jaakkola and Haussler 1999; Jaakkola et al. 1999; Ng and Jordan 2002; Lasserre et al. 2006; Bishop 2007), where y is a class and $\mathbf{x}$ is a description of an object to be classified. Given such models or estimates, it is possible to generate synthetic objects from the joint distribution. Generative learning contrasts to *discriminative learning* in which a model or estimate of P($y|\mathbf{x}$) is formed without reference to an explicit estimate of any of P($y,\mathbf{x}$), P($\mathbf{x}$), or P($\mathbf{x}|y$).

It is also common to categorize as discriminative approaches based on a decision function that directly map from input $\mathbf{x}$ onto the output y (such as ▸ support vector machines, ▸ neural networks, and ▸ decision trees), where the decision risk is minimized without estimation of P($y,\mathbf{x}$), P($\mathbf{x}|y$), or P($y|\mathbf{x}$) (Jaakkola and Haussler 1999).

The standard exemplar of generative learning is ▸ naïve Bayes and that of discriminative learning is ▸ logistic regression Another important contrasting pair is the generative ▸ hidden Markov model and discriminative ▸ conditional random field.

It is widely accepted that generative learning works well when samples are rare, while discriminative learning has better asymptotic error performance (Ng and Jordan 2002).

Motivation and Background

Efron (1975) provides an early examination of the generative/discriminative distinction. Efron performs an empirical comparison of the efficiency of the generative ▸ linear discriminant analysis (LDA) and discriminative ▸ logistic regression. His results show that logistic regression has 30 % less efficiency than LDA, which means the discriminative approach is 30 % slower to reach its asymptotic error than the generative approach.

Ng and Jordan (2002) give a theoretical discussion of the efficiency of generative ▸ naïve Bayes and discriminative ▸ logistic regression. This is an interesting pair because they both form linear models of forms that are directly equivalent to one another, the only substantive difference being the manner in which they parameterize those models. Their result shows that logistic regression converges toward its asymptotic error in order n samples, while naïve Bayes converges in order log$n$ samples. While logistic regression converges much slower than naïve Bayes, it has lower asymptotic error than naïve Bayes. These results suggest that it is desirable to use a generative approach when training data is scarce and to use a discriminative approach when there is enough training data. However, it is worth noting that the generative/discriminative distinction is not the only difference in how these two algorithms parameterize their models. Whereas logistic regression seeks to directly fit its model to the discriminative objective, P(y|$\mathbf{x}$), naïve Bayes does not directly fit P($y,\mathbf{x}$). Instead it fits its model to P(y) and each P(x$_i$|y) (where x$_i$ is an individual attribute), making the simplifying attribute independence assumption.

Recent research into the generative/discriminative learning distinction has concentrated on the area of hybrids of generative and discriminative learning as well as generative learning and discriminative learning in structured data learning or semi-supervised learning context.

In hybrid approaches, researchers seek to obtain the merits of both generative learning and discriminative learning. Some examples include the Fisher kernel for discriminative learning (Jaakkola and Haussler 1999), maxent discriminative learning (Jaakkola et al. 1999), and principled hybrids of generative and discriminative models (Lasserre et al. 2006; Zaidi et al. 2014).

In structured data learning, the output data have dependent relationships As an example of generative learning, hidden Markov models are used in structured data problems which need sequential decisions. The discriminative analogue is conditional random field models. Another example of discriminatively structured learning is max-margin Markov networks (Taskar et al. 2004).

In ▸ semi-supervised learning, co-training and multiview learning are usually applied to generative learning (Blum and Mitchell 1998). It is less straightforward to apply semi-supervised learning in traditional discriminative learning, since $P(y|\mathbf{x})$ is estimated by ignoring $P(\mathbf{x})$. Examples of semi-supervised learning methods in discriminative learning include transductive SVM, Gaussian processes, information regularization, and graph-based methods (Chapelle et al. 2006).

Generative Learning

Definition

Generative learning refers alternatively to any classification learning process that classifies by using an estimate of the joint probability $P(y, \mathbf{x})$ or to any classification learning process that classifies by using estimates of the prior probability P(y) and the conditional probability $P(\mathbf{x}|y)$, where y is a class and $\mathbf{x}$ is a description of an object to be classified. Given such models or estimates it is possible to generate synthetic objects from the joint distribution. Generative learning contrasts to discriminative learning in which a model or estimate of $P(y|\mathbf{x})$ is formed without reference to an explicit estimate of any of $P(\mathbf{x}), P(y, \mathbf{x})$, or $P(\mathbf{x}|y)$.

Definitions

There are many variations of genetic algorithms (GA). Here, wedescribe a simple scheme to introduce some of the key terms in genetic and evolutionary algorithms. See the main entry on ▸ Evolutionary Algorithms for references to specific methods.

In genetic learning, we assume that there is a population of individuals, each of which represents a candidate problem solver for a given task. GAs can be thought of as a family of general purpose search methods that are capable of solving a broad range of problems from optimization and scheduling to robot control. Like evolution, genetic algorithms test each individual from the population and only the fittest survive to reproduce for the next generation. The algorithm creates new generations until at least one individual is found that can solve the problem adequately.

Each problem solver is a *chromosome*. A position, or set of positions in a chromosome is called a *gene*. The possible values (from a fixed set of symbols) of a gene are known as *alleles*. For example, a simple genetic algorithm may define the set of symbols to be {0, 1}, and chromosome lengths are fixed. The most critical problem in applying a genetic algorithm is in finding a suitable encoding of the examples in the problem domain to a chromosome. A good choice of representation will make the search easier by limiting the size of the search space. A poor choice will result in a large search space. Choosing the size of the population can be problematic since a small population size provides an insufficient sample over the space of solutions for a problem and large population requires extensive evaluation and will be slow.

Each iteration in a genetic algorithm is called a *generation*. Each chromosome in a population is used to solve a problem. Its performance is evaluated and the chromosome is given a rating of fitness. The population is also given an overall fitness rating based on the performance of its members. The fitness value indicates how close a chromosome or population is to the required solution.

New sets of chromosomes are produced from one generation to the next. Reproduction takes place when selected chromosomes from one generation are recombined with others to form chromosomes for the next generation. The new ones are called *offspring*. Selection of chromosomes for reproduction is based on their fitness values. The average fitness of the population may also be calculated at the end of each generation. The strategy must be modified if too few or too many chromosomes survive. For example, at least 10 % and at most 60 % must survive.

Genetic Operators

Operators that recombine the selected chromosomes are called *genetic operators*. Two common operators are *crossover* and *mutation*. Crossover exchanges portions of a pair of chromosomes at a randomly chosen point called the crossover point. Some Implementations have more than one crossover point. For example, if there are two chromosomes, X and Y:

$$X = 1001\,01011, Y = 1110\,10010$$

and the crossover point is after position 4, the resulting offspring are:

$$O1 = 100110010, O2 = 1110\,01011$$

Offspring produced by crossover cannot contain information that is not already in the population, so an additional operator, *mutation*, is required. Mutation generates an offspring by randomly changing the values of genes at one or more gene positions of a selected chromosome. For example, if the following chromosome,

$$Z = 100101011$$

is mutated at positions 2, 4, and 9, then the resulting offspring is:

$$O = 110001010$$

The number of offspring produced for each new generation depends on how members are introduced so as to maintain a fixed population size. In a *pure* replacement strategy, the whole population is replaced by a new one. In an *elitist* strategy, a proportion of the population survives to the next generation.

Abstract

Genetic programming (GP) is an evolutionary algorithm-based methodology inspired by biological evolution, used to solve complex problems.

Genetic programming is a subclass of ▸ evolutionary algorithms, wherein a population of individual programs is evolved. The main mechanism behind genetic programming is that of a ▸ genetic algorithm, namely, the repeated cycling through four operations applied to the entire population: evaluate–select–crossover–mutate. Starting with an initial population of randomly generated programs, each individual is evaluated in the domain environment and assigned a fitness value representing how well the individual solves the problem at hand. Being randomly generated, the first-generation individuals usually exhibit poor performance. However, some individuals are better than others, that is, as in nature, variability exists, and through the mechanism of selection, these have a higher probability of being selected to parent the next generation. The size of the population is finite and usually constant.

Grammar learning

Definition

Grammatical inference is concerned with inferring grammars from positive (and possibly negative) examples (Angluin 1978; Korfiatis and Paliouras 2008; Sakakibara 2005). A context-free grammar (CFG) $\mathcal{G}$ (equivalent to a push-down finite-state automaton) is described by a four tuple $(\mathcal{Q}, \mathcal{E}, \delta, \Sigma)$:

- Σ is the alphabet of *terminal* symbols, upon which the grammar is defined.
- The pair $(\mathcal{Q}, \mathcal{E})$ defines a graph, where $\mathcal{Q}$ is the set of nodes (states), and $\mathcal{E}$ is the set of edges (production rules). $\mathcal{Q}$ includes one *starting* node q_0 and a set $\mathcal{Q}_f$ ($\mathcal{Q}_f \subset \mathcal{Q}$) of final or *accepting* nodes.
- Every edge in $\mathcal{E}$ is labeled by one or several letters in Σ, expressed through mapping $\delta : \mathcal{E} \mapsto 2^{\Sigma}$.
- Let $\mathcal{L}(\mathcal{G})$ denote the language associated to the grammar. Each string s in $\mathcal{L}(\mathcal{G})$ is generated along a random walk in the graph, starting in q_0 with an initially empty s. Upon traversing edge e, one symbol from $\delta(e)$ is concatenated to s. The walk ends upon reaching a final node ($e \in \mathcal{Q}_f$).

A CFG is determinist if all pairs of edges (q, q') and (q, q'') $(q' \neq q'')$ bear different labels $(\delta(q, q') \bigcap \delta(q, q'') = \emptyset)$.

One generalizes a given CFG by applying one or several operators, among the following: (1) introducing additional nodes and edges, (2) turning a node into an accepting one, and (3) *merging* two nodes q and q'. In the latter case, some non-determinism can be introduced (if some edges (q, r) and (q', r') have label(s) in common); enforcing a deterministic generalization is done using the *recursive determinization operator* (e.g., merging nodes r and r').

In general, grammatical inference proceeds as follows (Lang et al. 1998; Oncina and Garcia 1992). Let S be the set of positive examples, strings on alphabet Σ. The *prefix tree acceptor* (PTA), a most specific generalization of S, is constructed by associating to each character of every string a distinct node and applying the determinization operator. This PTA is thereafter iteratively generalized by merging a pair of nodes. Well-known grammar learners are RPNI (Oncina and Garcia 1992) and BLUE-FRINGE (Lang et al. 1998). RPNI uses a depth first search strategy and merges the pair of nodes which are closest to the start node, such that their deterministic generalization does not cover any negative example. BLUE-FRINGE uses a beam search from a candidate list, selecting the pair of nodes to be merged after the *evidence-driven* state merging (EDSM) criterion, i.e., such that their generalization involves a minimal number of final states.

Minimum cuts; Network clustering; Spectral clustering; Structured data clustering

Definition

Graph clustering refers to ▸ clustering of data in the form of graphs. Two distinct forms of clustering can be performed on graph data. Vertex clustering seeks to cluster the nodes of the graph into groups of densely connected regions based on either edge weights or edge distances. The second form of graph clustering treats the graphs as the objects to be clustered and clusters these objects on the basis of similarity. The second approach is often encountered in the context of structured or XML data.

Motivation and Background

Graph clustering is a form of ▸ graph mining that is useful in a number of practical applications including marketing, customer segmentation, congestion detection, facility location, and XML data integration (Lee et al. 2002). The graph clustering problems are typically defined into two categories:

- *Node clustering algorithms*: Node clustering algorithms are generalizations of multidimensional clustering algorithms in which we use functions of the multidimensional data points in order to define the distances. In the case of graph clustering algorithms, we associate numerical values with the edges. These numerical values need not satisfy traditional properties of distance functions such as the triangle inequality. We use these distance values in order to create clusters of nodes. We note that the numerical value associated with a given node may either be a distance value or a similarity value. Correspondingly, the objective function associated with the partitioning may either be minimized or maximized. We note that the problem of minimizing the intercluster similarity for a fixed number of clusters essentially reduces to the problem of *graph partitioning* or the *minimum multiway cut problem*. This is also referred to the problem of mining dense graphs and pseudocliques. Recently, the problem has also been studied in the database literature as that of *quasi-clique determination*. In this problem, we determine groups of nodes which are "almost cliques." In other words, an edge exists between any pair of nodes in the set with a high probability. A closely related problem is that of determining *shingles* (Gibson et al. 2005). Shingles are defined as those subgraphs which have a large number of common links. This is particularly useful for massive graphs which contain a large number of nodes. In such cases, a min-hash approach (Gibson et al. 2005) can be used in order to summarize the structural behavior of the underlying graph.

- *Graph clustering algorithms*: In this case, we have a (possibly large) number of graphs which need to be clustered based on their underlying structural behavior. This problem is challenging because of the need to match the structures of the underlying graphs and use these structures for clustering purposes. Such algorithms are discussed both in the context of classical graph data sets as well as semistructured data. In the case of semistructured data, the problem arises in the context of a large number of documents which need to be clustered on the basis of the underlying structure and attributes. It has been shown by Aggarwal et al. (2007) that the use of the underlying document structure leads to significantly more effective algorithms.

This chapter will discuss the different kinds of clustering algorithms and their applications. Each section will discuss a particular class of clustering algorithms and the different approaches which are commonly used for this class.

Graph Clustering as Minimum Cut

The graph clustering problem can be related to the minimum-cut and graph partitioning problems. In this case, it is assumed that the underlying graphs have weights on the edges. It is desired to partition the graphs in such a way so as to minimize the weights of the edges across the partitions. In general, we would like to partition the graphs into k groups of nodes. However, since the special case $k = 2$ is efficiently solvable, we would like to first provide a special discussion for this case. This version is polynomially solvable, since it is the mathematical dual of the maximum-flow problem. This problem is also referred to as the *minimum-cut problem*.

The minimum-cut problem is defined as follows. Consider a graph $G = (N, A)$ with node set N and edge set A. The node set N contains the source s and sink t. Each edge $(i, j) \in A$ has a weight associated with it which is denoted by u_{ij}. We note that the edges may be either undirected or directed, though the undirected case is often much more relevant for connectivity applications. We would like to partition the node set N into two groups S and $N - S$. The set of edges such that one end lies in S and the other lies in $N - S$ is denoted by $C(S, N - S)$. We would like to partition the node set N into two sets S and $N - S$, such that the sum of the weights in $C(S, N - S)$ is minimized. In other words, we would like to minimize $\sum_{(i,j)} \in C_{(S,N-S)} u_{ij}$. This is the unrestricted version of the minimum-cut problem. We will examine two variations of the minimum-cut problem:

- We wish to determine the global minimum $s - t$ cut with no restrictions on the membership of nodes to different partitions.
- We wish to determine the minimum $s - t$ cut, in which one partition contains the source node s and the other partition contains the sink node t.

It is easy to see that the former problem can be solved by using repeated applications of the latter algorithm. By fixing s and choosing different values of the sink t, it can be shown that the global minimum cut may be effectively determined.

It turns out that the maximum-flow problem is the mathematical dual of the minimum-cut problem. In the maximum-flow problem, we assume that the weight u_{ij} is a capacity of the edge (i, j). Each edge is allowed to have a *flow*x_{ij} which is at most equal to the capacity u_{ij}. Each node other than the source s and sink t is assumed to satisfy the *flow conservation property*. In other words, for each node $i \in N$ we have

$$\sum_{j:(i,j)\in A} x_{ij} = \sum_{j:(j,i)\in A} x_{ji}.$$

We would like to maximize the total flow originating from the source and reaching the sink t, subject to the above constraints. The maximum-flow problem is solved with the use of a variety of *augmenting path* and *preflow push algorithms*. Details of different kinds of algorithms may be found in the work by Ahuja et al. (1992).

A closely related problem to the minimum $s - t$ cut problem is that of determining a *global minimum cut* in an undirected graph. This particular case is more efficient than that of finding the $s - t$ minimum cut. One way of determining a minimum cut is by using a contraction-based edge-sampling approach. While the previous technique is applicable to both the directed and undirected versions of the problem, the contraction-based approach is applicable only to the undirected version of the problem. Furthermore, the contraction-based approach is applicable only for the case in which the weight of each edge is $u_{ij} = 1$. While the method can easily be extended to the weighted version by varying the edge-sampling probability, the polynomial running time bounds discussed by Tsay et al. (1999) do not apply to this case. The contraction approach is a probabilistic technique in which we successively sample the edges in order to collapse nodes into larger sets of nodes. By successively sampling different sequences of edges and picking the optimum value (Tsay et al. 1999), it is possible to determine a global minimum cut. The broad idea of the contraction-based approach is as follows. We pick an edge randomly in the graph and contract its two end points into a single node. We remove all the self-loops which are created as a result of the contraction. We may also create some parallel edges, which are allowed to remain, since they influence the sampling probability (Alternatively, we may replace parallel edges by a single edge of weight which is equal to the number of parallel edges. We use this weight in order to bias the sampling process.) of contractions. The process of contraction is repeated until we are left with two nodes. We note that each of this pair of "super-nodes" corresponds to a set of nodes in the original data. These two sets of nodes provide us with the final minimum cut. We note that the minimum cut will survive in this approach, if none of the edges in the minimum cut are sampled during the contraction. It has been shown by Tsay et al. that by using repeated contraction of the graph to a size of $\sqrt{n}$ nodes, it is possible to obtain a correct solution with high probability in $O(n^2)$ time.

Graph Clustering as Multiway Graph Partitioning

The *multiway graph partitioning problem* is significantly more difficult, and is NP-hard (Kernighan and Lin 1970). In this case, we wish to partition a graph into $k > 2$ components, so that the total weight of the edges whose ends lie in different partitions is minimized. A well-known technique for graph partitioning is the Kerninghan-Lin algorithm (Kernighan and Lin 1970). This classical algorithm is based on hill climbing (or more generally neighborhood-search technique) for determining the optimal graph partitioning. Initially, we start off with a random cut of the graph. In each iteration, we exchange a pair of vertices in two partitions to see if the overall cut value is reduced. In the event that the cut value is reduced, then the interchange is performed. Otherwise, we pick another pair of vertices in order to perform the interchange. This process is repeated until we converge to a optimal solution. We note that this optimum may not be a global optimum, but may only be a local optimum of the underlying data. The main variation in different versions of the Kerninghan-Lin algorithm is the policy which is used for performing the interchanges on the vertices. Some examples of strategies which may be used in order to perform the interchange are as follows:

- We randomly pick a pair of vertices and perform the interchange, if it improves the underlying solution quality.
- We test all possible vertex-pair interchanges (or a sample of possible interchanges), and pick the interchange which improves the solution by the greatest amount.
- A k-interchange is one in which a sequence of k interchanges are performed at one time. We can test any k-interchange and perform it, if it improves the underlying solution quality.
- We can pick the optimal k-interchange from a sample of possibilities.

We note that the use of more sophisticated strategies allows a better improvement in the objective function for each interchange, but also requires more time for each interchange. For example, the determination of an optimal k-interchange requires much more time than a straightforward interchange. This is a natural trade-off which may work out differently depending upon the nature of the application at hand. Furthermore, the choice of the policy also affects the likelihood of getting stuck at a local optimum. For example, the use of k-interchange techniques are far less likely to result in local optimum for larger values of k. In fact, by choosing the best interchange across all possible values of k it is possible to ensure that a global optimum is always reached. On the other hand, it is increasingly difficult to implement the algorithm efficiently with increasing value of k. This is because the time complexity of the interchange increases exponentially with the value of k.

Graph Clustering with k-Means

Two well-known (and related) techniques for clustering in the context of multidimensional data (Jain and Dubes 1998) are the k-medoid and k-means algorithms. In the k-medoid algorithm (for multidimensional data), we sample a small number of points from the original data as *seeds* and assign every other data point from the clusters to the closest of these seeds. The closeness may be defined based on a user-defined objective function. The objective function for the clustering is defined as the sum of the corresponding distances of data points to the corresponding seeds. In the next iteration, the algorithm interchanges one of the seeds for another randomly selected seed from the data, and checks if the quality of the objective function improves upon performing the interchange. If this is indeed the case, then the interchange is accepted. Otherwise, we do not accept the interchange and try another sample interchange. This process is repeated, until the objective function does not improve over a predefined number of interchanges. A closely related method is the k-means method. The main difference with the k-medoid method is that we do not use representative points from the original data after the first iteration of picking the original seeds. In subsequent iterations, we use the centroid of each cluster as the seed set for the next iteration. This process is repeated until the cluster membership stabilizes.

A method has been proposed by Rattigan et al. (2007), which uses the characteristics of both the k-means and k-medoids algorithms. As in the case of the conventional partitioning algorithms, it picks k graph nodes as seeds. The main differences from the conventional algorithms are in terms of computation of distances (for assignment purposes), and in determination of subsequent seeds. A natural distance function for graphs is the *geodesic distance*, or the smallest number of hops between a pair of nodes. In order to determine the seed set for the next iteration, we compute the *local closeness centrality* for each cluster, and use the corresponding node as the sample seed. Thus, while this algorithm continues to use seeds from the original data set (as in the k-medoids algorithm), it uses intuitive ideas from the k-means algorithms in order to determine the identity of these seeds.

Graph Clustering with the Spectral Method

Eigenvector techniques are often used in multidimensional data in order to determine the underlying correlation structure in the data. It is natural to question as to whether such techniques can also be used for the more general case of graph data. It turns out that this is indeed possible with the use of a method called *spectral clustering*.

In the spectral clustering method, we make use of the node-node adjacency matrix of the graph. For a graph containing n nodes, let us assume that we have an $n \times n$ adjacency matrix, in which the entry (i, j) correspond to the weight of the edge between the nodes i and j. This essentially corresponds to the similarity between nodes i and j. This entry is denoted by w_{ij}, and the corresponding matrix is denoted by W. This matrix is assumed to be symmetric, since we are working with undirected graphs. Therefore, we assume that $w_{ij} = w_{ji}$ for any pair (i, j). All diagonal entries of the matrix W are assumed to be 0. As discussed earlier, the aim of any node partitioning algorithm is to minimize (a function of) the weights across the partitions. The spectral clustering method constructs this minimization function in terms of the matrix structure of the adjacency matrix and another matrix which is referred to as the *degree matrix*.

The *degree matrix D* is simply a diagonal matrix in which all entries are zero except for the diagonal values. The diagonal entry d_{ii} is equal to the sum of the weights of the incident edges. In other words, the entry d_{ij} is defined as follows:

$$d_{ij} = \sum_{j=1}^{n} w_{ij}, \quad i = j,$$

$$0, \quad i \neq j.$$

We formally define the *Laplacian matrix* as follows: (*Laplacian matrix*): The Laplacian matrix L is defined by subtracting the weighted adjacency matrix from the degree matrix. In other words, we have

$$L = D - W.$$

This matrix encodes the structural behavior of the graph effectively and its eigenvector behavior can be used in order to determine the important clusters in the underlying graph structure. It can be shown that the Laplacian matrix L is positive semidefinite i.e., for any n-dimensional row vector $f = [f_1 \dots fn]$ we have $f \cdot L \cdot f^T \geq 0$. This can be easily shown by expressing L in terms of its constituent entries which are a function of the corresponding weights w_{ij}. Upon expansion, it can be shown that

$$f \cdot L \cdot f^{\mathrm{T}} = (1/2) \cdot \sum_{i=1}^{n} \sum_{j=1}^{n} w_{ij} \cdot (f_i - f_J)^2.$$

The Laplacian matrix L is positive semidefinite. Specifically, for any n-dimensional row vector $f = [f_1 \dots f_n]$, we have

$$f \cdot L \cdot f^T = (1/2) \cdot \sum_{i=1}^{n} \sum_{j=1}^{n} w_{ij} \cdot (f_i - f_J)^2.$$

At this point, let us examine some *interpretations* of the vector f in terms of the underlying graph partitioning. Let us consider the case in which each f_i is drawn from the set $\{0, 1\}$, and this determines a two-way partition by labeling each node either 0 or 1. The particular partition to which the node i belongs is defined by the corresponding label. Note that the expansion of the expression $f \cdot L \cdot f^T$ from the above relationship simply represents the sum of the weights of the edges across the partition defined by f. Thus, the determination of an appropriate value of f for which the function $f \cdot L \cdot f^T$ is minimized also provides us with a good node partitioning. Unfortunately, it is not easy to determine the *discrete values* of f which determine this optimum partitioning. Nevertheless, we will see later in this section that even when we restrict f to real values, this provides us with the intuition necessary to create an effective partitioning.

An immediate observation is that the indicator vector $f = [1 \dots 1]$ is an eigenvector with a corresponding eigenvalue of 0. We note that $f = [1 \dots 1]$ must be an eigenvector, since L is positive semidefinite and $f \cdot L \cdot f^T$ can be 0 only for eigenvectors with 0 eigenvalues. This observation can be generalized further in order to determine the number of connected components in the graph. We make the following observation.

The number of (*linearly independent*) *eigenvectors with zero eigenvalues for the Laplacian matrix L is equal to the number of connected components in the underlying graph.*

We observe that connected components are the most obvious examples of clusters in the graph. Therefore, the determination of eigenvectors corresponding to zero eigenvalues provides us the information about (relatively rudimentary set of) clusters. Broadly speaking, it may not be possible to glean such clean membership behavior from the other eigenvectors. One of the problems is that other than this particular rudimentary set of eigenvectors (which correspond to the connected components), the vector components of the other eigenvectors are drawn from the real domain rather than the discrete {0, 1} domain. Nevertheless, because of the nature of the natural interpretation of $f \cdot L \cdot f^T$ in terms of the weights of the edges across nodes with very differing values of f_i, it is natural to cluster together the nodes for which the values of f_i are as similar as possible across any particular eigenvector on an average. This provides us with the intuition necessary to define an effective spectral clustering algorithm, which partitions the data set into k clusters for any arbitrary value of k. The algorithm is as follows:

- Determine the k eigenvectors with the smallest eigenvalues. Note that each eigenvector has as many components as the number of nodes. Let the component of the jth eigenvector for the ith node be denoted by p_{ij}.
- Create a new data set with as many records as the number of nodes. The ith record in this data set corresponds to the ith node and has k components. The record for this node is simply the eigenvector components for that node, which are denoted by $pi_1 \ldots p_{ik}$.
- Since we would like to cluster nodes with similar eigenvector components, we use any conventional clustering algorithm (e.g., k-means) in order to create k clusters from this data set. Note that the main focus of the approach was to create a *transformation* of a structural clustering algorithm into a more conventional multidimensional clustering algorithm, which is easy to solve. The particular choice of the multidimensional clustering algorithm is orthogonal to the broad spectral approach.

The above algorithm provides a broad framework for the spectral clustering algorithm. The input parameter for the above algorithm is the number of clusters k. In practice, a number of variations are possible in order to tune the quality of the clusters which are found. More details on the different methods which can be used for effective spectral graph clustering may be found in Chung (1997).

Graph Clustering as Quasi-clique Detection

A different way of determining massive graphs in the underlying data is that of determining *quasi-cliques*. This technique is different from many other partitioning algorithms, in that it focuses on definitions which maximize the edge densities *within a partition*, rather than minimizing the edge densities across partitions. A clique is a graph in which every pair of nodes are connected by an edge. A quasi-clique is a relaxation on this concept, and is defined by imposing a lower bound on the degree of each vertex in the given set of nodes. Specifically, we define a γ-quasi-clique is as follows:

A k-graph ($k \geq 1$) G is a γ-quasi-clique if the degree of each node in the corresponding subgraph of vertices is at least $\gamma \cdot k$.

The value of γ always lies in the range (0, 1]. We note that by choosing $\gamma = 1$, this definition reverts to that of standard cliques. Choosing lower values of γ allows for the relaxations which are more true in the case of real applications. This is because we rarely encounter complete cliques in real applications, and at least some edges within a dense subgraph would always be missing. A vertex is said to be critical if its degree in the corresponding subgraph is the smallest integer which is at least equal to $\gamma \cdot k$.

The earliest piece of work on this problem is from Abello et al. (2002). The work of Abello et al. (2002) uses a greedy randomized adaptive search algorithm, GRASP, to find a quasi-clique with the maximum size. A closely related problem is that of finding *frequently occurring cliques* in *multiple data sets*. In other words, when multiple graphs are obtained from different data sets, some dense subgraphs occur frequently together in the different data sets. Such graphs help in determining *important dense patterns of behavior in different data sources*. Such techniques find applicability in mining important patterns in graphical representations of customers. The techniques are also helpful in mining cross-graph quasi-cliques in gene expression data. An efficient algorithm for determining cross graph quasi-cliques was proposed by Pei et al. (2005).

The main restriction of the work proposed by Pei et al. (2005) is that the support threshold for the algorithms is assumed to be 100 %. This restriction has been relaxed in subsequent work (Zeng et al. 2007). The work by Zeng et al. (2007) examines the problem of mining frequent, closed quasi-cliques from a graph database with arbitrary support thresholds.

Graph Clustering as Dense Subgraph Determination

A closely related problem is that of dense subgraph determination in massive graphs. This problem is frequently encountered in large graph data sets. For example, the problem of determining large subgraphs of web graphs was studied by Gibson et al. (2005). The broad idea in the min-hash approach is to represent the outlinks of a particular node as sets. Two nodes are considered similar if they share many outlinks. Thus, consider a node A with an outlink set S_A, and a node B with outlink set S_B. Then the similarity between the two nodes is defined by the *Jaccard coefficient*, which is defined as $\frac{S_A \cap S_B}{S_A \cup S_B}$. We note that explicit enumeration of all the edges in order to compute this can be computationally inefficient. Rather, a *min-hash approach* is used in order to perform the estimation. This *min-hash approach* is as follows. We sort the universe of nodes in a random order. For any set of nodes in random sorted order, we determine the first node $First(A)$ for which an outlink exists from A to $First(A)$. We also determine the first node $First(B)$ for which an outlink exists from B to $First(B)$. It can be shown that the Jaccard coefficient is an unbiased estimate of the probability that $First(A)$ and $First(B)$ are the same nodes. By repeating this process over different permutations over the universe of nodes, it is possible to accurately estimate the Jaccard coefficient. This is done by using a constant number of permutations c of the node order. The actual permutations are implemented by associated c different randomized hash values with each node. This creates c sets of hash values of size n. The sort-order for any particular set of hash-values defines the corresponding permutation order. For each such permutation, we store the minimum node index of the outlink set. Thus, for each node, there are c such minimum indices. This means that, for each node, a fingerprint of size c can be constructed. By comparing the fingerprints of two nodes, the Jaccard coefficient can be estimated. This approach can be further generalized with the use of every s element set contained entirely with S_A and S_B. Thus, the above description is the special case when s is set to 1. By using different values of s and c, it is possible to design an algorithm which distinguishes between two sets that are above or below a certain threshold of similarity.

The overall technique by Gibson et al. (2005) first generates a set of c shingles of size s for each node. The process of generating the c shingles is extremely straightforward. Each node is processed independently. We use the min-wise hash function approach in order to generate subsets of size s from the outlinks at each node. This results in c subsets for each node. Thus, for each node, we have a set of c shingles. Thus, if the graph contains a total of n nodes, the total size of this shingle fingerprint is $n \times c \times sp$, where sp is the space required for each shingle. Typically, sp will be $O(s)$, since each shingle contains s nodes. For each distinct shingle thus created, we can create a list of nodes which contain it. In general, we would like to determine groups of shingles which contain a large number of common nodes. In order to do so, the method by Gibson et al. performs a second-order shingling in which the meta-shingles are created from the shingles. Thus, this further compresses the graph in a data structure of size $c \times c$. This is essentially a constant-size data structure. We note that this group of meta-shingles have the property that they contain a large number of common nodes. The dense subgraphs can then be extracted from these meta-shingles. More details on this approach may be found in the work by Gibson et al.

Clustering Graphs as Objects

In this section, we will discuss the problem of clustering *entire graphs* in a *multigraph database*, rather than examining the node clustering problem within a single graph. Such situations are often encountered in the context of XML data, since each XML document can be regarded as a structural record, and it may be necessary to create clusters from a large number of such objects. We note that XML data is quite similar to graph data in terms of how the data is organized structurally. The attribute values can be treated as graph labels and the corresponding semistructural relationships as the edges. In has been shown by Aggarwal et al. (2007), Dalamagas et al. (2005), Lee et al. (2002), and Lian et al. (2004) that this structural behavior can be leveraged in order to create effective clusters.

Since we are examining entire graphs in this version of the clustering problem, the problem simply boils down to that of clustering arbitrary *objects*, where the objects in this case have structural characteristics. Many of the conventional algorithms discussed by Jain and Dubes (1998) (such as k-means type partitional algorithms and hierarchical algorithms) can be extended to the case of graph data. The main changes required in order to extend these algorithms are as follows:

- Most of the underlying classical algorithms typically use some form of distance function in order to measure similarity. Therefore, we need appropriate measures in order to define similarity (or distances) between structural objects.
- Many of the classical algorithms (such as k-means) use *representative objects* such as centroids in critical intermediate steps. While this is straightforward in the case of multidimensional objects, it is much more challenging in the case of graph objects. Therefore, appropriate methods need to be designed in order to create representative objects. Furthermore, in some cases it may be difficult to create representatives in terms of single objects. We will see that it is often more robust to use *representative summaries* of the underlying objects.

There are two main classes of conventional techniques, which have been extended to the case of structural objects. These techniques are as follows:

- *Structural distance-based approach*: This approach computes structural distances between documents and uses them in order to compute clusters of documents. One of the earliest work on clustering tree structured data is the *XClust algorithm* (Lee et al. 2002), which was designed to cluster XML schemas in order for efficient integration of large numbers of document type definitions (DTDs) of XML sources. It adopts the agglomerative hierarchical clustering method which starts with clusters of single DTDs and gradually merges the two most similar clusters into one larger cluster. The similarity between two DTDs is based on their element similarity, which can be computed according to the semantics, structure, and context information of the elements in the corresponding DTDs. One of the shortcomings of the XClust algorithm is that it does not make full use of the structure information of the DTDs, which is quite important in the context of clustering tree-like structures. The method by Chawathe (1999) computes similarity measures based on the structural edit-distance between documents. This edit-distance is used in order to compute the distances between clusters of documents.

  S-GRACE is hierarchical clustering algorithm (Lian et al. 2004). In the work by Lian et al., an XML document is converted to a structure graph (or s-graph), and the distance between two XML documents is defined according to the number of the common element-subelement relationships, which can capture better structural similarity relationships than the tree edit-distance in some cases (Lian et al.).

- *Structural summary-based approach*: In many cases, it is possible to create summaries from the underlying documents. These summaries are used for creating groups of documents which are similar to these summaries. The first summary-based approach for clustering XML documents was presented by Dalamagas et al. (2005). In the work by Dalamagas et al., the XML documents are modeled as rooted, ordered labeled trees. A framework for clustering XML documents by using structural summaries of trees is presented. The aim is to improve algorithmic efficiency without compromising cluster quality.

  A second approach for clustering XML documents is presented by Aggarwal et al. (2007). This technique is a partition-based algorithm. The primary idea in this approach is to use frequent-pattern mining algorithms in order to determine the summaries of frequent structures in the data. The technique uses a k-means type approach in which each cluster center comprises a set of frequent patterns which are local to the partition for that cluster. The frequent patterns are mined using the documents assigned to a cluster center in the last iteration. The documents are then further reassigned to a cluster center based on the average similarity between the document and the newly created cluster centers from the local frequent patterns. In each iteration the document assignment and the mined frequent patterns are iteratively reassigned until the cluster centers and document partitions converge to a final state. It has been shown by Aggarwal et al. that such a structural summary-based approach is significantly superior to a similarity function-based approach, as presented by Chawathe (1999). The method is also superior to the structural approach by Dalamagas et al. (2005) because of its use of more robust representations of the underlying structural summaries.

Conclusions and Future Research

In this chapter, we presented a review of the commonly known algorithms for clustering graph data. The problem of clustering graphs has been widely studied in the literature, because of its application to a variety of data mining and data management problems. Graph clustering algorithms are of two types:

- *Node clustering algorithms*: In this case, we attempt to partition the graph into groups of clusters so that each cluster contains groups of nodes which are densely connected. These densely connected groups of nodes may often provide significant information about how the entities in the underlying graph are interconnected with one another.
- *Graph clustering algorithms*: In this case, we have complete graphs available, and we wish to determine the clusters with the use of the structural information in the underlying graphs. Such cases are often encountered in the case of XML data, which are commonly encountered in many real domains.

We provided an overview of the different clustering algorithms available and the trade-offs with the use of different methods. The major challenges that remain in the area of graph clustering are as follows:

- *Clustering massive data sets*: In some cases, the data sets containing the graphs may be so large that they may be held only on disk. For example, if we have a dense graph containing 10^7 nodes, then the number of edges may be as high as 10^{13}. In such cases, it may not even be possible to store the graph effectively on disk. In the cases in which the graph can be stored on disk, it is critical that the algorithm should be designed in order to take the disk-resident behavior of the underlying data into account. This is especially challenging in the case of graph data sets, because the structural behavior of the graph interferes with our ability to process the edges sequentially for many applications. In the cases in which the graph is too large to store on disk, it is essential to design summary structures which can effectively store the underlying structural behavior of the graph. This stored summary can then be used effectively for graph clustering algorithms.

- *Clustering graph streams*: In this case, we have large graphs which are received as edge streams. Such graphs are more challenging, since a given edge cannot be processed more than once during the computation process. In such cases, summary structures need to be designed in order to facilitate an effective clustering process. These summary structures may be utilized in order to determine effective clusters in the underlying data. This approach is similar to the case discussed above in which the size of the graph is too large to store on disk.

In addition, techniques need to be designed for interfacing clustering algorithms with traditional database management techniques. In order to achieve this goal, effective representations and query languages need to be designed for graph data. This is a new and emerging area of research, and can be leveraged upon in order to further improve the effectiveness of graph algorithms.

Graph Kernels

Thomas Gärtner, Tamás Horváth, and
Stefan Wrobel
Fraunhofer IAIS, Schloss Birlinghoven,
University of Bonn, Sankt Augustin, Germany

Definition

The term *graph kernel* is used in two related but distinct contexts: On the one hand, graph kernels can be defined between graphs, that is, as a *kernel function* $k : \mathcal{G} \times \mathcal{G} \to \mathbb{R}$ where $\mathcal{G}$ denotes the set of all graphs un-der consideration. In the most common setting $\mathcal{G}$ is the set of all labeled undirected graphs. On the other hand, graph kernels can be defined between the vertices of a single graph, that is, as a kernel function $k : V \times V \to \mathbb{R}$ where V is the vertex set of the graph G under consideration. In the most common setting G is an undirected graph.

Motivation and Background

▶ Kernel methods are a class of machine learning algorithms that can be applied to any data set on which a valid, that is, positive definite, kernel function has been defined. Many kernel methods are theoretically well founded in statistical learning theory and have shown good predictive performance on many real–world learning problems.

Approaches for Kernels Between Graphs

One desireable property of kernels between graphs is that for non-isomorphic graphs $G, G' \in \mathcal{G}$ the functions $k(G, \cdot)$ and $k(G', \cdot)$ are not equivalent. If this property does not hold, the distance is only a pseudometric rather than a metric, that is, non-isomorphic graphs can be mapped to the same point in feature space and no kernel method can ever distinguish between the two graphs. However, it can be seen that computing graph kernels for which the property does hold is at least as hard as solving graph isomorphism (Gärtner et al. 2003).

For various classes of graphs, special purpose kernels have been defined such as for paths (▶ string kernels) and trees (Collins and Duffy 2002). These kernels are typically defined as the number of patterns that two objects have in common or as the inner product in a feature space counting the number of times a particular pattern occurs. The problem of computing a graph kernel where the patterns are all connected graphs, all cycles, or all paths and occurrence is determined by subgraph-isomorphism is, however, NP-hard (Gärtner et al. 2003).

Techniques that have been used to cope with the computational intractability of such graph kernels are (1) to restrict the considered patterns, for example, to bound the pattern size by a constant; (2) to restrict the class of graphs considered, for example, to trees or small graphs; (3) to define occurrence of a pattern differently, that is, not by subgraph-isomorphism; and (4) to approximate the graph kernel. Note that these four techniques can be combined.

While for technique (1) it is not immediately clear if the resulting graph kernel is feasible, technique (2) allows for fixed parameter tractable graph kernels. (Notice that even counting paths or cycles of length k in a graph is #W[1]-complete while the corresponding decision problem is fixed parameter tractable.) Though these will often still have prohibitive runtime requirements, it has been observed that enumerating cycles in real-world databases of small molecules is feasible (Horvath et al. 2004).

With respect to technique (3) it has been proposed to use graph kernels where the patterns are paths but the occurrences are determined by homomorphism (Gärtner et al. 2003; Kashima et al. 2003). Despite the explosion in the number of pattern occurrences (even very simple graphs can contain an infinite number of walks, that is, images of paths under homomorphism), if one downweights the influence of larger patterns appropriately, the kernel takes a finite value and closed form polynomial time computations exist. To increase the practical applicability of these graph kernels, it has been proposed to increase the number of labels by taking neighborhoods into account (Gärtner 2005) or to avoid "tottering" walks (Mahé et al. 2004).

Various approaches to approximate computation of graph kernels (4) exist. On the one hand, work on computing graph kernels based on restricting the patterns to frequent subgraphs (Deshpande et al. 2002) can be seen as approximations to the intractable all-subgraphs kernel. Computing such graph kernels is still NP-hard and no approximation guarantees are known. On the other hand, a recent graph kernel (Borgwardt et al. 2007) based on sampling small subgraphs of a graph at random is known to have a polynomial time algorithm with approximation guarantees.

The most common application scenario for such graph kernels is the prediction pharmaceutical activity of small molecules.

Approaches for Kernels on a Graph

Learning on the vertices of a graph is inherently *transductive*. Work on kernels between the vertices of a graph began with the "diffusion kernel" (Kondor and Lafferty 2002) and was later generalized in Smola and Kondor (2003) to a framework that contains the diffusion kernel as a special case. Intuitively, these kernels can be understood as comparing the neighborhoods of two vertices in the sense that the more neighbors two vertices have in common, the more similar they are. For classification, this definition is related to making the "cluster assumption", that is, assuming that the decision boundary between classes does not cross "high density" regions of the input space. To compute such graph kernels for increasing sizes of the neighborhood, one needs to compute the limit of a matrix poser series of the (normalized) graph Laplacian or its adjacency matrix. Different graph kernels arise from choosing different coefficients. In general, the limit of such matrix power series can be computed on the eigenvalues. For geometrically decaying parameters, the kernel matrix can also be computed by inverting a sparse matrix obtained by adding a small value to the diagonal of the Laplacian (in which case the kernel is called the "regularized Laplacian kernel") or the adjacency matrix.

In the case of the regularized Laplacian kernel, rather than first computing the kernel matrix and then applying an off-the-shelf implementation of a kernel method, it is often more effective to reformulate the optimization problem of the kernel method. Several possibilities for such reformulation have been proposed, including changing the variables as in Gärtner et al. (2006).

The most common application scenario for such graph kernels is the classification of entities in a social network.

Graph Mining

Deepayan Chakrabarti
Yahoo! Research, Sunnyvale, CA, USA

Definition

Graph Mining is the set of tools and techniques used to (a) analyze the properties of real-world graphs, (b) predict how the structure and properties of a given graph might affect some application, and (c) develop models that can generate realistic graphs that match the patterns found in real-world graphs of interest.

Motivation and Background

A graph $G = (V, E)$ consists of a set of edges, E connec-ting pairs of nodes from the set V; extensions allow for weights and labels on both nodes and edges. Graphs edges can be used to point *from* one node *to* another, in which case the graph is called directed; in an *undirected* graph, edges must point both ways: $i \rightarrow j \Leftrightarrow j \rightarrow i$. A variant is the bipartite graph $G = (V_1, V_2, E)$ where only edges linking nodes in V_1 to nodes in V_2 are allowed.

A graph provides a representation of the binary relationships between individual entities, and thus is an extremely common data structure. Examples include the graph of hyperlinks linking HTML documents on the Web, the social network graph of friendships between people, the bipartite graphs connecting users to the movies they like, and so on. As such, mining the graph can yield useful patterns (e.g., the communities in a social network) or help in applications (e.g., recommend new movies to a user based on movies liked by other "similar" users). Graph mining can also yield patterns that are common in many real-world graphs, which can then be used to design graph "generators" (e.g., a generator that simulates the Internet topology, for use in testing next-generation Internet protocols).

Structure of Learning System

We split up this discussion into three parts: the analysis of real-world graphs, realistic graph generators, and applications on graphs. Detailed surveys can be found in Newman (2003) and Chakrabarti and Faloutsos (2006).

Analysis of Real-World Graphs

Four basic types of large-scale patterns have been detected in real-world graphs. The first is the existence of power-laws, for instance in the degree distribution and eigenvalue distribution. Most nodes have very low degree while a few have huge degree. This has implications for algorithms whose running times are bounded by the highest degree. The second set of patterns is called the "small-world phenomenon," which state that the diameter (or effective diameter) of such graphs are very small with respect to their size. Recall that the diameter of a connected graph is the maximum number of hops needed to travel between any pair of nodes; the effective diameter is a more robust version that specifies the number of hops within which a large fraction (say, 90 %) of all pairs can reach each other. Examples include a diameter of around 4 for the Internet Autonomous System graph, around 19 for the entire US power grid, around 4 for the graph of actors who worked together in movies, and so on. Third, many large graphs exhibit "community effects," where each community consists of a set of nodes that are more tightly connected to other nodes in the community compared to nodes outside. One local manifestation of this effect is the relatively high *clustering coefficient* which counts, given all pairs of edges (i, j) and (j, k), the probability of the existence of the "transitive" edge (i, k). High clustering coefficients imply tight connections in neighborhoods, which is the basis of strong community structure. Finally, many large graphs were shown to increase in density as they evolve over time, that is, the number of edges grows according to a power-law on the number of nodes. In addition, even while more nodes and edges are being added, the diameter of the graph tends to decrease.

Graph Generators

Imagine designing an application that works on the Internet graph. Collecting the entire Internet graph in one place is hard, making the testing process for such an application infeasible. In such cases, a realistic graph generator can be used to simulate a large "Internet-like" graph, which can be used in place of the real graph. This synthetic graph must match the patterns typically found in the Internet, including the patterns discussed in the previous paragraph. Apart from generating such graphs, the generators can provide insights into the *process* by which large graphs came to attain their structure.

One example of this is the *preferential attachment* model. Starting with a small initial graph, this model adds one new node every step. The new node is connected to m previous nodes, with the probability of connecting to node i being proportional to its degree. This idea, popularly known as “the rich get richer,” can be shown to lead to a power-law degree distribution after a large number of nodes and edges have been added.

Many other models have also been proposed, which demonstrate graph generation as a random process, an optimization process, as a process on nodes embedded in some geographic space, and so on.

Applications

Some graph mining algorithms are meant to solve some application on any graph(s) provided as input to the algorithm. Several basic tools are commonly used in such applications, such as the ▸ Greedy Search Approach to Graph Mining the ▸ Inductive Database Search Approach to Graph Mining spectral methods, graph partitioning methods, and models based on random walks on graphs. *Tree Mining* is a special case of graph mining where the graphs are constrained to be trees. We will discuss a few such applications here.

Frequent subgraph mining: The aim is to find subgraphs that occur very frequently in the particular graph(s) in question (Kuramochi and Karypis 2001). This is quite useful in chemical datasets consisting of the graph structures of many different molecules (say, all protein molecules that have a certain chemical property); the frequent subgraphs in such molecules might represent basic structural units responsible for giving the molecules their special property. Unfortunately, the frequent subgraph problem subsumes the problem of subgraph isomorphism, and hence is NP-Hard. However, clever techniques have been devised to represent subgraphs so that checking for isomorphism can be done quickly in many cases.

Community detection: The problem is to detect tightly knit groups of nodes, where all nodes in the group have “similar” linkage structure. There are many algorithms, each optimizing for a different notion of similarity. Examples include graph partitioning methods such as spectral partitioning (Ng et al. 2002) and METIS that try to minimize the number of edges linking nodes across partitions, and co-clustering methods that aim for homogeneity in links across partitions.

Information diffusion and virus propagation: The spread of a contagious disease or a computer virus can be modeled (somewhat crudely) as a contact process on a graph, where the nodes are individuals who can get infected, and the links allow transmission of the contagion from an infected individual to an uninfected one. Similar models have been proposed to model the diffusion of information in social networks. The topology of the graph can be used to infer the most “influential” nodes in the graph, who are most capable of spreading the information quickly throughout the graph (Kempe et al. 2003).

Graph kernels: While subgraph isomorphism is a hard problem, we still need to be able to compare graphs on the basis of some similarity measure that can be computed in polynomial time. In the Kernel-Based Approach to Graph Mining graph kernels perform this task by computing similarities based on numbers of walks, paths, cyclic patterns, trees, etc.

Ranking on graphs: Given a graph (say, the Web hyperlink graph), we often need a ranking of the nodes in the graph. The ranking could be static (as in Page-Rank Brin and Page 1998) or it could depend on a user-specified query node. Such algorithms typically use some version of random walks on graphs (Lovász 1993), with the probability of the walk hitting a node being correlated with the importance of the node; such importances in turn yield a ranking of the nodes. Both static and query-dependent rankings can be useful in information retrieval settings, where a user desires information pertinent (i.e., “similar”) to her query.

Definition

Graphical models are a means of compactly representing multivariate distributions, allowing for efficient algorithms to be developed when dealing with high-dimensional data. At their core, graphical models make use of the fact that high-dimensional distributions tend to factorize around local interactions, meaning that they can be expressed as a product of low-dimensional terms.

The notation we shall use is defined in Table 1, and some core definitions are presented in Table 2.

A few examples of the types of data that can be efficiently represented using graphical models are shown in Fig. 1. Here we have high-dimensional distributions (e.g., the probability of observing the pixels of a particular image), which we model in terms of low-dimensional interactions. In each of the examples presented in Fig. 1, we are simply asserting that

$$\underbrace{p(x_A, x_B | x_C)}_{\text{function of three variables}} = \underbrace{p(x_A | x_C)\, p(x_B | x_C)}_{\text{functions of two variables}}, \quad (1)$$

which arises by a straightforward application of the product rule (Definition 1), along with the fact that X_A and X_B are *conditionally independent*, given X_C (Definition 3). The key observation we make is that while the left-hand side of (Eq. 1) is a function of three variables, its conditional independence properties allow it to be *factored* into functions of two variables (note that the name "graphical models" arises due to the fact that such interdependencies can be represented as a graph encoding the relationships between variables).

In general, we shall have a series of conditional independence statements about X:

$$\left\{ X_{A_i} \perp X_{B_i} \;\middle|\; X_{C_i} \right\}. \quad (2)$$

It is precisely these statements that define the "structure" of our multivariate distribution, which we shall express in the form of a graphical model.

Motivation and Background

Graphical models are ubiquitous as a means to model multivariate data, since they allow us to represent high-dimensional distributions *compactly*; they do so by exploiting the *interdependencies* that typically exist in such

Graphical Models, Table 1 Notation

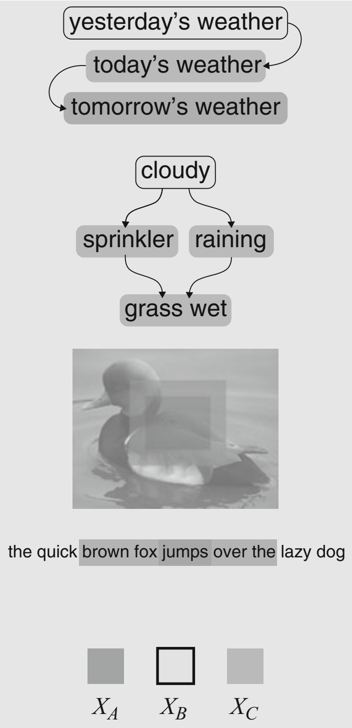
Notation	Description
$X = (X_1 \dots X_N)$	A random variable (we shall also use $X = (A, B, C \dots)$ in figures to improve readability)
$x = (x_1 \dots x_N)$	A *realization* of the random variable X
$\mathcal{X}$	The sample space (domain) of X
X_A	X can be indexed by a *set*, where we assume $A \subseteq \{1 \dots N\}$
$p(x)$	The probability that $X = x$
$\tilde{A}$	The *negation* of A, i.e., $\{1 \dots N\} \setminus A$
$X_A \perp X_B$	X_A and X_B are *independent*
$X_A \perp X_B \mid X_C$	X_A and X_B are *conditionally independent*, given X_C

Graphical Models, Table 2 Definitions

Definition 1 (product rule) $p(x_A, x_B) = p(x_A | x_B) p(x_B)$

Definition 2 (marginalization) $p(x_A) = \sum_{x_{\tilde{A}} \in \mathcal{X}_{\tilde{A}}} p(x_A, x_{\tilde{A}})$

Definition 3 (conditional independence) X_A and X_B are said to be conditionally independent (given X_C) iff $p(x_a | x_b, x_c) = p(x_a | x_c)$, for all x_a, x_b, and x_c; the conventional definition of "independence" is obtained by setting $X_C = \varnothing$



Graphical Models, Fig. 1 Some examples of conditional independence; we say that X_A and X_B are *conditionally independent*, given X_C, or more compactly $X_A \perp X_B \mid X_C$

data. Put simply, we can take advantage of the fact that high-dimensional distributions can often be decomposed into *low-dimensional factors* to develop efficient algorithms by making use of the distributive law: $ab + ac = a(b + c)$.

Some motivating examples are presented in Fig. 1; similar examples are ubiquitous in fields ranging from computer vision and pattern recognition to economics and the social sciences. Although we are dealing with high-dimensional data, we can make certain statements about the *structure* of the variables involved, allowing us to express important properties about the distribution compactly. Some of the properties we would like to compute include the probabilities of particular outcomes and the outcomes with the highest probability.

Theory

Directed Graphical Models

Due to the product rule (Definition 1), it is clear that *any* probability distribution can be written as

$$p(x) = \prod_{i=1}^{N} p(x_{\pi_i} | x_{<\pi_i}) \qquad (3)$$

for an arbitrary permutation π of the labels, where we define $<i := \{1 \dots i - 1\}$. For example any four-dimensional distribution can be written

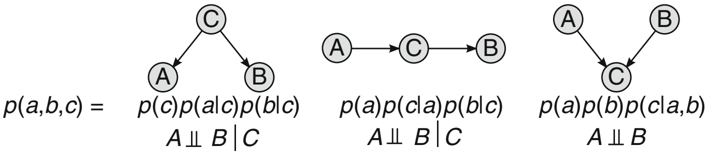
Graphical Models, Fig. 2 A directed model (*left*) and an undirected model (*right*). The joint distributions they represent are shown



Graphical Models, Fig. 3 Some simple Bayesian Networks and their implied independence statements. Note in particular that in the rightmost example, we *do not* have $A \perp B \mid C$

as

$$p(x_a, x_b, x_c, x_d) = p(x_c)p(x_b|x_c)p(x_d|x_c, x_b) \\ p(x_a|x_c, x_b, x_d). \qquad (4)$$

With this idea in mind, consider a model $p(x)$ for which we have the conditional independence statements:

$$\left\{p(x_{\pi_i}|x_{<\pi_i}) = p(x_{\pi_i}|x_{pa_{\pi_i}})\right\}, \qquad (5)$$

where $pa_{\pi_i} \subset <\pi_i$. We now have

$$p(x) = \prod_{i=1}^{N} p(x_{\pi_i}|x_{pa_{\pi_i}}). \qquad (6)$$

We can interpret pa_i as referring to the "parents" of the node i. Essentially, we are saying that a variable is conditionally independent on its nondescendants, given its parents.

We can represent (Eq. 6) using a directed acyclic graph (DAG) by representing each variable X_i as a node; an arrow is formed from X_j to X_i if $j \in pa_i$. An example of such a representation is given in Fig. 2. It can easily be shown that the resulting graph is always acyclic.

A *Bayesian Network* (a type of *directed* graphical model) is simply a set of probability distributions of the form $p(x) = \prod_{i=1}^{N} p(x_i|x_{pa_i})$. Every Bayesian Network can be represented as a DAG, though we often simply say that the Bayesian Network "is" the DAG. Some trivial examples and the type of independence statements they imply are shown in Fig. 3.

We finish this section with a simple lemma:

Lemma 1 (Topological Sort) *Every DAG has at least one permutation π that "sorts" the nodes such that each node has a larger index than its parents; in other words, the factorization associated to any DAG can be written in the form of (Eq. 6) for at least one π such that $\pi_i > j$ for all i, where $j \in pa_{\pi_i}$.*

Undirected Graphical Models

Although we have shown how conditional independence statements in the form of (Eq. 5) can be modeled using a DAG, there exist certain conditional independence statements that are not satisfied by *any* Bayesian Network, such as those in Fig. 4.

Markov random fields (or MRFs) allow for the specification of a different class of conditional independence statements, which are naturally represented by *undirected graphs* (UGs for short). The results associated with MRFs require a few additional definitions:

Definition 4 (Clique) A set of nodes X in a graph $\mathcal{G} = (V, E)$ is said to form a clique if $(X_i, X_j) \in E$ for every $X_i, X_j \in X$ (i.e., the subgraph X is fully connected).

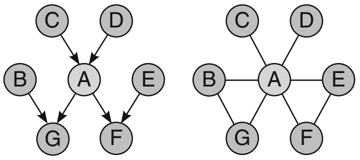
$A \perp\!\!\!\perp B$

Graphical Models, Fig. 4 There is no Bayesian Network that captures precisely the conditional independence properties of the Markov random field at *left*; there is no Markov random field that captures precisely the conditional independence properties of the Bayesian Network at *right*



Graphical Models, Fig. 5 The Markov blanket of the node A consists of its parents, its children, and the parents of its children (*left*). The corresponding structure for *undirected* models simply consists of the neighbors of A. Note that if we convert the directed model to an undirected one (using the procedure described in section "Conversion from Directed to Undirected Graphical Models"), then the Markov blankets of the two graphs are identical

Definition 5 (Maximal Clique) A clique X is said to be maximal if there is no clique Y such that $X \subset Y$.

A Markov random field is a probability distribution of the form $p(x) = \frac{1}{Z}\prod_{c \in \mathcal{C}} \psi_c(x_c)$, where $\mathcal{C}$ is the set of maximal cliques of $\mathcal{G}$, ψ_c is an arbitrary nonnegative real-valued function, and Z is simply a normalization constant ensuring that $\sum_x p(x) = 1$.

Conversion from Directed to Undirected Graphical Models

It is possible to convert a directed graphical model to an undirected graphical model via the following simple procedure:

- For every node X_i with parents pa_{X_i}, add undirected edges between every $X_j, X_k \in pa_{X_i}$.
- Replace all directed edges with undirected edges.

In other words, we are replacing statements of the form $p(x_A|x_B)$ with $\psi(x_A, x_B)$, so that the nodes $\{X_i\} \cup pa_{X_i}$ now form a clique in the undirected model. This procedure of "marrying the parents" is referred to as *moralization*. Naturally, the undirected model formed by this procedure does not precisely capture the conditional independence relationships in the directed version. For example, if it is applied to the graph in Fig. 4 (*right*), then the nodes A, B, and C form a clique in the resulting model, which does not capture the fact that $A \perp B$. However, we note that every term of the form $p(x_i|x_{pa_i})$ appears in some clique of the undirected model, meaning that it can include all of the factors implied by the Bayesian Network.

Characterization of Directed and Undirected Graphical Models

We can now present some theorems that characterize both Bayesian Networks and Markov random fields:

Lemma 2 (Local Markov Property) *A node in a DAG is conditionally independent of its non-descendants, given its parents (this is referred to as the "directed" local Markov property); a node in a UG is conditionally independent of its non-neighbors, given its neighbors.*

Definition 6 (Markov Blanket) Given a node A, its "Markov blanket" is the minimal set of nodes C such that $A \perp B \mid C$ for all other nodes B in the model (in other words, the minimal set of nodes that we must know to "predict" the behavior of A).

Lemma 3 (Markov Blankets of Directed and Undirected Graphs) *In a directed network, the Markov blanket of a node A (denoted $MB(A)$) consists of its parents, its children, and its children's (other) parents. In an undirected network, it simply consists of the node's neighbors (see Fig. 5).*

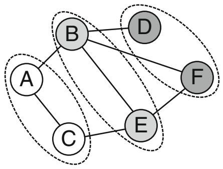
Definition 7 (d-separation) The notion of a Markov blanket can be generalized to the notion of "d-separation." A set of nodes A is said to be d-separated from a set B by a set C if every (undirected) path between A and B is "blocked" when C is in the conditioning set (i.e., when C is observed). A path is said to be blocked if **either** it contains (p_1, p_2, p_3) with $p_1 \rightarrow p_2 \leftarrow p_3$ (where arrows indicate edge directions) and neither p_2 nor any of its descendants are observed, **or** it contains (p_1, p_2, p_3) with $p_1 \rightarrow p_2 \rightarrow p_3$ and p_2 is observed, **or** it contains (p_1, p_2, p_3) with $p_1 \leftarrow p_2 \rightarrow p_3$ and p_2 is observed.

Applying (Definition 7) to the directed graphs in Fig. 1, we would say that the aqua regions (X_C) *d-separate* the red regions (X_A) from the white regions (X_B); *all conditional independence statements can simply be interpreted as d-separation in a DAG.*

The analogous notion of *graph separation* for Markov random fields is simpler than that of d-separation for Bayesian Networks. Given an undirected graph $\mathcal{G}$ and disjoint subsets of nodes A, B, C, if A is only reachable from B via C, this means that A is *separated* from B by C and these semantics encode the probabilistic fact that $A \perp B \mid C$. This is illustrated in Fig. 6.

In both the directed and undirected case, a Markov blanket of a node is simply the minimal set of nodes that d-separates/graph separates that node from all others.

A complete characterization of the class of probability distributions represented by Bayesian Networks can be obtained naturally once conditional independence statements are mapped to d-separation statements in a DAG. The following theorem settles this characterization.



Graphical Models, Fig. 6 The nodes $\{B, E\}$ form a *clique*; the nodes $\{B, E, F\}$ form a *maximal clique*. The nodes $\{B, E\}$ *separate* the nodes $\{A, C\}$ from $\{D, F\}$

Theorem 1 *Let p be a probability distribution that satisfies the conditional independence statements implied by d-separation in a DAG. Then p factors according to (Eq. 6). The converse also holds.*

For Markov random fields, an analogous characterization exists:

Theorem 2 (Hammersley-Clifford) *If a strictly positive probability distribution p satisfies the conditional independence statements implied by graph separation in an undirected graph $\mathcal{G}$, then*

$$p(x) = \frac{1}{Z} \prod_{c \in \mathcal{C}} \psi_c(x_c). \tag{7}$$

The converse also holds, albeit in a more general sense in that p need not be strictly positive.

It can be shown that

directed local Markov property		*local Markov property*
⇕		⇕
d-separation in a DAG	and (for positive p) that	*graph separation in a UG*
⇕		⇕
factorization of p by (Eq. 6)		*factorization of p by* (Eq. 7)

Knowing that directed models can be converted to undirected models, we shall consider inference algorithms in undirected models only.

Applications

Inference Algorithms in Graphical Models

The key observation that we shall rely on in order to do inference efficiently is the *distributive law*:

$$\underbrace{ab + ac}_{\text{three operations}} = \underbrace{a(b + c)}_{\text{two operations}}. \tag{8}$$

By exploiting the factorization in a graphical model, we can use this law to perform certain queries efficiently (such as computing the marginal with respect to a certain variable).

As an example, suppose we wish to compute the marginal $p(x_1)$ in an MRF with the following factorization:

$$p(x) = \frac{1}{Z} \prod_{i=1}^{N-1} \psi(x_i, x_{i+1}). \tag{9}$$

Note that the graph representing this model is simply a *chain*. Computing the sum in the naïve way requires computing

$$p(x_1) = \frac{1}{Z} \sum_{x_{\{2 \dots N\}}} \prod_{i=1}^{N-1} \psi(x_i, x_{i+1}), \tag{10}$$

whose complexity is $\Theta(\prod_{i=1}^{N} |\mathcal{X}_i|)$. However, due to the distributive law, the same result is simply

$$\begin{aligned} p(x_1) = \frac{1}{Z} \sum_{x_2} \Big[\psi(x_1, x_2) \sum_{x_3} \Big[\psi(x_2, x_3) \cdots \\ \sum_{x_{N-1}} \Big[\psi(x_{N-2}, x_{N-1}) \\ \sum_{x_N} \psi(x_{N-1}, x_N) \Big]\Big]\Big], \end{aligned} \tag{11}$$

whose complexity is $\Theta(\sum_{i=1}^{N-1} |\mathcal{X}_i||\mathcal{X}_{i+1}|)$. As a more involved example, consider computing the marginal with respect to A in the undirected model in Fig. 2; here we wish to compute

$$p(a) = \frac{1}{Z} \sum_{b,c,d,e,f} \psi(a,b)\psi(a,c)\psi(b,d) \psi(c,e)\psi(b,e,f) \tag{12}$$

$$= \frac{1}{Z} \sum_{b} \psi(a,b) \sum_{c} \psi(a,c) \sum_{d} \psi(b,d) \sum_{e} \psi(c,e) \sum_{f} \psi(b,e,f). \tag{13}$$

Exploiting the distributive law in this way is often referred to as the *Elimination Algorithm*. It is useful for computing the marginal with respect to a single variable. However, should we wish to compute the marginal with respect to *each* variable, for example, it is not an efficient algorithm as several operations shall be repeated.

Belief Propagation

In tree-structured models, the elimination algorithm can be adapted to avoid repeated computations, using a message-passing scheme known as *belief propagation*, or the *sum-product* algorithm. This is presented in Algorithm 3. Here the "cliques" in the model are simply edges. This algorithm was invented independently by many authors and is the most efficient among many variations.

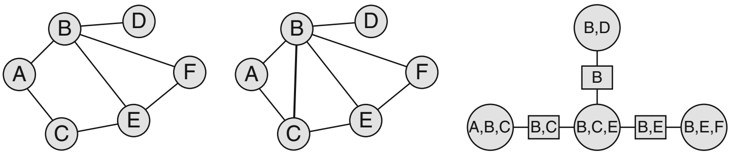
It can be easily demonstrated that the condition in Algorithm 3, Line 3, is always satisfied by some pair of edges until all messages have been passed: initially, it is satisfied by all of the "leaves" of the model; messages are then propagated inward until they reach the "root" of the tree; they are then propagated outward.

Maximum a Posteriori (MAP) Estimation

Algorithm 3 allows us to compute the *marginals* of the variables in a graphical model. There are other related properties that we may also wish to compute, such as finding which states have the

Algorithm 3 The *sum-product* algorithm

```
Input: an undirected, tree-structured graphical model $\mathcal{X}$
    with cliques $\mathcal{C}$ {the cliques are simply edges in this case}
1: define $m_{A \to B}(x_{A \cap B})$ to be the "message" from an edge $A$ to an adjacent edge $B$ {for example if $A = (a,b)$ and $B = (b,c)$ then we have $m_{(a,b) \to (b,c)}(x_b)$}
2: while there exist adjacent edges $A, B \in \mathcal{C}$ for which $m_{A \to B}$ has not been computed do
3:     find some $A \in \mathcal{C}$ such that $m_{C \to A}$ has been computed for every neighbor $C \in \Gamma(A)$, except $B$ {$\Gamma(A)$ returns the edges neighboring $A$; initially the condition is satisfied by all leaf-edges}
4:     $m_{A \to B}(x_{A \cap B}) := \sum_{x_{A \setminus B}} \{\psi_A(x_A) \prod_{C \in \Gamma(A) \setminus B} m_{C \to A}(x_{A \cap C})\}$
5: end while
6: for $A \in \mathcal{C}'$ do
7:     $marginal_A(x_A) := \psi_A(x_A) \prod_{C \in \Gamma(A)} m_{C \to A}(x_{A \cap C})$
8: end for
```



Graphical Models, Fig. 7 The graph at *left* is not chordal, since the cycle (A, B, E, C) does not contain a chord; adding the edge (B, C) results in a chordal (or triangulated) graph (*center*). The graph at *right* is a junction tree for the graph at *center*; the cliques of the triangulated graph form the nodes (*circles*); their *intersection sets* are shown as squares. Note that this is not the only junction tree that we could form – the node $\{B, D\}$ could connect to any of the other three nodes

highest probability (the *maximum a posteriori*, or simply "MAP" states). To do so, we note that the operations $(+, \times)$ used in Algorithm 3 can be replaced by $(\max, \times)$. This variant is usually referred to as the *max-product* (as opposed to *sum-product*) algorithm. Indeed, different quantities can be computed by replacing $(+, \times)$ by any pair of operations that form a *semiring* (Aji and McEliece 2000).

The Junction Tree Algorithm

Algorithm 3 applies only for tree-structured graphs. We can generalize this algorithm to general graphs. We do so by working with a different type of tree-structured graph, whose *nodes* contain the *cliques* in our original graph. We begin with some definitions:

Definition 8 (Chordal Graph) A graph $\mathcal{G}$ is said to be chordal if every cycle $(c_1 \dots c_n)$ in $\mathcal{G}$ contains a chord (i.e., an edge (c_i, c_j) such that $j > (i + 1)$).

Definition 9 (Clique Graph, Clique Tree) A clique graph $\mathcal{H}$ of a graph $\mathcal{G}$ is a graph whose nodes consist of (maximal) cliques in $\mathcal{G}$ and whose edges correspond to intersecting cliques in $\mathcal{G}$. A clique tree is a clique graph without cycles.

Definition 10 (Junction Tree) A clique tree $\mathcal{H}$ of $\mathcal{G}$ is said to form a junction tree if for every pair of nodes A, B (i.e., maximal cliques in $\mathcal{G}$), the path between them $(P_1 \dots P_m)$ satisfies $(A \cap B) \subset P_i$ for all $i \in \{1 \dots m\}$.

The algorithms we shall define apply only if the graph in question is *chordal*, or "triangulated" (Definition 8); this can always be achieved by adding additional edges to the graph, as demonstrated in Fig. 7; adding additional edges means increasing the size of the maximal cliques in the graph.

Finding the "optimal" triangulation (i.e., the one that minimizes the size of the maximal cliques) is an NP-complete problem. In practice, triangulation algorithms vary from simple greedy heuristics (e.g., select a node that has as few neighbors as possible) to complex approximation algorithms working within a factor of the optimal solution (Amir 2001).

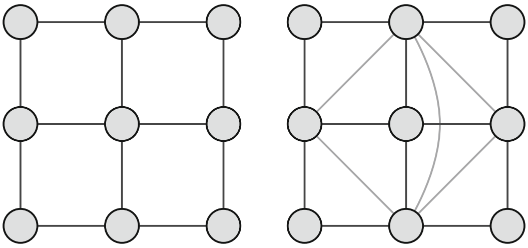
The problem of actually *generating* a junction tree from the triangulated graph is easily solved by a maximum spanning tree algorithm (where we prefer edges corresponding to pairs of cliques with large intersections).

Theorem 3 *Let $\mathcal{G}$ be a triangulated graph and $\mathcal{H}$ a corresponding clique tree. If the sum of the cardinalities of the intersection sets of $\mathcal{H}$ is maximum, then $\mathcal{H}$ is a junction tree. The converse also holds.*

If the nodes and edges in Algorithm 3 are replaced by the nodes (maximal cliques in $\mathcal{G}$) and edges (intersecting cliques in $\mathcal{G}$) of $\mathcal{H}$, then we recover the *junction tree algorithm*.

Approximate Inference

The act of triangulating the graph in the junction tree algorithm may have the effect of increasing the size of its maximal cliques, as in Fig. 8. This may be a problem, as its running time is exponential in the size of the maximal cliques in the *triangulated* graph (this size minus one is referred to as the *tree-width* of the graph, e.g., a chain has a tree-width of 1).



Graphical Models, Fig. 8 The graph above at *left* has maximal cliques of size two; in order to triangulate it, we must introduce maximal cliques of size four (*right*)

There are a variety of approximate algorithms that allow us to perform inference more efficiently:

Variational approximation. If doing inference in a graphical model $\mathcal{X}$ is intractable, we might search for a model $\mathcal{Y}$ for which inference is tractable and which is "similar" to $\mathcal{X}$ in terms of the KL-divergence between $p(x)$ and $p(y)$ (Wainwright and Jordan 2008).

Loopy belief propagation. We can build a clique graph from a graph that has not been triangulated, simply by connecting all cliques that intersect (in which case, the clique graph will contain loops). If we then propagate messages in some *random* order, we can obtain good approximations under certain conditions (Ihler et al. 2005).

Gibbs sampling. Given an estimate $x_{A\backslash B}$ of a set of variables $X_{A\backslash B}$, we can obtain an estimate of x_B by sampling from the conditional distribution $p(x_B|x_{A\backslash B})$. If we choose $B = \{X_i\}$, and repeat the procedure for random choices of $i \in \{1 \ldots N\}$, we obtain the procedure known as *Gibbs sampling* (Geman and Geman 1984).

There are several excellent books and tutorial papers on graphical models. A selection of tutorial papers includes Aji and McEliece (2000), Kschischang et al. (2001), Murphy (1998), and Wainwright and Jordan (2008); review articles include Roweis and Ghahramani (1997) and Smyth (1998), to name but a few.

Other signicant works include Koller and Friedman (2009), Jensen (2001) (introductory books), Edwards (2000) (undirected models), Pearl (1988, 2000) (directed models), Cowell et al. (2003) (exact inference), Jordan (1998) (learning and approximate inference), and Lauritzen (1996, Lauritzen and Spiegelhalter 1988) (a comprehensive mathematical theory).

There is also a variety of closely related models and extensions:

Gaussian graphical models. We have assumed throughout that our probability distributions are *discrete*; however, the only condition we require is that they are *closed under multiplication and marginalization*. This property is also satisfied for *Gaussian* random variables.

Hidden Markov models. In many applications, the variables in our model may be *hidden*. The above algorithms can be adapted to infer properties about our hidden states, given a sequence of observations.

Kalman filters. Kalman filters employ both of the above ideas, in that they include hidden state variables taking values from a *continuous* space using a Gaussian noise model. They are used to estimate the states of *linear dynamic systems* under noise.

Factor graphs. Factor graphs employ an alternate message-passing scheme, which may be preferable for computational reasons. Inference remains approximate in graphs with loops, though approximate solutions may be obtained more efficiently than by loopy belief propagation (Kschischang et al. 2001).

Relational models. Relational models allow us to explore the relationships between objects in order to predict the behavior and properties of each. Graphical models are used to predict the properties of an object based on others that relate to it (Getoor and Taskar 2007).

Learning. Often, we would like to *learn* either the parameters or the structure of the model from (possibly incomplete) data. There is an extensive variety of approaches; a collection of papers appears in Jordan (1998).

Deep learning. Deep belief networks can also be viewed as instances of graphical models, which impose a particular structure on the relationships between input variables, output variables, and hidden units. In particular, deep belief nets assume that complex relationships can be broken down into (a massive number of) purely pairwise interactions.

Graphs

Tommy R. Jensen
Alpen-Adria-Universität Klagenfurt, Klagenfurt, Austria

Definition

Graph Theory is (dyadic) relations on collections specified objects. In its most common, a *graph* is a pair $G = (V, E)$ of a (finite) set of *vertices* V and a set of *edges* E (or *links*). Each edge e is a 2-element subset $\{u, v\}$ of V, usually abbreviated as $e = uv$; u and v are called the *endvertices* of e, they are mutually *adjacent* and each is *incident* to e in G. This explains the typical model of a *simple graph*.

A *directed graph* or ▶ digraph is a more general structure, in which the edges are replaced by ordered pairs of distinct elements of the vertex set V, each such pair being referred to as an *arc*. Another generalization of a graph is a *hypergraph* or “set-system” on V, in which the *hyperedges* may have any size. Various concepts in graph theory extend naturally to *multigraphs*, in which each pair of (possibly identical) vertices may be adjacent via several edges (respectively *loops*). Also studied are *infinite graphs*, for which the vertex and edge sets are not restricted to be finite.

A graph is conveniently depicted graphically by representing each vertex as a small circle, and representing each edge by a curve that joins its two endvertices. A digraph is similarly depicted by adding an arrow on the curve representing an *arc* showing the direction from its *tail* to its (possibly identical) *head*.

Motivation and Background

One of the very first results in graph theory appeared in Leonhard Euler's paper on Seven Bridges of Königsberg, published in 1736. The paper contained the complete solution to the problem whether, when given a graph, it is possible to locate an *Euler tour*, that is, a sequence of adjacent edges (each edge imagined to be traversed from one end to the other) that uses every edge exactly once. Figure 1 illustrates the four main parts of the city of Königsberg with the seven bridges connecting them; since this graph contains four vertices of odd degree, it does not allow an Euler tour.

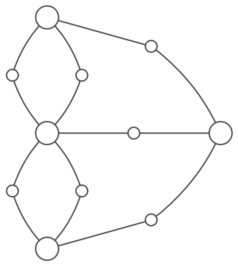
Applications of graphs are numerous and widespread. Much of the success of graph theory is due to the ease at which ideas and proofs may be communicated pictorially in place of, or in conjunction with, the use of purely formal symbolism.

Theory

Isomorphism

A graph drawing should not be confused with the graph itself (the underlying abstract structure) as there are several ways to structure the graph drawing. It only matters which vertices are connected to which others by how many edges, the exact layout may be suited for the particular purpose at hand. It is often a problem of independent interest to optimize a drawing of a given graph in terms of aesthetic features.

Graphs, Fig. 1 A graph of the city of Königsberg

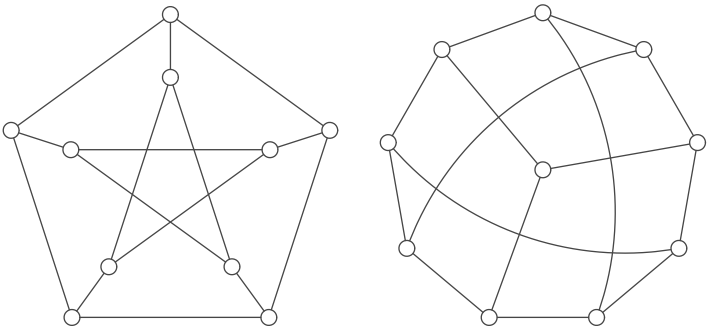


In practice it is often difficult to decide if two drawings represent the same graph (as in Fig. 2). This decision problem has gained increasing status in complexity theory, with growing suspicion that this problem may fall in a new class of problems, which lies between the familar classes of polynomially solvable and NP-complete ► (NP-completeness) problems (supposing that these classes are indeed distinct; for issues related to the complexities of decision and optimization problems see Garey and Johnson 1979). Nonetheless it is customary in the treatment of abstract graphs to consider two graphs identical if they are isomorphic. A closely related problem, the *subgraph isomorphism problem*, an NP-complete problem, consists in finding a given graph as a subgraph of another given graph.

Whereas there seems common agreement in the graph theoretic community on what constitutes a drawing of a graph, it may be considered a weakness, and sometimes a source of confusion, that even the most central general sources on the fundamentals of graph theory, such as the monographs (Berge 1976; Bondy and Murty 2007; Diestel 2005), do not agree on a common formalization of the theory.

Classes of Graphs

Important special classes of graphs are *bipartite graphs*, for which the vertex set is partitionable into two classes A, B with every edge having one end in A and one in B; in particular the *complete bipartite graph* $K_{m,n}$ has $|A| = m, |B| = n$, and every vertex in A is joined to every vertex in B. The *complete graph* K_n consists of n vertices that are all pairwise adjacent. A *path* of length n consists of vertices $v_0, v_1, \ldots, v_n$ with edges $v_{i-1}v_i$ for $i = 1, 2, \ldots, n$; such a path *joins* its two endvertices v_0 and v_n. A *circuit* of length n consists of a path of length $n - 1$ together with an additional edge between the two endvertices of the path. A graph is *connected* if each pair of its vertices is joined by at least one path within the graph. Of central importance to the study of efficient search procedures in computer science is the class of *trees*, those connected graphs that



Graphs, Fig. 2 Two drawings of the same graph

contain no circuits. Most definitions have various natural counterparts for directed graphs, in particular a *tournament* is a directed graph in which each pair of vertices is joined by exactly one arc.

Properties of Graphs

Finding a complete subgraph of a given order in an input graph is called the *clique problem*. The complementary problem of finding an independent set is called the *independent set problem*. The *longest path problem* and the *longest circuit problem* have as special cases the *Hamilton path problem* and the *Hamilton circuit problem*, the latter two problems asking to find a path, respectively a circuit, that uses all vertices of the given graph. Each of these problems (or a suitable modification of it) belongs to the complexity class of NP-complete problems, hence is generally believed to be very difficult to solve efficiently. The weighted version of the Hamilton circuit problem, the so-called *travelling salesman problem* is of central importance in combinatorial optimization.

A graph is called *planar* if it may be drawn in the Euclidian plane without any two of its edges crossing except where they meet at a common endvertex. This is often a convenient way of representing a graph, whenever it is doable. A theorem of Kuratowski states that a graph is planar if and only if it contains homeomorphic copies of neither the complete bipartite graph $K_{3,3}$ (the three-houses-three-utilities-graph) nor the complete graph K_5. A main branch of graph theory is concerned with investigating relationships between the topological and combinatorial properties of graphs (Mohar and Thomassen 2001).

In 1852, Francis Guthrie posed the *four color problem*, asking if it is possible to color the countries of any map, using only four colors, in such a way that all pairs of bordering countries receive different colors. Equivalently, by representing dually every country as a vertex of a graph, with two vertices joined by an edge if their countries share a stretch of common border, the question is whether it is possible to color the vertices of a planar graph using four colors, so that any two adjacent vertices receive distinct colors. This problem, was solved a century later in 1976 by Kenneth Appel, Wolfgang Haken, and John Koch, who invested massive amounts of computing time to complete a graph theoretic approach developed by various mathematicians over a period of most of the preceding part of the twentieth century.

The problem of *coloring* a possibly nonplanar graph with a minimal number of colors, that is, to partition its vertex set into as few independent sets as possible, is a well-studied problem (e.g., see Jensen and Toft 1995), though NP-hard in general. In fact it is already an NP-complete problem to ask whether a given planar graph allows a coloring using at most three colors (see Garey et al. 1976). The recent strong perfect graph theorem provides one of quite few known examples of a fairly rich class of graphs, the *Berge graphs*, for which the coloring problem has a satisfactory solution (see Chudnovsky et al. 2006).

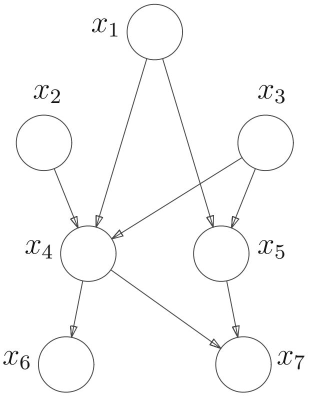
Other well-solved problems include finding a largest *matching* in a given graph; a largest set of edges no two of which share a common endvertex (see Lovász and Plummer (1986) for a thorough treatment of *matching theory*). The most interesting special case asks to find a *perfect matching*, having the property that every vertex is paired up with a unique vertex of the graph adjacent to it. For the special case of bipartite graphs (the *marriage problem*), the problem was solved by Dénes König in 1931. Even when given for every pair of vertices a measure of the desirability of pairing up these particular vertices (the *weighted matching problem*), there exists an efficient solution to the problem of finding an optimum matching of maximal total weight, discovered by Jack Edmonds in 1959.

Applications

As an example of a visualization application, Fig. 3 shows a digraph to symbolize for a collection of seven stochastic variables $x_1, \ldots, x_7$ that their joint distribution is given by the product

$$p(x_1)\,p(x_2)\,p(x_3)\,p(x_4|x_1,x_2,x_3)\,p(x_5|x_1,x_3) \\ \times\, p(x_6|x_4)\,p(x_7|x_4,x_5) \qquad (1)$$

In addition to visualization of a network, a process, a search procedure, or any hierarchical structure, there are many applications using implementations of known graph algorithms on computers, so that the graph in question will only exist as an abstract datastructure within a program and thus remains invisible to the user.



Graphs, Fig. 3 Reproduced from Bishop (2006, p. 362)

There are different ways to store graphs in a computer. Often a combination of list and matrix structures will be preferred for storage and dynamic manipulation of a graph by an algorithm. List structures are often preferred for sparse graphs as they have smaller memory requirements. Matrix structures on the other hand provide faster access but can consume a large amount of memory if a graph contains many vertices. In most cases it is convenient to represent a graph or digraph by an array containing, for each edge or arc, the pair of vertices that it joins, together with additional information, such as the weight of the edge, as appropriate. It may be an advantage in addition to store for each vertex a list of the vertices adjacent to it, or alternatively, a list of the edges incident to it, depending on the application.

The adjacency matrix of a graph, multigraph, or digraph on n vertices is an $n \times n$ matrix in which the *ij*-entry is the number of edges or arcs that join vertex i to vertex j (or more generally, the weight of a single such edge or arc). As a storage device this is inferior for sparse graphs, those with relatively few edges, but gains in importance when an application naturally deals with very dense graphs or multigraphs.

Future Directions

In recent years the theory of *graph minors* has been an important focus of graph theoretic research. A graph H is said to be a *minor* of a graph G if there exists a subgraph of G from which H can be obtained through a sequence of *edge contractions*, each consisting of the identification of the two ends of an edge e followed by the removal of e. A monumental effort by Neil Robertson and Paul Seymour has resulted in a proof of the Robertson–Seymour theorem (Robertson and Seymour 2004; see also Diestel 2005), with the important consequence that for any set $\mathcal{G}$ of graphs that is closed under taking minors, there exists a finite set of obstruction graphs, such that G is an element of $\mathcal{G}$ precisely if G does not contain any minor that belongs to the obstruction set. This theorem has several important algorithmic consequences, many still waiting to be fully explored.

A particularly challenging unsolved problem is the *Hadwiger conjecture* (see Jensen and Toft 1995), stating that any graph G that does not allow a vertex coloring with as few as k colors will have to contain the complete graph K_{k+1} as a minor. The special cases of $k \leq 5$ colors have been shown to be consequences of the four color theorem. But the problem remains open for all larger values of k.

Other central areas of research relate to the notoriously hard problems of vertex- and edge-coloring, and of Hamilton paths and circuits. These have important applications, but it is not expected that any satisfactory necessary and sufficient conditions will be found for their existence. Hence the study of sufficient conditions of practical value is lively pursued.

A list of open problems in graph theory can be found in Bondy and Murty (2007).

Greedy Search

Claude Sammut
The University of New South Wales, Sydney,
NSW, Australia

At each step in its search, a greedy algorithm makes the best decision it can at the time and continues without backtracking. For example, an algorithm may perform a ▸ general-to-specific search and at each step, commits itself to the specialization that best fits that training data, so far. It continues without backtracking to change any of its decisions. Greedy algorithms are used in many machine-learning algorithms, including decision tree learning (Breiman et al. 1984; Quinlan 1993) and ▸ rule learning algorithms, such as sequential covering.

Greedy Search Approach of Graph Mining

Lawrence Holder
Washington State University, Pullman, WA,
USA

Definition

▶ Greedy search is an efficient and effective strategy for searching an intractably large space when sufficiently informed heuristics are available to guide the search. The space of all subgraphs of a graph is such a space. Therefore, the greedy search approach of ▶ graph mining uses heuristics to focus the search toward subgraphs of interest while avoiding search in less interesting portions of the space. One such heuristic is based on the compression afforded by a subgraph; that is, how much is the graph compressed if each instance of the subgraph is replaced by a single vertex. Not only does compression focus the search, but it has also been found to prefer subgraphs of interest in a variety of domains.

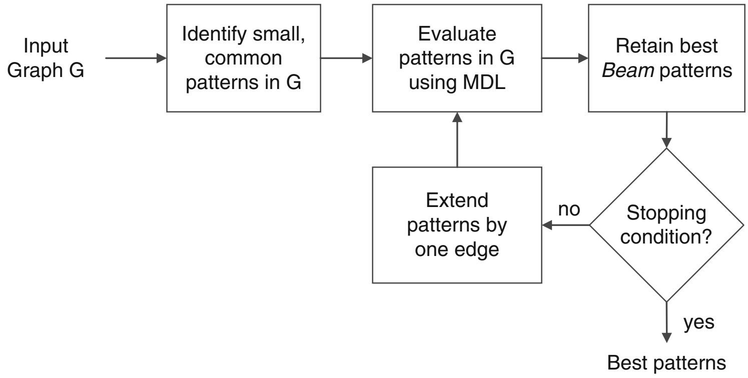
Motivation and Background

Many data mining and machine learning methods focus on the attributes of entities in the domain, but the relationships between these entities also represents a significant source of information, and ultimately, knowledge. Mining this relational information is an important challenge both in terms of representing the information and facing the additional computational obstacles of analyzing both entity attributes and relations. One efficient way to represent relational information is as a graph, where vertices in the graph represent entities in the domain, and edges in the graph represent attributes and relations among the entities. Thus, mining graphs is an important approach to extracting relational information. The main alternative to a graph-based representation is first-order logic, and the methods for mining this representation fall under the area of inductive logic programming. Here, the focus is on the graph representation.

Several methods have been developed for mining graphs (Washio and Motoda 2003), but most of these methods focus on finding the most frequent subgraphs in a set of graph transactions (e.g., FSG (Kuramochi and Karypis 2001), gSpan (Yan and Han 2002), Gaston (Nijssen and Kok 2004)) and use efficient exhaustive, rather than heuristic search. However, there are other properties besides frequency of a subgraph pattern that are relevant to many domains. One such property is the amount of compression afforded by the subgraph pattern, when each instance of the pattern is replaced by a single vertex. Searching for the most frequent subgraphs can be made efficient mainly through the exploitation of the downward closure property, which essentially says one can prune any extension of a subgraph that does not meet the minimum support frequency threshold. Unfortunately, the compression of a subgraph does not satisfy the downward closure property; namely, while a small extension of a subgraph may have less compression, a larger extension may have greater compression. Therefore, one cannot easily prune extensions and must search a larger portion of the space of subgraphs. Thus, one must resort to a greedy search method to search this space efficiently.

As with any greedy search approach, the resulting solution may sometimes be suboptimal, that is, the resulting subgraph pattern is not the pattern with maximum compression. The extent to which optimal solutions are missed depends on the type of greedy search and the strength of the heuristics used to guide the search. One approach is embodied in the graph-based induction (GBI) method (Matsuda et al. 2002; Yoshida et al. 1994). GBI continually compresses the input graph by identifying frequent triples of vertices, some of which may represent previously compressed portions of the input graph. Candidate triples are evaluated using a measure similar to information gain.

A similar approach recommended here is the use of a beam search strategy coupled with a compression heuristic based on the ▶ minimum description length (MDL) principle (Rissanen



Input Graph G
Identify small, common patterns in G

Best patterns

Greedy Search Approach of Graph Mining, Fig. 1 Structure of the greedy search approach of graph mining

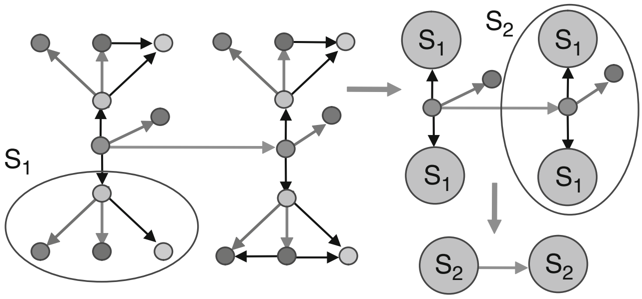
1989). The goal is to perform unsupervised discovery of a subgraph pattern that maximizes compression, which is essentially a tradeoff between frequency and size. Once the capability to find such a pattern exists, it can be used in an iterative discovery-and-compress fashion to perform hierarchical conceptual clustering, and it can be used to perform supervised learning, that is, find patterns that compress the positive graphs, but not the negative graphs. This approach has been well studied (Cook and Holder 2000, 2007; Gonzalez et al. 2002; Holder and Cook 2003; Jonyer et al. 2001; Kukluk et al. 2007) and has proven successful in several domains (Cook et al. 2001; Eberle and Holder 2006; Holder et al. 2005; You et al. 2006).

Structure of Learning System

Figure 1 depicts the structure of the greedy search approach of graph mining. The input data is a labeled, directed graph G. The search begins by identifying the set of small common patterns in G, that is, all vertices with unique labels having a frequency greater than one. The algorithm then iterates by evaluating the patterns according to the search heuristic, retaining the best patterns, and extending the best patterns by one edge until the stopping condition is met.

The search is guided by the minimum description length (MDL) principle, which seeks to minimize the description length of the entire data set. The evaluation heuristic based on the MDL principle assumes that the best pattern is the one that minimizes the description length of the input graph when compressed by the pattern. The description length of the pattern S given the input graph G is calculated as $DL(G, S) = DL(S) + DL(G|S)$, where $DL(S)$ is the description length of the pattern, and $DL(G|S)$ is the description length of the input graph compressed by the pattern. The search seeks a pattern S that minimizes $DL(G,S)$.

While several greedy search strategies apply here (e.g., hill climbing, stochastic), the strategy that has been found to work best is the ▸ beam search. Of the patterns currently under consideration, the system retains only the best *Beam* patterns, where *Beam* is a user-defined parameter. These patterns are then extended by one edge in all possible ways according to the input graph, the extended patterns are evaluated, and then again, all but the best *Beam* patterns are discarded. This process continues until the stopping condition is met. Several stopping conditions are applicable here, including a user-defined limit on the number of patterns considered, the exhaustion of the search space, or the case in which all extensions of a pattern evaluate to a lesser value than their parent pattern. Once meeting the stopping condition, the system returns the best patterns. Note that while the naïve approach to implementing this algorithm would require an NP-complete subgraph isomorphism procedure to collect the instances of each pattern, a more efficient approach takes advantage of the fact that new patterns are always one-edge extensions of existing patterns, and, therefore, the instances of the extended patterns can be identified by search-



Greedy Search Approach of Graph Mining, Fig. 2 Example of the greedy search approach of graph mining

ing the extensions of the parent's instances. This process does require several isomorphism tests, which is the computational bottleneck of the approach, but avoids the subgraph isomorphism problem.

Once the search terminates, the input graph can be compressed using the best pattern. The compression procedure replaces all instances of the pattern in the input graph by single vertices, which represent the pattern's instances. Incoming and outgoing edges to and from the replaced instances will point to, or originate from the new vertex that represents the instance. The algorithm can then be invoked again on this compressed graph.

Figure 2 illustrates the process on a simple example. The system discovers pattern S$_1$, which is used to compress the data. A second iteration on the compressed graph discovers pattern S$_2$. Because instances of a pattern can appear in slightly different forms throughout the data, an inexact graph match, based on graph edit distance, can be used to address noise by identifying similar pattern instances.

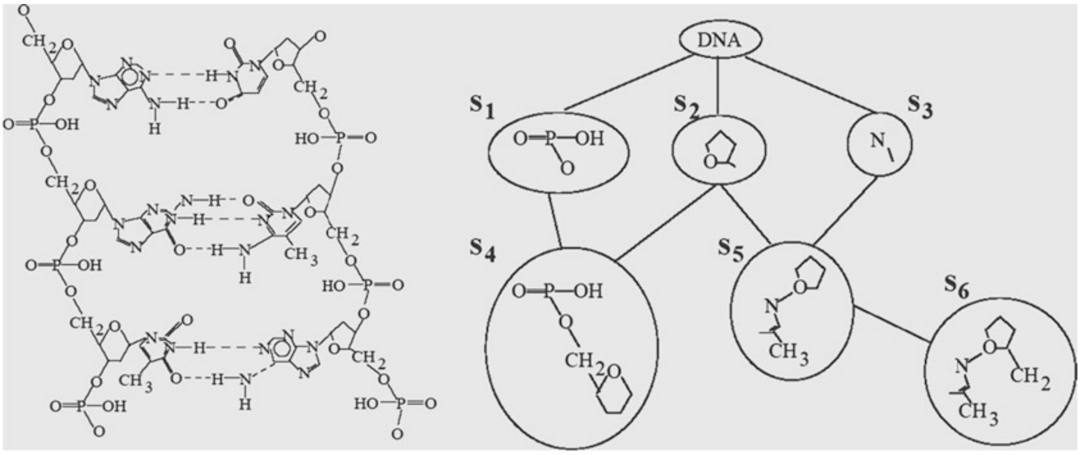
Graph-Based Hierarchical Conceptual Clustering

Given the ability to find a prevalent subgraph pattern in a larger graph and then compress the graph with this pattern, iterating over this process until the graph can no longer be compressed will produce a hierarchical, conceptual clustering of the input data (Jonyer et al. 2001). On the ith iteration, the best subgraph S_i is used to compress the input graph, introducing new vertices labeled S_i in the graph input to the next iteration. Therefore, any subsequently discovered subgraph S_j can be defined in terms of one or more of S_is, where $i < j$. The result is a *lattice*, where each cluster can be defined in terms of more than one parent subgraph. For example, Fig. 3 shows such a clustering done on a DNA molecule.

Graph-Based Supervised Learning

Extending a graph-based data mining approach to perform ▸ supervised learning involves the need to handle negative examples (focusing on the two-class scenario). In the case of a graph the negative information can come in three forms. First, the data may be in the form of numerous smaller graphs, or graph transactions, each labeled either positive or negative. Second, data may be composed of two large graphs: one positive and one negative. Third, the data may be one large graph in which the positive and negative labeling occurs throughout. The first scenario is closest to the standard supervised learning problem in that one has a set of clearly defined examples (Gonzalez et al. 2002). Let G^+ represent the set of positive graphs, and G^- represent the set of negative graphs. Then, one approach to supervised learning is to find a subgraph that appears often in the positive graphs, but not in the negative graphs. This amounts to replacing the information-theoretic measure with simply an error-based measure. This approach will lead the search toward a small subgraph that discriminates well. However, such a subgraph does not necessarily compress well, nor represent a characteristic description of the target concept.

One can bias the search toward a more characteristic description by using the information-theoretic measure to look for a subgraph that compresses the positive examples, but not the



Greedy Search Approach of Graph Mining, Fig. 3 Iterative application of the greedy search approach of graph mining yields the hierarchical, conceptual clustering on the right given an input graph representing the portion of DNA structure depicted on the left

negative examples. If $I(G)$ represents the description length (in bits) of the graph G, and $I(G|S)$ represents the description length of graph G compressed by subgraph S, then one can look for an S that minimizes $I(G^+|S) + I(S) + I(G^-) - I(G^-|S)$, where the last two terms represent the portion of the negative graph incorrectly compressed by the subgraph. This approach will lead the search toward a larger subgraph that characterizes the positive examples, but not the negative examples.

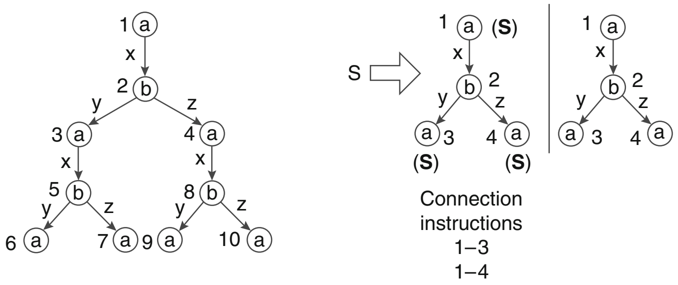
Finally, this process can be iterated in a set-covering approach to learn a disjunctive hypothesis. If using the error measure, then any positive example containing the learned subgraph would be removed from subsequent iterations. If using the information-theoretic measure, then instances of the learned subgraph in both the positive and negative examples (even multiple instances per example) are compressed to a single vertex. Note that the compression is a lossy one, that is, one does not keep enough information in the compressed graph to know how the instance was connected to the rest of the graph. This approach is consistent with the goal of learning general patterns, rather than mere compression.

Graph Grammar Inference

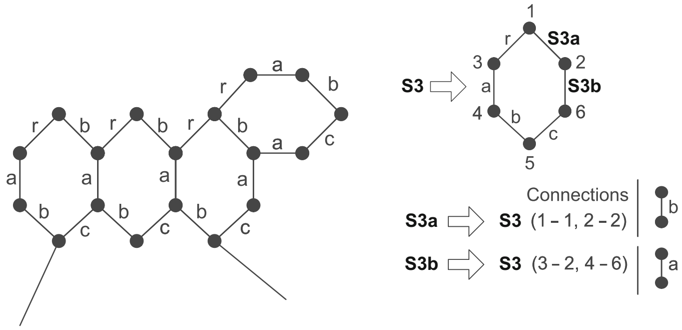
In the above algorithms the patterns are limited to non-recursive structures. In order to learn subgraph motifs, or patterns that can be used as the building blocks to generate arbitrarily large graphs, one needs the ability to learn graph grammars. The key to the inference of a graph grammar is the identification of overlapping structure. One can detect the possibility of a recursive graph-grammar production by checking if the instances of a pattern overlap. If a set of instances overlap by a single vertex, then one can propose a recursive node-replacement graph grammar production. Figure 4 shows an example of a node-replacement graph grammar (right) learned from a simple, repetitive input graph (left). The input graph in Fig. 4 is composed of three overlapping substructures. Based on how the instances overlap, one can also infer connection instructions that describe how the pattern can connect to itself. For example, the connection instructions in Fig. 4 indicate that the graph can grow by connecting vertex 1 of one pattern instance to either vertex 3 or vertex 4 of another pattern instance.

If a set of pattern instances overlap by an edge, then one can propose a recursive edge-replacement graph grammar production. Figure 5 shows an example of an edge-replacement graph grammar (right) learned from the input graph (left). Connection instructions describe how the motifs can connect via the edge labeled “a” or the edge labeled “b.”

Apart from the inclusion of recursive patterns, the greedy search approach of graph mining is



Greedy Search Approach of Graph Mining, Fig. 4 The node-replacement graph grammar (*right*) inferred from the input graph (*left*). The connection instructions indicate how the pattern can connect to itself



Greedy Search Approach of Graph Mining, Fig. 5 The edge-replacement graph grammar (*right*) inferred from the input graph (*left*). The connection instructions indicate how the pattern can connect to itself

unchanged. Both recursive and non-recursive patterns are evaluated according to their ability to compress the input graph using the MDL heuristic. After several iterations of the approach, the result is a graph grammar consisting of recursive and non-recursive productions that both describe the input graph and provide a mechanism for generating graphs with similar properties.

Programs and Data

Most of the aforementioned functionality has been implemented in the SUBDUE graph-based pattern learning system. The SUBDUE source code and numerous sample graph data files are available at http://www.subdue.org.

Applications

Many relational domains, from chemical molecules to social networks, are naturally represented as a graph, and a graph mining approach is a natural choice for extracting knowledge from such data. Three such applications are described below.

A huge amount of biological data that has been generated by long-term research encourages one to move one's focus to a systems-level understanding of bio-systems. A biological network, containing various biomolecules and their relationships, is a fundamental way to describe bio-systems. Multi-relational data mining finds the relational patterns in both the entity attributes and relations in the data. A graph consisting of vertices and edges between these vertices is a natural data structure to represent biological networks. The greedy search approach of graph mining has been applied to find patterns in metabolic pathways (You et al. 2006). Graph-based supervised learning finds the unique substructures in a specific type of pathway, which help one understand better how pathways differ. Unsupervised learning shows hierarchical clusters that describe the common substructures in a specific type of pathway, which allow one to better understand the common features in pathways.

Social network analysis is the mapping and measuring of relationships and flows between people, organizations, computers, or other information processing entities. Such analysis is naturally done using a graphical representation of the domain. The greedy approach of graph mining has been applied to distinguish between criminal and legitimate groups based on their mode of communication (Holder et al. 2005). For example, terrorist groups tend to exhibit communications chains; whereas, legitimate groups (e.g., families) tend to exhibit more hub-and-spoke communications.

▶ Anomaly detection is an important problem for detecting fraud or unlawful intrusions. However, anomalies are typically rare and, therefore, present a challenge to most mining algorithms that rely on regularity and frequency to detect patterns. With the graph mining approach's ability to iteratively compress away regularity in the graph, what is left can be construed as anomalous. To distinguish this residual structure from noise, one can compare its regularity with the probability that such structure would appear randomly. The presence of rare structure that is unlikely to appear by chance suggests an anomaly of interest. Furthermore, most fraudulent activity attempts to disguise itself by mimicking legitimate activity. Therefore, another method for finding such anomalies in graphs is to first find the normative pattern using the greedy search approach of graph mining and then find unexpected deviations to this normative pattern. This approach has been applied to detect anomalies in cargo data (Eberle and Holder 2006).

Future Directions

One of the main challenges in approaches to graph mining is scalability. Since most relevant graph operations (e.g., graph and subgraph isomorphism) are computationally expensive, they can be applied to only modest-sized graphs that can fit in the main memory. Clearly, there will always be graphs larger than can fit in main memory, so efficient techniques for mining in such graphs are needed. One approach is to keep the graph in a database and translate graph mining operations into database queries. Another approach is to create abstraction hierarchies of large graphs so that mining can occur at higher-level, smaller graphs to identify interesting regions of the graph before descending down into more specific graphs. Traditional high-performance computing techniques of partitioning a problem into subproblems, solving the subproblems, and then recomposing a solution do not always work for graph mining problems, because partitioning the problem means breaking links which may later turn out to be important. New techniques and architectures are needed to improve the scalability of graph mining operations.

Another challenge for graph mining techniques is dynamic graphs. Most graphs represent data that can change over time. For example, a social network can change as people enter and leave the network, new links are established and old links are discarded. First, one would like to be able to mine for static patterns in the presence of the changing data, which will require incremental approaches to graph mining. Second, one would like to mine patterns that describe the evolution of the graph over time, which requires mining of time slice graphs or the stream of graph transaction events. Third, the dynamics can reside in the attributes of entities (e.g., changing concentrations of an enzyme in a metabolic pathway), in the relation structure between entities (e.g., new relationships in a social network), or both. Research is needed on efficient and effective techniques for mining dynamic graphs.

Group Detection

Hossam Sharara and Lise Getoor
University of Maryland, College Park, MD, USA

Synonyms

Community detection; Graph clustering; Modularity detection

Definition

Group detection can defined as the clustering of nodes in a graph into groups or communities. This may be a hard partitioning of the nodes, or may allow for overlapping group memberships. A community can be defined as a group of nodes that share dense connections among each other, while being less tightly connected to nodes in different communities in the network. The importance of communities lies in the fact that they can often be closely related to modular units in the system that have a common function, e.g., groups of individuals interacting with each other in a society (Girvan and Newman 2002), WWW pages related to similar topics (Flake et al. 2002), or proteins having the same biological function within the cell (Chen and Yuan 2006).

Motivation and Background

The work done in group detection goes back as early as the 1920s when Stuart Rice clustered data by hand to investigate political blocks (Rice 1927). Another early example is the work of George Homans (1950) who illustrated how simple rearrangement of the rows and columns of data matrices helped to reveal their underlying structure. Since then, group detection has attracted researchers from different areas such as sociology, mathematics, physics, marketing, statistics, and computer science.

Group detection techniques vary from simple similarity-based ▸ clustering algorithms that follow the classical assumption that the data points are independent and identically distributed, to more advanced techniques that take into consideration the existing relationships between nodes in addition to their attributes, and try to characterize the different distributions present in the data.

Theory Solution

A network is defined as a graph $G = (V, E)$ consisting of a set of nodes $v \in V$, and a set of edges $e \in E$. In the case of weighted networks,

$w(v_i, v_j)$ denotes the weight of the edge connection nodes v_i and v_j. A community, or a group, C is a subgraph $C(V', E')$ of the original graph $G(V, E)$ whose nodes and edges are subsets of the original graph's nodes and edges; i.e., $V' \subset V$ and $E' \subset E$.

Following the definition of the community, we can expect that all the vertices in any community must be connected by a path within the same community. This property is referred to in literature as *connectedness*, which implies that in the case of disconnected graphs, we can analyze each connected component separately, as communities cannot span different components.

Another important property that follows from the definition of a community is that the group of vertices within a community should share denser connections among each other, and fewer connections with the other vertices in the network. To quantify this measure, the link density of a group $\delta(C)$ is defined as the ratio between the number of internal edges in that group and the maximum number of possible internal edges:

$$\delta(C) = \frac{|E'|}{|V'| \times (|V'| - 1)/2} \qquad (1)$$

Thus, for any community C, we require that $\delta(C) > \delta(G)$; where $\delta(G)$ is the average link density of the whole network. Similarly, the average link density between different communities, calculated using the ratio between the number of edges emanating from a group and terminating in another, and the maximum number possible of such edges, should generally be low.

Approaches

Beyond the intuitive discussion above, the precise definition of what constitutes a community involves multiple aspects. One important aspect is whether communities form hard partitions of the graph or nodes can belong to several communities. Overlapping communities do commonly occur in natural settings, especially in social networks. Currently, only a few methods are able to handle overlapping communities (Palla et al. 2005).

Other aspects should also be taken into consideration when defining community structure, such as whether link weights and/or directionalities are utilized, and whether the definition allows for hierarchical community structure, which means that communities may be parts of larger ones. However, one of the most important aspect that comes into consideration in community detection is whether the definition depends on global or local network properties. The main difference between the two approaches is whether the communities are defined in the scope of the whole network structure, such as methods based on centrality measures (Girvan and Newman 2002), global optimization methods (Newman and Girvan 2004), spectral methods (Arenas et al. 2006), or information-theoretic methods (Rosvall and Bergstrom 2008). Local methods, on the other hand, define communities based on purely local network structure, such as detecting cliques of different sizes, clique percolation method (Palla et al. 2005), and subgraph fitness method (Lancichinetti et al. 2009).

Local Techniques

Local methods for community detection basically rely on defining a set of properties that should exist in a community, then finding maximal subgraphs for which these set of properties hold. This formulation corresponds to finding maximal cliques in the network, where a clique is a subgraph in which all its vertices are directly connected.

However, there are some issues that rises from the previous formulation. First, finding cliques in a graph is an NP-Complete problem, thus most solutions will be approximate based on heuristic methods. Another more semantic issue is the interpretation of communities, especially in the context of social networks, where different individuals have different centralities within their corresponding groups, contradicting with the degree symmetry of the nodes in cliques. To overcome these drawbacks, the notion of a clique is relaxed to n-clique, which is a maximal subgraph where each pair of vertices are at most n-steps apart from each other.

Clustering Techniques

► Data clustering is considered one of the earliest techniques for revealing group structure, where data points are grouped based on the similarity between their corresponding features according to a given similarity measure. The main objective of traditional clustering methods is to obtain clusters or groups of data points possessing high intra-cluster similarity and low inter-cluster similarity. Classical data clustering techniques can be divided into partition-based methods such as k-means clustering (MacQueen 1967), spectral clustering algorithms (Alpert et al. 1999), and hierarchical clustering methods (Hartigan 1975), which are the most popular and the most commonly used in many fields.

One of the main advantages of the hierarchical clustering techniques is their ability to provide multiple resolutions at which the data can be grouped. In general, hierarchical clustering can be divided into agglomerative and divisive algorithms. The agglomerative algorithm is a greedy bottom-up one that starts with clusters including single data points then successively merge the pairs of clusters with the highest similarity. Divisive algorithms work in an opposite direction, where initially all the data points are regarded as one cluster, which is successively divided into smaller ones by splitting groups of nodes having the lowest similarity. In both algorithms, clusters are represented as a dendrogram, whose depths indicate the steps at which two clusters are joined. This representation clarifies which communities are built up from smaller modules, and how these smaller communities are organized, which can be particularly useful in the case of the presence of a normal hierarchy of community structure in the data. Hierarchical clustering techniques can easily be used in network domains, where data points are replaced by individual nodes in the network, and the similarity is based on edges between them.

Centrality-Based Techniques

One of the methods for community detection that is based on the global network structure is the one proposed by Girvan and Newman (2002), where they proposed an algorithm based on the betweenness centrality of edges to be able to recover the group structure within the network. Betweenness centrality is a measure of centrality of nodes in networks, defined for each node as the number of shortest paths between pairs of nodes in the network that run through it. The Girvan–Newman algorithm extended this definition for edges in the network as well, where the betweenness centrality of an edge is defined as the number of shortest paths between pairs of nodes that run along it.

The basic idea behind the algorithm is exploiting the fact that the number of edges connecting nodes from different communities is sparse. Following from that, all shortest paths between nodes from different communities should pass along one of these edges, increasing their edge betweenness centrality measure. Therefore, by following a greedy approach and removing edges with highest betweenness centrality from the network successively, the underlying community structure will be revealed. One of the major drawbacks of the algorithm is the time complexity, which is $O(|E|^2|V|)$ generally, and $O(|V|^3)$ for sparse networks. The fact that the edge betweenness needs only to be recalculated only for the edges affected by the edge removal can be factored in, which makes the algorithm efficient in sparse networks with strong community structure, but not very efficient on dense networks.

Modularity-Based Techniques

The concept of modularity was introduced by Newman and Girvan (2004) as a measure to evaluate the quality of a set of extracted communities in a network, and has become one of the most popular quality functions used for community detection. The basic idea is utilizing a *null model*: a network having the same set of nodes as the original one, but with random edges placed between them taking into account preserving the original node degrees. The basic idea is that the created random network is expected to contain no community structure, thus by comparing the number of edges within the extracted communities against the expected number of edges in the same communities from the random network, we can judge the quality of the extracted community structure. More specifically, the modularity Q is defined as follows

$$Q = \frac{1}{2|E|} \sum_{ij} \left[A_{ij} - \frac{\deg(i) \times \deg(j)}{2|E|} \right] \delta_k(c_i, c_j) \quad (2)$$

where A_{ij} is the element of the adjacency matrix of the network denoting the number of edges between nodes i and j, $\deg(i)$ and $\deg(j)$ are the degrees of nodes i and j respectively, c_i and c_j are the communities to which nodes i and j belong respectively, and δ_k refers to the kronecker delta. The summation runs over all pairs of nodes within the same community.

Clearly, a higher modularity value indicates that the average link density within the extracted community is larger than that of the random network where no community structure is present. Thus, modularity maximization can be used as the objective for producing high-quality community structure. However, modularity maximization is an NP-hard problem. Nevertheless, there have been several algorithms for finding fairly good approximations of the modularity maximum in reasonable amount of time.

One of the first modularity maximization algorithms was introduced by Newman in 2004. It is a greedy hierarchical agglomerative clustering algorithm, which starts with individual nodes and merges them in the order of increasing the overall modularity of the resulting configuration. The time complexity of this greedy algorithm is $O(|V|(|E| + |V|))$ or $O(|V|^2)$ for sparse networks, which enables the user to run community detection on large networks in a reasonable amount of time.

Issues

One of the main issues with the methods of group detection in network setting is the focus on the network structure, without taking into consideration other properties of nodes and edges in the network. This issue often results in a lack of correspondence between the extracted communities and the functional groups in the network (Shalizi et al. 2007). This also leads to another common problem which is how to validate the resulting communities produced by any of the proposed techniques.

Although in network settings there are often different types of interactions between entities of different natures, most group detection methods work on single-mode networks, which have just a single node and edge type. Fewer works focus on finding groups in more complex, multimodal settings, where nodes from different types have multiple types of interactions with each other. One of the most common approaches to deal with these types of networks is projecting them into a series of individual graphs for each node type. However, this approach results in losing some of the information that could have been retained by operating collectively on the original multi-relational network.

Another issue also gaining interest is developing methods for group detection in dynamic network settings (Tantipathananandh and Berger-Wolf 2009), where the underlying network structure changes over time. Most of the previous work on group detection focused on static networks, and handles the dynamic case by either analyzing a snapshot of the network at a single point in time, or aggregating all interactions over the whole time period. Both approaches do not capture the dynamics of change in the network structure, which can be an important factor in revealing the underlying communities.

Hidden Markov Models

Antal van den Bosch
Centre for Language Studies, Radboud
University, Nijmegen, The Netherlands

Abstract

Starting from the concept of regular Markov models we introduce the concept of hidden Markov model, and the issue of estimating the output emission and transition probabilities between hidden states, for which the Baum-Welch algorithm is the standard choice. We mention typical application in which hidden Markov models play a central role, and mention a number of popular implementations.

Definition

Hidden Markov models (HMMs) form a class of statistical models in which the system being modeled is assumed to be a Markov process with hidden states. From observed output sequences generated by the Markov process, both the output emission probabilities from the hidden states and the transition probabilities between the hidden states can be estimated with dynamic programming methods. The estimated model parameters can then be used for various sequence analysis purposes.

Motivation and Background

The states of a regular Markov model, named after Russian mathematician Andrey Markov (1865–1922), are directly observable; hence its only parameters are the state transition probabilities. In many real-world cases, however, the states of the system that one wants to model are not directly observable. For instance, in speech recognition, the audio is the observable stream, while the goal is to discover the phonemes (the

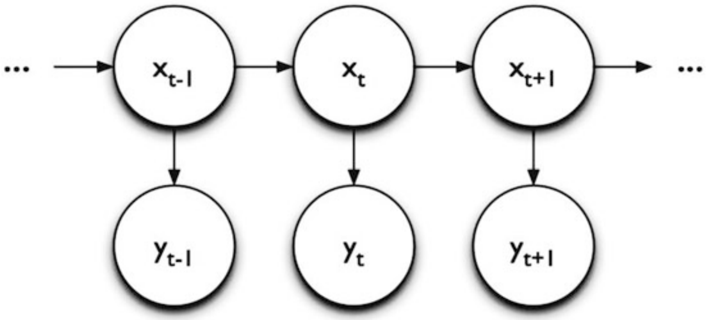
DOI 10.1007/978-1-4899-7687-1



Hidden Markov Models, Fig. 1 Architecture of a hidden Markov model

categorical elements of speech) that emitted the audio. Hidden Markov models offer one type of architecture to estimate hidden states through indirect means. Dynamic programming methods have been developed that can estimate both the output emission probabilities and the transition probabilities between the hidden states, either from observations of output sequences only (an unsupervised learning setting) or from pairs of aligned output sequences and gold-standard hidden sequences (a supervised learning setting).

Structure of the Learning System

Figure 1 displays the general architecture of a hidden Markov model. Each circle represents a variable x_i or y_i occurring at time i; x_t is the discrete value of the hidden variable at time t. The variable y_t is the output variable observed at the same time t, said to be emitted by x_t. Arrows denote conditional dependencies. Any hidden variable is only dependent on its immediate predecessor; thus, the value of x_t is only dependent on that of x_{t-1} occurring at time $t-1$. This deliberate simplicity is referred to as the Markov assumption. Analogously, observed variables such as y_t are conditionally dependent only on the hidden variables occurring at the same time t, i.e., x_t in this case.

Typically, a start state x_0 is used as the first hidden state (not conditioned by any previous state), as well as an end state x_{n+1} that closes the hidden state sequence of length n. Start and end states usually emit meta-symbols signifying the "start" and "end" of the sequence.

An important constraint on the data that can in principle be modeled in a hidden Markov model is that the hidden and output sequences need to be discrete, aligned (i.e., one y_t for each x_t), and of equal length. Sequence pairs that do not conform to these constraints need to be discretized (e.g., in equal-length time slices) or aligned where necessary.

Training and Using Hidden Markov Models

Hidden Markov models can be trained both in an unsupervised and a supervised fashion. First, when only observed output sequences are available for training, the model's conditional probabilities from this indirect evidence can be estimated through the Baum-Welch algorithm (Baum et al. 1970), a form of unsupervised learning, and an instantiation of the expectation-maximization (EM) algorithm (Dempster et al. 1977).

When instead aligned sequences of gold-standard hidden variables and output variables are given as supervised training data, both the output emission probabilities and the state transition probabilities can be straightforwardly estimated from frequencies of co-occurrence in the training data.

Once trained, it is possible to find the most likely sequence of hidden states that could have generated a particular (test) output sequence by the Viterbi algorithm (Viterbi 1967).

Applications of Hidden Markov Models

Hidden Markov models are known for their successful application in pattern recognition tasks such as speech recognition (Rabiner 1989) and DNA sequencing (Kulp et al. 1996) but also in sequential pattern analysis tasks such as in part-of-speech tagging (Church 1988).

Their introduction in speech recognition in the 1970s (Jelinek 1998) led the way toward the introduction of stochastic methods in general in the field of natural language processing in the 1980s and 1990s (Charniak 1993; Manning and Schütze 1999) and into text mining and information extraction in the late 1990s and onward (Freitag and McCallum 1999). In a similar way, hidden Markov models started to be used in DNA pattern recognition in the mid-1980s and have gained widespread usage throughout bioinformatics since (Durbin et al. 1998; Burge and Karlin 1997).

Programs

Many implementations of hidden Markov models exist. Three noteworthy packages are the following:

- UMDHMM by Tapas Kanungo. Implements the forward-backward, Viterbi, and Baum-Welch algorithms (Kanungo 1999)
- JAHMM by Jean-Marc François. A versatile Java implementation of algorithms related to hidden Markov models (François 2006)
- HMMER by Sean Eddy. An implementation of profile HMM software for protein sequence analysis (Eddy 2007)

Hierarchical Reinforcement Learning

Bernhard Hengst
University of New South Wales, Sydney, NSW, Australia

Definition

Hierarchical reinforcement learning (HRL) decomposes a ▶ reinforcement learning problem into a hierarchy of subproblems or subtasks such that higher-level parent-tasks invoke lower-level child tasks as if they were primitive actions. A decomposition may have multiple levels of hierarchy. Some or all of the subproblems can themselves be reinforcement learning problems. When a parent-task is formulated as a reinforcement learning problem it is commonly formalized as a semi-Markov decision problem because its actions are child-tasks that persist for an extended period of time. The advantage of hierarchical decomposition is a reduction in computational complexity if the overall problem can be represented more compactly and reusable subtasks learned or provided independently. While the solution to a HRL problem is optimal given the constraints of the hierarchy there are no guarantees in general that the decomposed solution is an optimal solution to the original reinforcement learning problem.

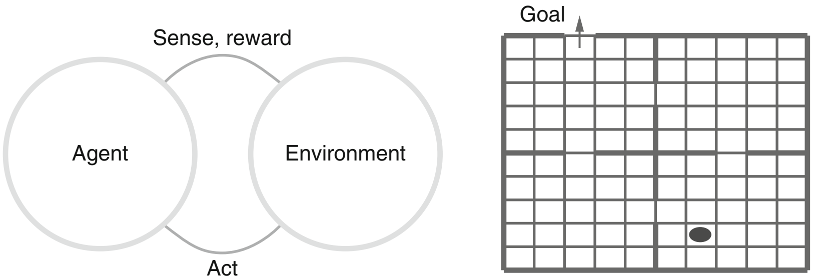
Motivation and Background

Bellman's "curse of dimensionality" beleaguers reinforcement learning because the problem representation grows exponentially in the number of state and action variables. The complexity we encounter in natural environments has a property, near decomposability, that may be exploited using hierarchical models to greatly simplify our understanding and control of behavior. Human societies have used hierarchical organizations to solve complex tasks dating back to at least Egyptian times. It seems natural, therefore, to introduce hierarchical structure into reinforcement learning to solve more complex problems.

When large problems can be decomposed hierarchically there may be improvements in the time and space complexity for both learning and execution of the overall task. Hierarchical decomposition is a divide-and-conquer strategy that solves the smaller subtasks and puts them back together for a more cost-effective solution to the larger problem. The subtasks defined over the larger problem are stochastic macro-operators that execute their policy until termination. If there are multiple ways to terminate a subtask the optimal subtask policy will depend on the context in which the subtask is invoked. Subtask policies usually persist for multiple time-steps and are hence referred to as *temporally extended actions*. Temporally extended actions have the potential to transition through a much smaller "higher-level" state-space, reducing the size of the original problem. For example, navigating through a house may only require room states to represent the abstract problem if room-leaving temporally extended actions are available to move through each room. A room state in this example is referred to as an *abstract state* as the detail of the exact position in the room is abstracted away. Hierarchical reinforcement learning can also provide opportunities for subtask reuse. If the rooms are similar, the policy to leave a room will only need to be learnt once and can be transferred and reused.

Early developments of hierarchical learning appeal to analogies of boss – subordinate models. Ashby (1956) discusses the "amplification" of regulation in very large systems through hierarchical control – a doctor looks after a set of mechanics who in turn maintain thousands of air-conditioning systems. Watkins (1989) used a navigator – helmsman hierarchical control example to illustrate how reinforcement learning limitations may be overcome. Early examples of hierarchical reinforcement learning include Singh's Hierarchical-DYNA (Dyna, a class of architectures for intelligent systems based on approximating dynamic programming methods. Dyna architectures integrate trial-and-error (reinforcement) learning and execution-time planning into a single process operating alternately on the world and on a learned model of the world Sutton et al. 1999) (Singh 1992), Kaelbling's Hierarchical Distance to Goal (HDG) (Kaelbling 1993), and Dayan and Hinton's Feudal reinforcement learning (Dayan and Hinton 1992). The latter explains hierarchical structure in terms of a management hierarchy. The example has four hierarchical levels and employs abstract states, which they refer to as "information hiding".

Close to the turn of the last century three approaches to hierarchical reinforcement learning were developed relatively independently: Hierarchies of Abstract Machines (HAMs) (Parr



Hierarchical Reinforcement Learning, Fig. 1 *Left*: The agent view of reinforcement learning. *Right*: A four-room environment with the agent in one of the rooms show as a *solid black* oval

and Russell 1997); the Options framework (Sutton et al. 1999); and MAXQ value function decomposition (Dietterich 2000). Each approach has different emphases, but a common factor is the use of temporally extended actions and the formalization of HRL in terms of semi-Markov decision process theory (Puterman 1994) to solve the higher-level abstract reinforcement learning problem.

Hierarchical reinforcement learning is still an active research area. More recent extensions include: continuous state-space; concurrent actions and multi-agency; use of average rewards (Ghavamzadeh and Mahadevan 2002); continuing problems; policy-gradient methods; partial-observability and hierarchical memory; factored state-spaces and graphical models; and basis functions. Hierarchical reinforcement learning also includes hybrid approaches such as Ryan's reinforcement learning teleo-operators (RL-TOPs) (Ryan and Reid 2000) that combines planning at the top level and reinforcement learning at the more stochastic lower levels. Please see Barto and Mahadevan (2003) for a survey of recent advances in hierarchical reinforcement learning. More details can be found in the section on recommended reading.

In most applications the structure of the hierarchy is provided as background knowledge by the designer. Some researchers have tried to learn the hierarchical structure from the agent–environment interaction. Most approaches look for subgoals or subtasks that try to partition the problem into near independent reusable subproblems.

Structure of Learning System

Structure of HRL

The agent view of reinforcement learning illustrated on the left in Fig. 1 shows an agent interacting with an environment. At regular time-steps the agent takes actions in the environment and receives sensor observations and rewards from the environment. A hierarchical reinforcement learning agent is given or discovers background knowledge that explicitly or implicitly provides a decomposition of the environment. The agent exploits this knowledge to solve the problem more efficiently by finding an action policy to optimize a measure of future reward, as for reinforcement learning.

We will motivate the machinery of hierarchical reinforcement learning with the simple example shown in Fig. 1 (right). This diagram shows a four-room house with doorways between adjoining rooms and a doorway in the top left room leading outside. Each cell represents a possible position of the agent. We assume the agent always starts in the bottom left room position as shown by the black oval. It is able to sense its position in the room and which room it occupies. It can move one step in any of the four compass directions each time-step. It also receives a reward of -1 at each time-step. The objective is to leave the house via the least-cost route. We assume that the actions are stochastic with an 80 % chance of moving in the intended direction and a 20 % chance of staying in place. Solving this problem in a straightforward manner using reinforcement learning requires storage for 400 Q values defined over 100 states and 4 actions.

If the state space is decomposed into the four identical rooms a hierarchical reinforcement learner could solve this problem more efficiently. For example, we could solve two subproblems. One that finds an optimal solution to leave a room to the North and another to leave a room to the West. When learning these subtasks, leaving a room in any other way is disallowed. Each of these subproblems requires storage for 100 Q values – 25 states and 4 actions.

We also formulate and solve a higher-level problem that consists of only the four rooms as states. These are abstract states because, as previously explained, the exact position in the room has been abstracted away. In each abstract state we allow a choice of only one or the other of the learnt room-leaving actions. These are temporally extended actions because, once invoked, they will usually persist for multiple time-steps until the agent exits the room. We proceed to solve this higher-level problem in the usual way using reinforcement learning. The proviso is that the reward on completing a temporally extended action is the sum of rewards accumulated since invocation of the subtask. The higher-level problem requires storage for only 8 Q values – 4 states and 2 actions.

Once learnt, execution of the higher-level policy will determine the optimal room-leaving action to invoke given the current room – in this case to leave the room via the West doorway. Control is passed to the room-leaving subtask that leads the agent out of the room through the chosen doorway. Upon leaving the room, the subtask is terminated and control is passed back to the higher level that chooses the next optimal room-leaving action until the agent finally leaves the house. The total number of Q values required for the hierarchical reinforcement formulation is 200 for the two subtasks and eight for the higher-level problem, a total of 208. This almost halves the storage requirements compared to the "flat" formulation with corresponding savings in time complexity. In this example, hierarchical reinforcement learning finds the same optimal policy that a less efficient reinforcement learner would find, but this is not always the case.

The above example hides many issues that hierarchical reinforcement learning needs to address, including: safe state abstraction; appropriately accounting for accumulated subtask reward when initial conditions change or rewards are discounted; optimality of the solution; and learning of the hierarchical structure itself. In the next sections we will touch on these issues as we discuss the semi-Markov decision problem formalism and review several approaches to hierarchical reinforcement learning.

Semi-Markov Decision Problem Formalism

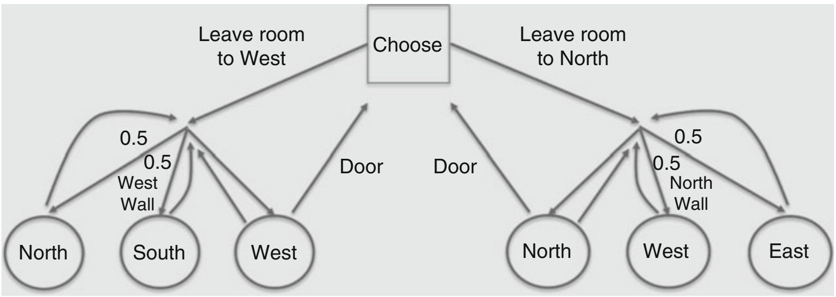
The common underlying formalism in hierarchical reinforcement learning is the semi-Markov decision process (SMDP). A SMDP generalizes a ▸ Markov decision process by allowing actions to be temporally extended. We will state the discrete time equations following Dietterich (2000), recognizing that in general SMDPs are formulated with real-time valued temporally extended actions (Puterman 1994).

Denoting the random variable N to be the number of time steps that a temporally extended action a takes to complete when it is executed starting in state s, the state transition probability function for the result state s' and the expected reward function are given by (1) and (2) respectively.

$$T_{ss'}^{N,a} = Pr\{s_{t+N} = s' | s_t = s, a_t = a\} \quad (1)$$

$$R_{ss'}^{N,a} = E\left\{ \sum_{n=1}^{N} \gamma^{n-1} r_{t+n} | s_t \right.$$
$$\left. = s, a_t = a, s_{t+N} = s' \right\} \quad (2)$$

$R_{ss'}^{N,a}$ is the expected sum of N future discounted rewards. The discount factor $\gamma \in [0, 1]$. When set to less than 1, γ insures that the value function will converge for continuing or infinite-horizon problems. The Bellman "backup" equations for the value function $V(s)$ for an arbitrary policy π and optimal policies (denoted by $*$) are similar to those for MDPs with the sum taken with respect to s' and N.



Hierarchical Reinforcement Learning, Fig. 2 An abstract machine for a HAM that provides routines for leaving rooms to the West and North of the house in Fig. 1 *right*

$$V^{\pi}_{m}(s) = \sum_{s',N} T^{N,\pi(s)}_{ss'} \left[R^{N,pi(s)}_{ss'} + \gamma^{N} V^{\pi}_{m}(s') \right] \tag{3}$$

$$V^{*}_{m}(s) = \max_{a} \sum_{s',N} T^{N,a}_{ss'} \left[R^{N,a}_{ss'} + \gamma^{N} V^{*}_{m}(s') \right] \tag{4}$$

For problems that are guaranteed to terminate, the discount factor γ can be set to 1. In this case the number of steps N can be marginalized out and the sum taken with respect to s alone. The above equations are then similar to the ones for MDPs with the expected primitive reward replaced with the expected sum of rewards to termination of the temporally extended action. All the methods developed for reinforcement learning using primitive actions work equally well for problems using temporally extended actions.

Approaches to Hierarchical Reinforcement Learning

Hierarchies of Abstract Machines (HAMs)

In the HAM approach to hierarchical reinforcement learning (Parr and Russell 1997), the designer specifies subtasks by providing stochastic finite state automata called abstract machines. While in practice several abstract machines may allow some to call others as subroutines (hence hierarchies of abstract machines), in principle this is equivalent to specifying one large abstract machine with two types of states. Action states, that specify the action to be taken given the state of the MDP to be solved and choice states with nondeterministic actions.

An abstract machine is a triple $\langle \mu, I, \delta \rangle$, where μ is a finite set of machine states, I is a stochastic function from states of the MDP to be solved to machine states that determines the initial machine state, and δ is a stochastic next-state function mapping machine states and MDP states to next machine states. The parallel action of the MDP and an abstract machine yields a discrete-time higher-level SMDP with the abstract machine's action states generating a sequence of temporally extended actions between choice states. Only a subset of states of the original MDP are associated with choice-points, potentially reducing the higher-level problem significantly.

Continuing with our four-room example, the abstract machine in Fig. 2 provides choices for leaving a room to the West or the North. In each room it will take actions that move the agent to a wall, and perform a random walk along the wall until it finds the doorway. Only five states of the original MDP are states of the higher-level SMDP. These states are the initial state of the agent and the states on the other side of doorways where the abstract machine enters choice states. Reinforcement learning methods update the value function for these five states in the usual way with rewards accumulated since the last choice state. The optimal policy consists of the three temporally extended actions sequentially leaving a room to the West, North, and North again.

Solving the SMDP will yield an optimal policy for the agent to leave the house subject to the constraints of the abstract machine. In this case it is not a globally optimal policy because a random walk along walls to find a doorway is inefficient.

The HAM approach is predicated on engineers and control theorists being able to design good controllers that will realize specific lower level behaviors. HAMs are a way to partially specify procedural knowledge to transform an MDP to a reduced SMDP. In the most general case HAMs can be Turing machines that execute any computable mapping of the agent's complete sensory-action history.

Options

For an MDP with finite states S and actions A, *options* generalize one-step primitive actions to include temporally extended actions (Sutton et al. 1999). Options consist of three components: a policy $\pi : S \times A \rightarrow [0, 1]$, a termination condition $\beta : S \rightarrow [0, 1]$, and an initiation set $I \subseteq S$. An option $\langle I, \pi, \beta \rangle$ is available in state s if and only if $s \in I$. If an option is invoked, actions are selected according to π until the option terminates according to β. These options are called Markov options because intra-option actions taken by policy π depend only on the current state s. It is possible to generalize options to semi-Markov options in which policies and termination conditions make their choices dependent on all prior events since the option was initiated. In this way it is possible, for example, to "time-out" options after some period of time has expired. For their most general interpretation, options and HAMs appear to have similar functionality, but different emphases.

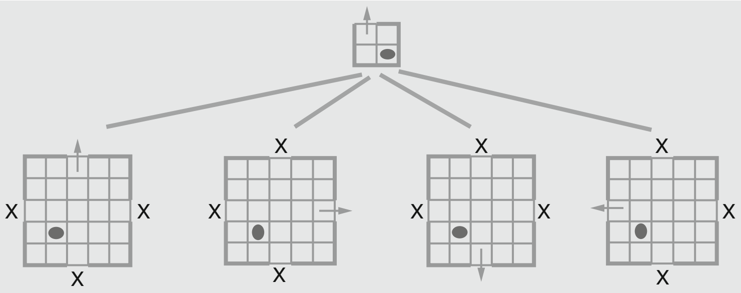
Options were intended to augment the primitive actions available to an MDP. The temporally extended actions executed by the options yield a SMDP. As for HAMs, if options replace primitive actions, the SMDP can be considerably reduced. There is debate as to benefits when primitive actions are retained. Reinforcement learning may be accelerated because the value function can be backed-up over greater distances in the state-space and the inclusion of primitive actions guarantees convergence to the globally optimal policy, but the introduction of additional actions increased the storage and exploration necessary.

In a similar four-room example to that of Fig. 1, the authors (Sutton et al. 1999) show how options can learn significantly faster proceeding on a room-by-room basis, rather than position by position. When the goal is not in a convenient location, able to be reached by the given options, it is possible to include primitive actions as special-case options and still accelerate learning for some problems. For example, with room-leaving options alone, it is not possible to reach a goal in the middle of a room. Primitive actions are required when the room containing the goal state is entered. Although the inclusion of primitive actions guarantees convergence to the globally optimal policy, this may create extra work for the learner.

MAXQ

The MAXQ (Dietterich 2000) approach to hierarchical reinforcement learning restricts subtasks to subsets of states, actions, and policy fragments of the original MDP without introducing extra state, as is possible with HAMs and semi-Markov options. The contribution of MAXQ is the decomposition of the value function over the hierarchy and provision of opportunities for state abstraction. An MDP is manually decomposed into a hierarchical directed acyclic graph of subtasks called a task-hierarchy. Each subtask is a smaller (semi-)MDP. In decomposing the MDP the designer specifies the active states and terminal states for each subtask. Terminal states are typically classed either as goal terminal states or non-goal terminal states. Using disincentives for non-goal terminal states, policies are learned for each subtask to encourage them to terminate in goal terminal states. The actions available in each subtask can be primitive actions or other (child) subtasks. Each sub-task can invoke any of its child subtasks as a temporally extended action. When a task enters a terminal state, it, and all its children, abort and return control to the calling subtask.

Figure 3 shows a task-hierarchy for the previous four-room problem. The four lower-level subtasks are sub-MDPs for a generic room, where a separate policy is learnt to exit a room by each of the four possible doorways. The arrow indicates a transition to a goal terminal state and the "×"s indicate non-goal terminal states. States, actions, transitions, and rewards are inherited



Hierarchical Reinforcement Learning, Fig. 3 A task-hierarchy decomposing the four-room problem in Fig. 1. The four lower-level subtasks are generic room-leaving sub-MDPs, one for leaving a room in each compass direction

from the original MDP. The rewards on transition to terminal states are engineered to encourage the agent to avoid non-goal terminal states and terminate in goal states. The higher-level problem (SMDP) consists of just four states representing the rooms. Any of the subtasks (room-leaving actions) can be invoked in any of the rooms.

A key feature of MAXQ is that it represents the value of a state as a decomposed sum of subtask completion values plus the value of the immediate primitive action. A completion value is the expected (discounted) cumulative reward to complete the subtask after taking the next (temporally extended) action when following a policy over subtasks. The sum includes all the tasks invoked on the path from the root task in the task hierarchy right down to the primitive action. For a rigorous mathematical treatment the reader is referred to Dietterich (2000). The Q function is expressed recursively (5) as the value for completing the subtask plus the completion value for the overall problem after the subtask has terminated. In this equation, i is the subtask identifier, s is the current state, action a is the child subtask (or primitive action), and π is a policy for each subtask.

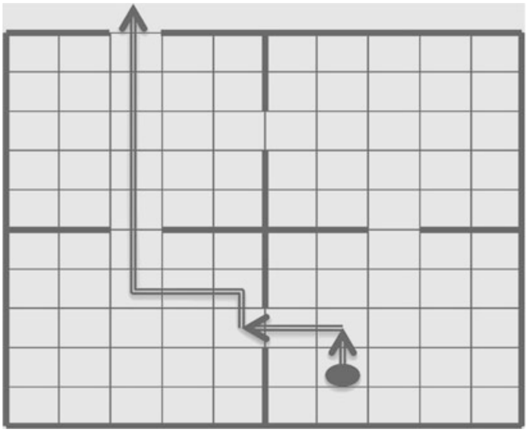
$$Q^{\pi}(i, s, a) = V^{\pi}(a, s) + C^{\pi}(i, s, a) \qquad (5)$$

We describe the basic idea for the task-hierarchy shown in Fig. 3 for the optimal policy. The value of the agent's state has three components determined by the two levels in the task-hierarchy plus a primitive action. For the agent state, shown in Fig. 4 by a solid black oval, the value function represents the expected reward for taking the next primitive action to the North, completing the lower-level subtask of leaving the room to the West, and completing the higher-level task of leaving the house. The benefit of decomposing the value function is that it can be represented much more compactly because only the completion values for non-primitive subtasks and primitive actions need be stored.

The example illustrates two types of state abstraction. As all the rooms are similar we can ignore the room identity when we learn intra-room navigation policies. Secondly, when future rewards are not discounted, the completion value after leaving a room is independent of the starting state in that room. These "funnel" actions allow the intra-room states to be abstracted into a single state for each room as far as the completion value is concerned. The effect is that the original problem can be decomposed into a small four-state SMDP at the top level and four smaller subtask MDPs.

Optimality

Hierarchical reinforcement learning can at best yield solutions that are hierarchically optimal, assuming convergence conditions are met, meaning that they are consistent with the task-hierarchy. MAXQ introduces another form of optimality – recursive optimality. MAXQ optimizes subtask policies to reach goal states ignoring the needs of their parent tasks. This has the advantage that subtasks can be reused in various contexts, but they may not therefore be optimal in each situation. A recursively optimal solution cannot be better than a hierarchical optimal solution. Both recursive and hierarchical optimality can be arbitrarily worse than the globally optimal solution if a designer chooses a poor HAM, option or hierarchical decomposition.



Hierarchical Reinforcement Learning, Fig. 4 The components of the decomposed value function for the agent following an optimal policy for the four-room problem in Fig. 1. The agent is shown as a *solid black* oval at the starting state

The stochastic nature of MDPs means that the condition under which a temporally abstract action is appropriate may have changed after the action's invocation and that another action may become a better choice because of "stochastic drift." A subtask policy proceeding to termination in this situation may be suboptimal. By constantly interrupting the subtask, as for example in HDG (Kaelbling 1993), a better subtask may be chosen. Dietterich calls this "polling" procedure hierarchical greedy execution. While this is guaranteed to be no worse than the hierarchically optimal or recursively optimal solution and may be considerably better, it still does not provide any global optimality guarantees. Great care is required while learning with hierarchical greedy execution. Hauskrecht et al. (1998) discuss decomposition and solution techniques that make optimality guarantees, but unfortunately, unless the MDP can be decomposed into very weakly coupled smaller MDPs, the computational complexity is not necessarily reduced. Benefits will still accrue if the options or subtask policies can be reused and amortized over multiple MDPs.

Automatic Decomposition

In the above approaches the programmer is expected to manually decompose the overall problem into a hierarchy of subtasks. Methods to automatically decompose problems include ones that look for subgoal bottleneck or landmark states, and ones that find common behavior trajectories or region policies. For example, in Fig. 1 the agent will exit one of the two starting room doorways on the way to the goal. The states adjacent to each doorway will be visited more frequently in successful trials than other states.

Both NQL (nested Q learning) Digney (1998) and McGovern (2002) use this idea to identify subgoals. Moore et al. (1999) suggest that, for some navigation tasks, performance is insensitive to the position of landmarks and an (automatic) randomly generated set of landmarks does not show widely varying results from more purposefully positioned ones. Hengst has explored automatic learning of MAXQ-like task-hierarchies from the agent's interactive experience with the environment, automatically finding common regions and generating subgoals when the agent's prediction fails. Methods include state abstraction with discounting for infinite horizon problems and decompositions of problems to form partial-order task-hierarchies (Hengst 2008). When there are no cycles in the causal graph the variable influence structure analysis (VISA) algorithm (Jonsson and Barto 2006) performs hierarchical decomposition of factored Markov decision processes using a given dynamic Bayesian network model of actions. Konidaris and Barto (2009) introduce a skill discovery method for reinforcement learning in continuous domains that constructs chains of skills leading to an end-of-task reward.

Given space limitations we cannot adequately cover all the research in hierarchical reinforcement learning, but we trust that the material above will provide a starting point.

Higher-Order Logic

John Lloyd
The Australian National University, Canberra,
ACT, Australia

Definition

Higher-order logic is a logic that admits so-called higher-order functions, which are functions that can have functions as arguments or return a function as a result. The expressive power that comes from higher-order functions makes the logic highly suitable for representing individuals, predicates, features, background theories, and hypotheses and performing the necessary reasoning, in machine learning applications.

Motivation and Background

Machine learning tasks naturally require knowledge representation and reasoning. The individuals that are the subject of learning, the training examples, the features, the background theory, and the hypothesis languages all have to be represented. Furthermore, reasoning, usually in the form of computation, has to be performed.

Logic is a convenient formalism in which knowledge representation and reasoning can be carried out; indeed, it was developed exactly for this purpose. For machine learning applications, quantification over variables is generally needed, so that, at a minimum, ▸ first-order logic should be used. Here, the use of higher-order logic for this task is outlined. Higher-order logic admits higher-order functions that can have functions as arguments or return a function as a result. This means that the expressive power of higher-order logic is greater than first-order logic so that some expressions of higher-order logic are difficult or impossible to state directly in first-order logic. For example, sets can be represented by ▸ predicates which are terms in higher-order logic, and operations on sets can be implemented by higher-order functions. Grammars that generate spaces of predicates can be easily expressed. Also the programming idioms of functional programming languages become available.

The use of higher-order logic in learning applications began around 1990 when researchers argued for the advantages of lifting the concept of ▸ least general generalization in the first-order setting to the higher-order setting (Dietzen and Pfenning 1992; Feng and Muggleton 1992; Lu et al. 1998). A few years later, Muggleton and Page (1994) advocated the use of higher-order concepts, especially sets, for learning applications. Then the advantages of a type system and also higher-order facilities for concept learning were presented in Flach et al. (1998). Higher-order logic is also widely used in other parts of computer science, for example, theoretical computer science, functional programming, and verification of software.

Most treatments of higher-order logic can be traced back to Church's simple theory of types (Church 1940). Recent accounts can be found, for example, in Andrews (2002), Fitting (2002), and Wolfram (1993). For a highly readable account of the advantages of working in higher-order rather than first-order logic, Farmer (2008) is strongly recommended. An account of higher-order logic specifically intended for learning applications is in Lloyd (2003), which contains much more detail about the knowledge representation and reasoning issues that are discussed below.

Theory

Logic

To begin, here is one formulation of the syntax of higher-order logic which gives prominence to a type system that is useful for machine learning applications, in particular.

An *alphabet* consists of four sets: a set $\mathfrak{T}$ of type constructors, a set $\mathfrak{P}$ of parameters, a set $\mathfrak{C}$ of constants, and a set $\mathfrak{V}$ of variables. Each type constructor in $\mathfrak{T}$ has an arity. The set $\mathfrak{T}$ always includes the type constructor Ω of arity 0. Ω is the type of the booleans. Each constant in $\mathfrak{C}$ has a signature (i.e., type declaration). The set $\mathfrak{V}$ is denumerable. Variables are typically denoted by $x, y, z, \ldots$. The parameters are type variables that provide polymorphism in the logic; they are ignored for the moment.

Here is the definition of a type (for the non-polymorphic case).

Definition A *type* is defined inductively as follows:

1. If T is a type constructor of arity k and $\alpha_1, \ldots, \alpha_k$ are types, then $T \ \alpha_1 \ldots \alpha_k$ is a type. (Thus, a type constructor of arity 0 is a type.)
2. If α and β are types, then $\alpha \to \beta$ is a type.

3. If $\alpha_1, \ldots, \alpha_n$ are types, then $\alpha_1 \times \cdots \times \alpha_n$ is a type.

The set $\mathfrak{C}$ always includes the following constants:

1. $\top$ and $\bot$, having signature Ω.
2. $=_\alpha$, having signature $\alpha \to \alpha \to \Omega$, for each type α.
3. $\neg$, having signature $\Omega \to \Omega$.
4. $\wedge$, $\vee$, $\longrightarrow$, $\longleftarrow$, and $\longleftrightarrow$, having signature $\Omega \to \Omega \to \Omega$.
5. Σ_α and Π_α, having signature $(\alpha \to \Omega) \to \Omega$, for each type α.

The intended meaning of $=_\alpha$ is identity (i.e., $=_\alpha x\ y$ is $\top$ if x and y are identical), the intended meaning of $\top$ is true, the intended meaning of $\bot$ is false, and the intended meanings of the connectives $\neg$, $\wedge$, $\vee$, $\longrightarrow$, $\longleftarrow$, and $\longleftrightarrow$ are as usual. The intended meanings of Σ_α and Π_α are that Σ_α maps a predicate to $\top$ if the predicate maps at least one element to $\top$ and Π_α maps a predicate to $\top$ iff the predicate maps all elements to $\top$.

Here is the definition of a term (for the non-polymorphic case).

Definition A *term*, together with its type, is defined inductively as follows:

1. A variable in $\mathfrak{V}$ of type α is a term of type α.
2. A constant in $\mathfrak{C}$ having signature α is a term of type α.
3. If t is a term of type β and x a variable of type α, then $\lambda x.t$ is a term of type $\alpha \to \beta$.
4. If s is a term of type $\alpha \to \beta$ and t a term of type α, then $(s\ t)$ is a term of type β.
5. If $t_1, \ldots, t_n$ are terms of type $\alpha_1, \ldots, \alpha_n$, respectively, then $(t_1, \ldots, t_n)$ is a term of type $\alpha_1 \times \cdots \times \alpha_n$.

A *formula* is a term of type Ω. Terms of the form $(\Sigma_\alpha\ \lambda x.t)$ are written as $\exists_\alpha\, x.t$, and terms of the form $(\Pi_\alpha\ \lambda x.t)$ are written as $\forall_\alpha x.t$ (in accord with the intended meaning of Σ_α and Π_α). Thus, in higher-order logic, each quantifier is obtained as a combination of an abstraction acted on by a suitable function (Σ_α or Π_α).

The polymorphic version of the logic extends what is given above by also having available parameters. The definition of a type as above is then extended to polymorphic types that may contain parameters, and the definition of a term as above is extended to terms that may have polymorphic types.

Reasoning in higher-order logic can consist of theorem proving, via resolution or tableaus, for example, or can consist of equational reasoning, as is embodied in the computational mechanisms of functional programming languages, for example. Theorem proving and equational reasoning can even be combined to produce more flexible reasoning systems. Determining whether a formula is a theorem is, of course, undecidable.

The semantics for higher-order logic is generally based on Henkin (1950) models. Compared with first-order interpretations, the main extra ingredient is that, for each (closed) type of the form $\alpha \to \beta$, there is a domain that consists of some set of functions from the domain corresponding to α to the domain corresponding to β. There exist proof procedures that are sound and complete with respect to this semantics (Andrews 2002; Fitting 2002).

The logic includes the λ-calculus. Thus, the rules of λ-conversion are available:

1. (α-Conversion) $\lambda x.t \succ_\alpha \lambda y.(t\{x/y\})$, if y is not free in t.
2. (β-Reduction) $(\lambda x.s\ t) \succ_\beta s\{x/t\}$.
3. (η-Reduction) $\lambda x.(t\ x) \succ_\eta t$, if x is not free in t.

Here $s\{x/t\}$ denotes the result of replacing free occurrences of x in s by t, where free variable capture is avoided by renaming the relevant bound variables in s.

Higher-order generalization is introduced through the concept of least general generalization as follows (Feng and Muggleton 1992). A term s is *more general* than a term t if there is a substitution θ such that $s\theta$ is λ-convertible to t. A term t is a *common generalization* of a set T of terms if t is more general than each of the terms in T. A term t is a *least general generalization* of a set T of terms if t is a common generalization of T and, for all common generalizations s of T, t is not strictly more general than s.

Knowledge Representation

In machine learning applications, the individuals that are the subject of learning need to be represented. Using logic, individuals are most naturally represented by (closed) terms. In higher-order logic, advantage can be taken of the fact that sets can be identified with predicates (their characteristic functions). Thus, the set $\{1, 2\}$ is the term

$$\lambda x.\text{if } x = 1 \text{ then } \top \text{ else if } x = 2 \text{ then } \top \text{ else } \bot.$$

This idea generalizes to multisets and similar abstractions. For example,

$$\lambda x.\text{if } x = A \text{ then } 42 \text{ else if } x = B \text{ then } 21 \text{ else } 0$$

is the multiset with 42 occurrences of A and 21 occurrences of B (and nothing else). Thus, abstractions of the form

$$\lambda x.\text{if } x = t_1 \text{ then } s_1 \text{ else } \ldots \text{ if}$$
$$x = t_n \text{ then } s_n \text{ else } s_0$$

are adopted to represent (extensional) sets, multisets, and so on.

These considerations motivate the introduction of the class of basic terms that are used to represent individuals (Lloyd 2003). The definition of basic terms is an inductive one consisting of three parts. The first part covers data types such as lists and trees and uses the same constructs for this as are used in functional programming languages. The second part uses abstractions to cover data types such as (finite) sets and multisets, for which the data can be represented by a finite lookup table. The third part covers data types that are product types and therefore allows the representation of tuples. The definition is inductive in the sense that basic terms include lists of sets of tuples, tuples of sets, and so on.

It is common in learning applications to need to generate spaces of predicates. This is because features are typically predicates and logical hypothesis languages contain predicates. Thus, there is a need to specify grammars that can generate spaces of predicates. In addition to first-order approaches based on refinement operators or antecedent description grammars, higher-order logic offers another approach to this task based on the idea of generating predicates by composing certain primitive functions.

Predicate rewrite systems are used to define spaces of standard predicates, where standard predicates are predicates in a particular syntactic form that involves composing certain functions (Lloyd 2003). A predicate rewrite is an expression of the form $p \rightarrowtail q$, where p and q are standard predicates. The predicate p is called the *head* and q is the *body* of the rewrite. A predicate rewrite system is a finite set of predicate rewrites. One should think of a predicate rewrite system as a kind of grammar for generating a particular class of predicates. Roughly speaking, this works as follows. Starting from the weakest predicate *top*, all predicate rewrites that have *top* (of the appropriate type) in the head are selected to make up child predicates that consist of the bodies of these predicate rewrites. Then, for each child predicate and each redex (i.e., subterm selected for expansion) in that predicate, all child predicates are generated by replacing each redex by the body of the predicate rewrite whose head is identical to the redex. This generation of predicates continues to produce the entire space of predicates given by the predicate rewrite system.

Predicate rewrite systems are a convenient mechanism to specify precise control over the space of predicates that is to be generated. Note that predicate rewrite systems depend essentially on the higher-order nature of the logic since standard predicates are obtained by composition of functions and composition is a higher-order function.

Other ingredients of learning problems, such as background theories and training examples, can also be conveniently represented in higher-order logic.

Reasoning

Machine learning applications require that reasoning tasks be carried out, for example, computing the value of some predicate on some individual. Generally, reasoning in (higher-order) logic can be either theorem proving or purely equational reasoning or a combination of both.

A variety of proof systems have been developed for higher-order logic; these include Hilbert-style systems (Andrews 2002) and tableau systems (Fitting 2002).

Purely equational reasoning includes the computational models of functional programming languages and therefore can be usefully thought of as computation. Typical examples of this approach include the declarative programming languages of Curry (Hanus 2006) and Escher (Lloyd 2003) which are extensions of the functional programming language of Haskell (Peyton Jones 2003). For both Curry and Escher, the Haskell computational model is generalized in such a way as to admit the logic programming idioms.

Alternatively, by suitably restricting the fragment of the logic considered and the proof system, computation systems in the form of declarative programming languages can be developed. A prominent example of this approach is the logic programming language λProlog that was introduced in the 1980s (Nadathur and Miller 1998). In λProlog, program statements are higher-order hereditary Harrop formulas, a generalization of the definite ▶ clauses used by ▶ Prolog. The language provides an elegant use of λ-terms as data structures, metaprogramming facilities, universal quantification, and implications in goals, among other features.

Applications

Higher-order logic has been used in a variety of machine learning settings including decision tree learning, kernels, Bayesian networks, and evolutionary computing. Decision tree learning based on the use of higher-order logic as the knowledge representation and reasoning language is presented in Bowers et al. (2000) and further developed in Ng (2005b). Kernels and distances over individuals represented by basic terms are studied in Gärtner et al. (2004). In Gyftodimos and Flach (2005), Bayesian networks over basic terms are defined, and it is shown there how to construct probabilistic classifiers over such networks. In Ng et al. (2008), higher-order logic is used as the setting for studying probabilistic modeling, inference, and learning. An evolutionary approach to learning higher-order concepts is demonstrated in Kennedy and Giraud-Carrier (1999). In addition, the learnability of hypothesis languages expressed in higher-order logic is investigated in Ng (2005a, 2006).

Recurrent associative memory

Definition

The Hopfield network is a binary, fully recurrent network that, when started on a random activation state, settles the activation over time into a state that represents a solution (Hopfield and Tank 1986). This architecture has been analyzed thoroughly using tools from statistical physics. In particular, with symmetric weights, no self-connections, and asynchronous neuron activation updates, a Lyapunov function exists for the network, which means that the network activity will eventually settle. The Hopfield network can be used as an associate memory or as a general optimizer. When used as an associative memory, the weight values are computed from the set of patterns to be stored. During retrieval, part of the pattern to be retrieved is activated, and the network settles into the complete pattern. When used as an optimizer, the function to be optimized is mapped into the Lyapunov function of the network, which is then solved for the weight values. The network then settles to a state that represents the solution. The basic Hopfield architecture can be extended in many ways, including continuous neuron activations. However, it has limited practical value mostly because it is not strong in either of the above task: as an associative memory, its capacity is approximately $0.15N$ in practice (where N is the number of neurons), and as an optimizer, it often settles into local optima instead of the global one. The ▶ Boltzmann machine extends the architecture with hidden neurons, allowing for better performance in both tasks. However, the Hopfield network has had a large impact in the field because the theoretical techniques developed for it have inspired theoretical approaches for other architectures as well, especially for those of self-organizing systems (e.g., ▶ self-organizing maps, ▶ adaptive resonance theory).

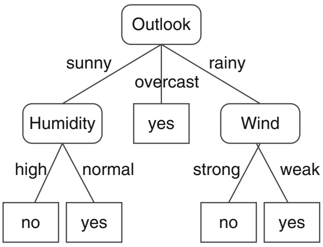
Representation language

Definition

The *hypothesis language* used by a machine learning system is the language in which the hypotheses (also referred to as patterns or models) it outputs are described.

Motivation and Background

Most machine learning algorithms can be seen as a procedure for deriving one or more hypotheses from a set of observations. Both the input (the observations) and the output (the hypotheses) need to be described in some particular language. This language is respectively called the ▶ Observation Language or the hypothesis



IF Outlook=sunny AND Humidity=high THEN Play=no
IF Outlook=sunny AND Humidity=normal THEN Play=yes
IF Outlook=overcast THEN Play=yes
IF Outlook=rainy AND Wind=strong THEN Play=no
IF Outlook=rainy AND Wind=weak THEN Play=yes

Hypothesis Language, Fig. 1 A decision tree and an equivalent rule set

language. These terms are mostly used in the context of symbolic learning, where these languages are often more complex than in subsymbolic or statistical learning. For instance, hypothesis languages have received a lot of attention in the field of ▸ Inductive Logic Programming, where systems typically take as one of their input parameters a declarative specification of the hypothesis language they are supposed to use (which is typically a strict subset of full clausal logic). Such a specification is also called a ▸ Language Bias.

Examples of Hypothesis Languages

The hypothesis language used obviously depends on the learning task that is performed. For instance, in predictive learning, the output is typically a function, and thus the hypothesis language must be able to represent functions; whereas in clustering the language must have constructs for representing clusters (sets of points). Even for one and the same goal, different languages may be used; for instance, decision trees and rule sets can typically represent the same type of functions, so the difference between these two is mostly syntactic.

In the following section, we discuss briefly a few different formalisms for representing hypotheses. For most of these, there are separate entries in this volume that offer more detail on the specifics of that formalism.

Decision Trees and Rule Sets

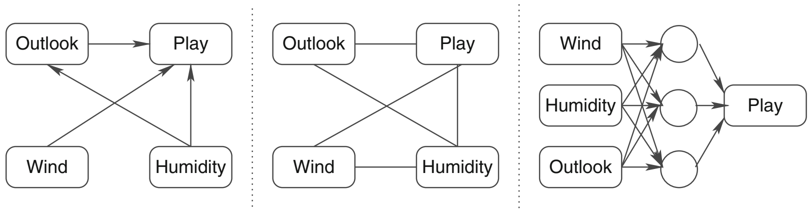
A ▸ Decision Tree represents a decision process where consecutive tests are performed on an instance to determine the value of its target variable, and at each step in this process, the test that is performed depends on the outcome of previous tests. Each leaf of the tree contains the set of all instances that fulfill the conjunctions of all conditions on the path from the root to this leaf, and as such a tree can easily be written as a set of if-then rules where each rule contains one such conjunction. If the target variable is boolean, this format corresponds to disjunctive normal form.

Figure 1 shows a decision tree and the corresponding rule set. (Inspired by Mitchell 1997).

Graphical Models

The term “graphical models” usually refers to probabilistic models where the joint distribution over a set of variables is defined as the product of a number of joint distributions over subsets of these variables (i.e., a factorization), and this factorization is defined by a graph structure. The graph may be directed, in which case we speak of a ▸ Bayesian Network, undirected, in which case we speak of a ▸ Markov Network, or even a mix of the two (so-called chain graphs). In a Bayesian network, the constituent distributions of the factorization are conditional probability functions associated with each node. In a Markov network, the constituent distributions are potential functions associated with each clique in the graph.

Two learning settings can be distinguished: learning the parameters of a graphical model given the model structure (the graph), and learning both structure and parameters of the model. In the first case, the graph is in fact a language bias specification: the user forces the learner to return a hypothesis that lies within the set of hypotheses



Hypothesis Language, Fig. 2 A Bayesian network, a Markov network, and a neural network

representable by this particular structure. In the second case, the structure of the graph makes explicit certain independencies that are hypothesized to exist between the variables (thus it is part of the hypothesis itself).

Figure 2 shows examples of possible graphical models that might be learned from data. For details about the interpretation of such graphical models, we refer to the respective entries in this encyclopedia.

Neural Networks

► Neural Networks are typically used to represent complex nonlinear functions. A neural network can be seen as a directed graph where the nodes are variables and edges indicate which variables depend on which other variables. Some nodes represent the observed input variables x_i and output variables y, and some represent new variables introduced by the network. Typically, a variable depends, in a nonlinear way, on a linear combination of those variables that directly precede it in the directed graph. The parameters of the network are numerical edge labels that represent the weight of a parent variable in that linear combination.

As with graphical models, one can learn the parameters of a neural network with a given structure, in which case the structure serves as a language bias; or one can learn both the structure and the parameters of the network.

Figure 2 shows an example of a neural network. We refer to the respective entry for more information on neural networks.

Instance-Based Learning

In the most basic version of ► instance-based learning, the training data set itself represents the hypothesis. As such, the hypothesis language is simply the powerset of the observation language. Because many instance-based learners rescale the dimensions of the input space, the vector containing the rescaling factors can be seen as part of the hypothesis. Similarly, some methods derived from instance-based learning build a model in which the training set instances are replaced by prototypes (one prototype being representative for a set of instances) or continuous functions approximating the instances.

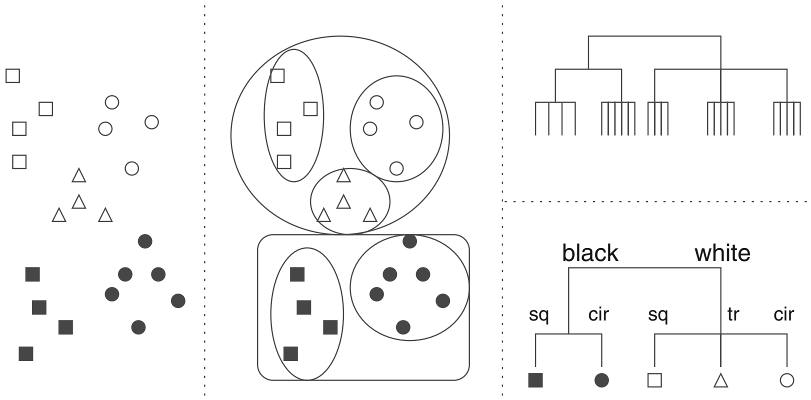
H

Clustering

In clustering tasks, there is an underlying assumption that there is a certain structure in the data set; that is, the data set is really a mixture of elements from different groups or clusters, with each cluster corresponding to a different population. The goal is to describe these clusters or populations and to indicate which data elements belong to which cluster.

Some clustering methods define the clusters extensionally, that is, they describe the different clusters in the dataset by just enumerating the elements in the dataset that belong to them. Other methods add an intensional description to the clusters, defining the properties that an instance should have in order to belong to the cluster; as such, these intensional methods attempt to describe the population that the cluster is a sample from. Some methods recursively group the clusters into larger clusters, building a cluster hierarchy. Figure 3 shows an example of such a cluster hierarchy.

The term “mixture models” typically refers to methods that return a probabilistic model (e.g., a Gaussian distribution with specified parameters) for each separate population identified. Being



Hypothesis Language, Fig. 3 A hierarchical clustering: *left*, the data set; *middle*: an extensional clustering shown on the data set; *right*, above: the corresponding extensional clustering tree; *right*, below: a corresponding intensional clustering tree, where the clusters are described based on color and shape of their elements

probabilistic in nature, these methods typically also assign data elements to the populations in a probabilistic, as opposed to deterministic, manner.

First-Order Logic Versus Propositional Languages

In symbolic machine learning, a distinction is often made between the so-called attribute-value (or propositional) and relational (or first-order) languages. The terminology "propositional" versus "first-order" originates in logic. In ▶ Propositional Logic, only the existence of propositions, which can be true or false, is assumed, and these propositions can be combined with the usual logical connectives into logical formulae. In ▶ First-Order Predicate Logic, the existence of a universe of objects is assumed as well as the existence of predicates that can express certain properties of and relationships between these objects. By adding variables and quantifiers, one can describe deductive reasoning processes in first-order logic that cannot be described in propositional logic. For instance, in propositional logic, one could state propositions *Socrates_is_human* and *all_humans_are_mortal* (both are statements that may be true or false), but there is no inherent relationship between them. In first order logic, the formulae $human(Socrates)$ and $\forall x\colon human(x) \rightarrow mortal(x)$ allow one to deduce $mortal(Socrates)$. A more extensive explanation of the differences between propositional and first-order logic can be found in the entry on ▶ First-Order Logic.

Many machine learning approaches use an essentially propositional language for describing observations and hypotheses. In the fields of Inductive Logic Programming and ▶ Relational Learning, more powerful languages are used, with an expressiveness closer to that of first-order logic. Many of the representation languages mentioned above, which are essentially propositional, have been extended towards the first-order logic context.

The simplest example is that of rule sets. If-then rules have a straightforward counterpart in first-order logic in the form of ▶ Clauses, which are usually written as logical implications where all variables are interpreted as universally quantified. For instance, the rule "IF Human = true THEN Mortal = true" can be written in clausal form as

$$\mathrm{mortal}(x) \leftarrow \mathrm{human}(x). \tag{1}$$

Propositional rules correspond to clauses that refer to only one object (and the object reference is implicit). A rule such as

$$\mathrm{grandparent}(x, y) \leftarrow \mathrm{parent}(x, z), \mathrm{parent}(z, y) \tag{2}$$

(expressing that, for any x, y, z, whenever x is a parent of z and z is a parent of y, x is a grandparent of y) has no translation into propositional logic that retains the inference capacity of the first-order logic clause.

Clauses are a natural first-order logic equivalent to the if-then rules typically returned by rule learners, and many of the other representation languages have also been upgraded to the relational or first-order-logic context. For instance, several researchers (e.g., Blockeel and De Raedt 1998) have upgraded the formalism of decision trees toward "structural" or "first-order logic" decision trees. Probabilistic relational models (Getoor et al. 2001) and Bayesian logic programs (Kersting and De Raedt 2001) are examples of how Bayesian networks have been upgraded, while Markov networks have been lifted to "Markov logic" (Richardson and Domingos 2006).

Further Reading

Most of the literature on hypothesis and observation languages is found in the area of inductive logic programming. Excellent starting points, containing extensive examples of bias specifications, are *Relational Data Mining* by Džeroski and Lavra (2001), *Logic for Learning* by Lloyd (2003), and *Logical and Relational Learning* by De Raedt (2008).

De Raedt (1998) compares a number of different observation and hypothesis languages with respect to their expressiveness, and indicates relationships between them.

Hypothesis Space

Hendrik Blockeel
Katholieke Universiteit Leuven, Heverlee, Leuven, Belgium
Leiden Institute of Advanced Computer Science, Heverlee, Belgium

Synonyms

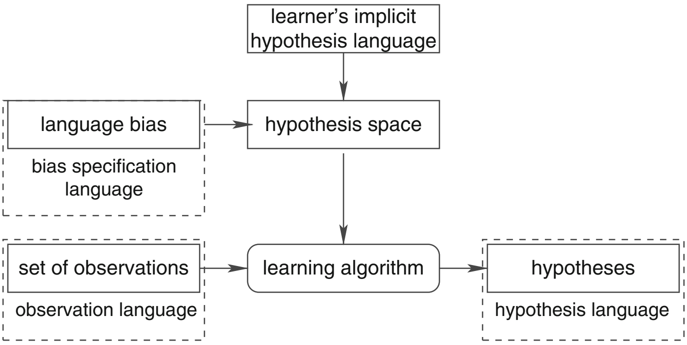
Model space

Definition

The *hypothesis space* used by a machine learning system is the set of all hypotheses that might possibly be returned by it. It is typically defined by a ▶ Hypothesis Language, possibly in conjunction with a ▶ Language Bias.

Motivation and Background

Many machine learning algorithms rely on some kind of search procedure: given a set of observations and a space of all possible hypotheses that



Hypothesis Space, Fig. 1 Structure of learning systems that derive one or more hypotheses from a set of observations

might be considered (the "hypothesis space"), they look in this space for those hypotheses that best fit the data (or are optimal with respect to some other quality criterion).

To describe the context of a learning system in more detail, we introduce the following terminology. The key terms have separate entries in this encyclopedia, and we refer to those entries for more detailed definitions.

A learner takes observations as inputs. The ▸ Observation Language is the language used to describe these observations.

The hypotheses that a learner may produce, will be formulated in a language that is called the Hypothesis Language. The *hypothesis space* is the set of hypotheses that can be described using this hypothesis language.

Often, a learner has an implicit, built-in, hypothesis language, but in addition the set of hypotheses that can be produced can be restricted further by the user by specifying a language bias. This language bias defines a subset of the hypothesis language, and correspondingly a subset of the hypothesis space. A separate language, called the ▸ Bias Specification Language, is used to define this language bias. Note that while elements of a hypothesis language refer to a single hypothesis, elements of a bias specification language refer to sets of hypotheses, so these languages are typically quite different. Bias specification languages have been studied in detail in the field of ▸ Inductive Logic Programming.

The terms "hypothesis language" and "hypothesis space" are sometimes used in the broad sense (the language that the learner is inherently restricted to, e.g., Horn clauses), and sometimes in a more narrow sense, referring to the smaller language or space defined by the language bias.

The structure of a learner, in terms of the above terminology, is summarized in Fig. 1.

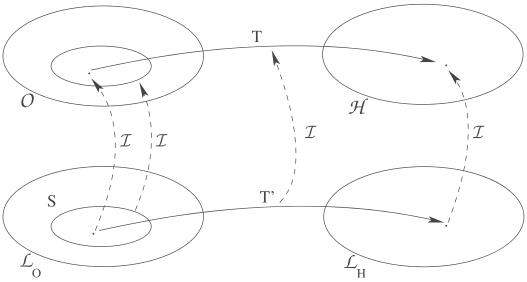
Theory

For a given learning problem, let us denote with $\mathcal{O}$ the set of all possible observations (sometimes also called the instance space), and with $\mathcal{H}$ the hypothesis space, i.e., the set of all possible hypotheses that might be learned. Let $2X$ denote the power set of a set X. Most learners can then be described abstractly as a function $T : 2^{\mathcal{O}} \rightarrow \mathcal{H}$, which takes as input a set of observations (also called the training set) $S \subseteq \mathcal{O}$, and produces as output a hypothesis $h\epsilon\mathcal{H}$.

In practice, the observations and hypotheses are represented by elements of the observation language $\mathcal{L}_O$ and the hypothesis language $\mathcal{L}_H$, respectively. The connection between language elements and what they represent is defined by functions $\mathcal{I}_O : \mathcal{L}_O \rightarrow \mathcal{O}$ (for observations) and $\mathcal{I}_H : \mathcal{L}_H \rightarrow \mathcal{H}$ (for hypotheses). This mapping is often, but not always, bijective. When it is not bijective, different representations for the same hypothesis may exist, possibly leading to redundancy in the learning process.

We will use the symbol $\mathcal{I}$ as a shorthand for $\mathcal{I}_O$ or $\mathcal{I}_H$. We also define the application of $\mathcal{I}$ to any set S as $\mathcal{I}_S = \{\mathcal{I}(x)|x \in S\}$, and to any function f as $\mathcal{I}(f) = g \Leftrightarrow \forall x : g(\mathcal{I}(x)) = \mathcal{I}(f(x))$.

Thus, a machine learning system really implements a function $T' : 2^{\mathcal{L}_O} \rightarrow \mathcal{L}_H$, rather than a function $T : 2^{\mathcal{O}} \rightarrow \mathcal{H}$. The connection



Hypothesis Space, Fig. 2 Illustration of the interpretation function $\mathcal{I}$ mapping $\mathcal{L}_O, \mathcal{L}_H$, and T' onto $\mathcal{O}, \mathcal{H}$, and T

between T' and T is straightforward: for any $S \subseteq \mathcal{L}_O$ and $h \in \mathcal{L}_H, T'(S) = h$ if and only if $T(\mathcal{I}(S)) = \mathcal{I}(h)$; in other words: $T = \mathcal{I}(T')$.

Figure 2 summarizes these languages and spaces and the connections between them. We further illustrate them with a few examples.

Example 1 In supervised learning, the observations are usually pairs (x, y) with $x \in X$ an instance and $y \in Y$ its label, and the hypotheses are functions mapping X onto Y. Thus $\mathcal{O} = X \times Y$ and $\mathcal{H} \subseteq Y^X$, with Y^X the set of all functions from X to Y. $\mathcal{L}_O$ is typically chosen such that $\mathcal{I}(\mathcal{L}_O) = \mathcal{O}$, i.e., each possible observation can be represented in $\mathcal{L}_O$. In contrast to this, in many cases $\mathcal{I}(\mathcal{L}_H)$ will be a strict subset of Y^X, i.e., $\mathcal{I}(\mathcal{L}_H) \subset Y^X$. For instance, $\mathcal{L}_H$ may contain representations of all polynomial functions from X to Y if $X = \mathbf{R}^n$ and $Y = \mathbf{R}$ (with $\mathbf{R}$ the set of real numbers), or may be able to represent all conjunctive concepts over X when $X = \mathbf{B}^n$ and $Y = \mathbf{B}$ (with $\mathbf{B}$ the set of booleans).

When $\mathcal{I}(\mathcal{L}_H \subset Y^X$, the learner cannot learn every imaginable function. Thus, $\mathcal{L}_H$ reflects an inductive bias that the learner has, called its *language bias*. We can distinguish an implicit language bias, inherent to the learning system, and corresponding to the hypothesis language (space) in the broad sense, and an explicit language bias formulated by the user, corresponding to the hypothesis language (space) in the narrow sense.

Example 2 Decision tree learners and rule set learners use a different language for representing the functions they learn (call these languages $\mathcal{L}_{DT}$ and $\mathcal{L}_{RS}$, respectively), but their language bias is essentially the same: for instance, if $X = \mathbf{B}^n$ and $Y = \mathbf{B}, \mathcal{I}(\mathcal{L}_{DT}) = \mathcal{I}(\mathcal{L}_{RS}) = Y^X$: both trees and rule sets can represent any boolean function from $\mathbf{B}^n$ to $\mathbf{B}$.

In practice a decision tree learner may employ constraints on the trees that it learns, for instance, it might be restricted to learning trees where each leaf contains at least two training set instances. In this case, the actual hypothesis language used by the tree learner is a subset of the language of all decision trees.

Generally, if the hypothesis language in the broad sense is $\mathcal{L}_H$ and the hypothesis language in the narrow sense is $\mathcal{L}'_H$, then we have $\mathcal{L}'_H \subseteq \mathcal{L}_H$ and the corresponding spaces fulfill (in the case of supervised learning)

$$\mathcal{I}(\mathcal{L}'_H) \subseteq \mathcal{I}(\mathcal{L}_H) \subseteq Y^X. \qquad (1)$$

Clearly, the choice of $\mathcal{L}_O$ and $\mathcal{L}_H$ determines the kind of patterns or hypotheses that can be expressed. See the entries on Observation Language and Hypothesis Language for more details on this.

Further Reading

The term "hypothesis space" is ubiquitous in the machine learning literature, but few articles discuss the concept itself. In Inductive Logic Programming, a significant body of work exists on how to define a language bias (and thus a hypothesis space), and on how to automatically weaken the bias (enlarge the hypothesis space) when a given bias turns out to be too strong. The expressiveness of particular types of learners (e.g., classes of ▶ Neural Networks) has been studied, and this relates directly to the hypothesis space they use. We refer to the respective entries in this volume for more information on these topics.

Immune Network

A proposed theory that the immune system is capable of achieving immunological memory by the existence of a mutually reinforcing network of B-cells. This network of B-cells forms due to the ability of the paratopes, located on B-cells, to match against the idiotopes on other B-cells. The binding between the idiotopes and paratopes has the effect of stimulating the B-cells. This is because the paratopes on B-cells react to the idiotopes on similar B-cells, as it would an antigen. However, to counter the reaction there is a certain amount of suppression between the B-cells which acts as a regulatory mechanism. This interaction of the B-cells due to the network was said to contribute to a *stable* memory structure and account for the retainment of memory cells, even in the absence of antigen. This interaction of cells forms the basis of inspiration for a large number of AIS algorithms, for example aiNET.

Incremental Learning

Paul E. Utgoff
University of Massachusetts, Amherst, MA, USA

Definition

Incremental learning refers to any ▸ online learning process that learns the same model as would be learned by a ▸ batch learning algorithm.

Motivation and Background

Incremental learning is useful when the input to a learning process occurs as a stream of distinct observations spread out over time, with the need or desire to be able to use the result of learning at any point in time, based on the input observations received so far. In principle, the stream of observations may be infinitely long, or the next observation long delayed, precluding any hope of waiting until all the observations have been received. Without the ability to forestall learning, one must commit to a sequence of hypotheses or other learned artifacts based on the inputs observed up to the present. One would rather not simply accumulate and store all the inputs and, upon receipt of each new one, apply a batch learning algorithm to the entire sequence of inputs received so far. It would be preferable computationally if the existing hypothesis or other artifact of learning could be updated in response to each newly received input observation.

Theory

Consider the problem of computing the balance in one's checkbook account. Most would say that this does not involve learning, but it illustrates an important point about incremental algorithms. One procedure, a batch algorithm based on the fundamental definition of balance, is to compute the balance as the sum of the deposits less the sum of the checks and fees. As deposit, check, and fee transactions accumulate, this definition remains valid. There is an expectation that there will be more transactions in the future, and there is also a need to compute the balance periodically to ensure that no contemplated check or fee will cause the account to become overdrawn. We cannot wait to receive all of the transactions and then compute the balance just once.

One would prefer an incremental algorithm for this application, to reduce the cost of computing the balance after each transaction. This can be accomplished by recording and maintaining one additional piece of information, the balance after the nth transaction. It is a simple matter to prove that the balance after n transactions added to the amount of transaction $n + 1$ provides the balance after $n + 1$ transactions. This is because the sums of the fundamental definition for $n + 1$ transactions can be rewritten as the sums of the fundamental definition for n transactions plus the amount of the nth transaction. This incremental algorithm reduces the computation necessary to know the balance after each transaction, but it increases the bookkeeping effort somewhat due to the need for an additional variable.

Now consider the problem of learning the mean of a real-valued variable from a stream of observed values of this variable. Though simple, most would say that this does involve learning, because one estimates the mean from observations, without ever establishing the mean definitively. The fundamental definition for the mean requires summing the observed values and then dividing by the number of observed values. As each new observation is received, one could compute the new mean. However, one can reduce the computational cost by employing an incremental algorithm. For n observations, we could just as well have observed exactly the n occurrences of the mean. The sum of these observations divided by n would produce the mean. If we were to be provided with an $n + 1$ observation, we could compute the new sum of the $n + 1$ observations as n cases of the mean value plus the new observation, divided by $n + 1$. This reduces the cost of computing the mean after each observation to one multiplication, two addition, and one division operations. There is a small increase in bookkeeping in maintaining the counter n of how many observations have been received and the mean m after n observations.

In both of the above examples, the need to record the fundamental data is eliminated. Only a succinct summary of the data needs to be retained. For the checkbook balance, only the balance after n transactions needs to be stored, making the specific amounts for the individual transactions superfluous. For the mean of a variable, only the mean m after n observations and the number n of observations need to be retained, making the specific values of the individual observations superfluous. Due to this characteristic, incremental algorithms are often characterized as memoryless, not because no memory at all is required but because no memory of the original data items is needed. An incremental algorithm is not required to be memoryless, but the incremental algorithm must operate by modifying its existing knowledge, not by hiding the application of the corresponding batch algorithm to the accumulated set of observations. The critical issue is the extent to which computation is reduced compared to starting with all the data observations and nothing more. An essential aspect for an incremental algorithm is that the obtained result be identical to that indicated by the fundamental definition of the computation to be performed.

A point of occasional confusion is whether to call an algorithm incremental when it makes adjustments to its data structures in response to a new data observation. The answer depends on whether the result is the same that one would obtain when starting with all the observations in hand. If the answer is no, then one may have an online learning algorithm that is not an incremental learning algorithm. For example, consider two alternative formulations of the problem mentioned above of learning the mean of a variable. Suppose that the count of observations, held in the variable n, is not permitted to exceed some constant, say 100. Then the mean after n observations coupled with the minimum of n and 100 no longer summarizes all n observations accurately. Consider a second reformulation. Suppose that the most recent 100 observations are held in a queue. When a new observation is received, it replaces the oldest of the 100 observations. Now the algorithm can maintain a moving average, but not the overall overage. These may be desirable, if one wishes to remain responsive to drift in the observations, but that is another matter. The algorithm would not be considered incremental because it does not produce the same result for all n observations that the corresponding batch algorithm would for these same n observations. The algorithm would be online, and it would be memoryless, but it would not be computing the same learned artifact as the batch algorithm.

These two latter reformulations raise the issue of whether the order in which the observations are received is relevant. It is often possible to determine this by looking at the fundamental definition of the computation to be performed. If the operator that aggregates the observations is commutative, then order is not important. For the checking account balance example above, the fundamental aggregation is accomplished in the summations, and addition is commutative, so the order of the transactions is not relevant to the resulting balance. If a fundamental algorithm operates on a set of observations, then aggregation of a new observation into a set of observations is accomplished by the set union operator, which is commutative. Can one have an incremental algorithm for which order of the observations is important? In principle, yes, provided that the result of the incremental algorithm after observation n is the same as that of the fundamental algorithm for the first n observations.

A final seeming concern for an incremental learning algorithm is whether the selection of future observations ($n+1$ and beyond) is influenced by the first n observations. This is a red herring, because for the n observations, the question of whether the learning based on these observations can be accomplished by a batch algorithm or a corresponding incremental algorithm remains. Of course, if one needs to use the result of learning on the first k instances to help select the $k + 1$ instance, then it would be good sense to choose an incremental learning algorithm. One would rather not apply a batch algorithm to each and every prefix of the input stream. This would require saving the input stream and it would require doing much more computation than is necessary.

We can consider a few learning scenarios which suit incremental learning. An ▸ active learner uses its current knowledge to select the next observation. For a learner that is inducing a classifier, the observation would be an unclassified instance. The active learner selects an unclassified instance, which is passed to an oracle that attaches a correct class label. Then the oracle returns the labeled instance as the next observation for the learner. The input sequence is no longer one of instances for which each was drawn independently according to a probability distribution over the possible instances. Instead, the distribution is conditionally dependent on what the learner currently believes. The learning problem is sequential in its nature. The observation can be delivered in sequence, and an incremental learning algorithm can modify its hypothesis accordingly. For the n observations received so far, one could apply a corresponding batch algorithm, but this would be unduly awkward.

▸ Reinforcement learning is a kind of online learning in which an agent makes repeated trials in a simulated or abstracted world in order to learn a good, or sometimes optimal, policy that maps states to actions. The learning artifact is typically a function V over states or a function Q over state-action pairs. As the agent moves from state to state, it can improve its function over time. The choice of action depends on the current V or Q and on the reward or punishment received at each step. Thus, the sequence of observations consists of state-reward pairs or state-action-reward triples. As with active learning, the sequence of observations can be seen as being conditionally dependent on what the learner currently believes at each step. The function V or Q can be modified after each observation, without retaining the observation. When the function is approximated in an unbiased manner, by using a lookup table for discrete points in the function domain, there is an analogy with the problem of computing a checkbook balance, as described above. For each cell of the lookup table, its value is its initial value plus the sum of the changes, analogously for transactions. One can compute the function value by computing this sum, or one can store the sum in the cell, as the net value of all the changes. An incremental algorithm is preferable both for reasons of time and space.

A k-nearest classifier (see ▸ Instance-Based Learning) is defined by a set of training instances, the observations, and a distance metric that returns the numeric distance between any two instances. The difference between the batch algorithm and the incremental algorithm is slight. The batch algorithm accepts all the observations at once, and the incremental algorithm simply adds each new observation to the set of observations. If, however, there were data structures kept in the background to speed computation, one could distinguish between building those data structures once (batch) and updating those data structures (incremental). One complaint might be that all of the observations are retained. However, these observations do not need to be revisited when a new one arrives. There is an impact on space, but not on time.

A ▸ decision tree classifier may be correct for the n observations observed so far. When the $n+1$ observation is received, an incremental algorithm will restructure the tree as necessary to produce the tree that the batch algorithm would have built for these $n + 1$ observations. To do this, it may be that no restructuring is required at all or that restructuring is needed only in a subtree. This is a case in which memory is required for saving observations in the event that some of them may be needed to be reconsidered from time to time. There is a great savings in time over running the corresponding batch algorithm repeatedly.

Applications

Incremental learning is pervasive, and one can find any number of applications described in the literature and on the web. This is likely due to the fact that incremental learning offers computational savings in both time and space. It is also likely due to the fact that human and animal learning takes place over time. There are sound reasons for incremental learning being essential to development.

Future Directions

Increasingly, machine learning is confronted with the problem of learning from input streams that contain many millions, or more, of observations. Indeed, the stream may produce millions of observations per day. Streams with this many instances need to be handled by methods whose memory requirements do not grow much or at all. Memoryless online algorithms are being developed that are capable of handling this much throughput. Consider transaction streams, say of a telephone company, or a credit card company, or a stock exchange, or a surveillance camera, or eye-tracking data, or mouse movement data. For such a rich input stream, one could sample it, thereby reducing it to a smaller stream. Or, one could maintain a window of observations, giving a finite sample that changes but does not grow over time. There is no shortage of applications that can produce rich input streams. New methods capable of handling such heavy streams have already appeared, and we can expect to see growth in this area.

Induction

James Cussens
University of York, Heslington, UK

Definition

Induction is the process of inferring a general rule from a collection of observed instances. Sometimes it is used more generally to refer to any inference from premises to conclusion where the truth of the conclusion does not follow deductively from the premises, but where the premises provide evidence for the conclusion. In this more general sense, induction includes *abduction* where facts rather than rules are inferred. (The word "induction" also denotes a different, entirely deductive form of argument used in mathematics.)

Theory

Hume's Problem of Induction

The *problem of induction* was famously set out by the great Scottish empiricist philosopher David Hume (1711–1776), although he did not actually use the word "induction" in this context. With characteristic bluntness, he argued that:

> there can be no *demonstrative* arguments to prove *that those instances of which we have had no experience resemble those of which we have had experience* (Hume 1739, Part 3, Section 6).

Since scientists (and machine-learning algorithms) *do* infer future-predicting general laws from past observations, Hume is led to the following unsettling conclusion concerning human psychology (and statistical inference):

> It is not, therefore, reason, which is the guide of life, but custom. That alone determines the mind, in all instances, to suppose the future conformable to the past (Hume 1740).

That general laws cannot be demonstrated (i.e., deduced) from data is generally accepted. Hume, however, goes further: he argues that past observations do not even affect the *probability* of future events:

> Nay, I will go farther, and assert, that he could not so much as prove by any *probable* arguments, that the future must be conformable to the past. All probable arguments are built on the supposition, that there is this conformity betwixt the future and the past, and therefore can never prove it. This conformity is a *matter of fact*, and if it must be proved, will admit of no proof but from experience. But our experience in the past can be a proof of nothing for the future, but upon a supposition, that there is a resemblance betwixt them. This therefore is a point, which can admit of no proof at all, and which we take for granted without any proof (Hume 1740).

Induction and Probabilistic Inference

Hume's unwavering skepticism concerning prediction appears at variance with the predictive accuracy of machine learning algorithms: there is much experimental evidence that ML algorithms, once trained on "past observations," make predictions on unseen cases with an accuracy far in excess of what can be expected by chance. This apparent discrepancy between Hume's philosophy and practical experience of statistical inference can be explored using a familiar example from the literature on induction. Let e be the statement that all swans seen so far have been white and let h be the general rule that all swans are white. Since h implies e it follows that $P(e|h) = 1$ and so, using Bayes' theorem, we have that

$$P(h|e) = \frac{P(h)P(e|h)}{P(e)} = \frac{P(h)}{P(e)}. \qquad (1)$$

So $P(h|e) > P(h)$ as long as $P(e) < 1$ and $P(h) > 0$. This provides an explanation for the predictive accuracy of hypotheses supported by data: given supporting data they just have increased probability of being true. Of course, most machine learning outputs are not "noise-free" rules like h; almost always hypotheses claim a certain distribution for future data where no particular observation is ruled out entirely – some are just more likely than others. The same basic argument applies: if $P(h) > 0$ then as long as the observed data is more likely given the hypothesis than it is a priori, that is, as long as $P(e|h)/P(e) > 1$, then the probability of h will increase. Even in the (common) case where each hypothesis in the hypothesis space depends on real-valued parameters and so $P(h) = 0$ for all h, Bayes theorem still produces an increase in the probability *density* in the neighborhoods of hypotheses supported by the data.

In all these cases, it appears that e is giving "inductive support" to h. Consider, however, $h\prime$ which states that all swans until now have been white and *all future swans will be black*. Even in this case, we have that $P(h'|e) > P(h')$ as long as $P(e) < 1$ and $P(h') > 0$, though h and h' make entirely contradictory future predictions. This is a case of Goodman's paradox. The paradox is the result of confusing probabilistic inference with inductive inference. Probabilistic inference, of which Bayes theorem is an instance, is entirely deductive in nature – the conclusions of all probabilistic inferences follow with absolute certainty from their premises (and the axioms of probability). $P(h|e) > P(h)$ for $P(e) < 1$ and $P(h) > 0$ essentially because e has (deductively) ruled out some data that might have refuted h, not because a "conformity betwixt the future and the past" has been established.

Good performance on unseen data can still be explained. Statistical models (equivalently machine learning algorithms) *make assumptions* about the world. These assumptions (so far!) often turn out to be correct. Hume noted that the principle "that like objects, placed in like circumstances, will always produce like effects" (Hume 1739, Part 3, Section 8) although not deducible from first principles, has been established by "sufficient custom." This is called the *uniformity of nature* principle in the philosophical literature. It is this principle which informs machine learning systems. Consider the standard problem of predicting class labels for attribute-value data using labeled data as training. If an unlabeled test case has attribute values which are "close" to those of many training examples all of which have the same class label then in most systems the test case will be labeled also with this class. Different systems differ in how they measure "likeness": they differ in their ▶ inductive bias. A system which posited h' above on the basis of e would have an inductive bias strongly at variance with the uniformity of nature principle.

These issues resurfaced within the machine learning community in the 1990s. This ML work focused on various "▶ *no-free-lunch theorems*." Such a theorem essentially states that a uniformity of nature assumption is required to justify any given inductive bias. This is how Wolpert puts in one of the earliest "no-free-lunch" papers:

> This paper proves that it is impossible to justify a correlation between reproduction of a training set and generalization error off of the training set using only a priori reasoning. As a result, the use in the real world of any generalizer which fits a hypothesis function to a training set (e.g., the use of back-propagation) is implicitly predicated on an assumption about the physical universe (Wolpert 1992).

Note that in Bayesian approaches inductive bias is encapsulated in the prior distribution: once a prior has been determined all further work in Bayesian statistics is entirely deductive. Therefore it is no surprise that inductivists have sought to find "objective" or "logical" prior distributions to provide a firm basis for inductive inference. Foremost among these is Rudolf Carnap (1891–1970) who followed a logical approach – defining prior distributions over "possible worlds" (first-order models) which were in some sense uniform (Carnap 1950). A modern extension of this line of thinking can be found in Bacchus et al. (1996).

Popper

Karl Popper (1902–1994) accepted the Humean position on induction yet sought to defend science from charges of irrationality (Popper 1934). Popper *replaced* the problem of induction by the problem of criticism. For Popper, scientific progress proceeds by conjecturing universal laws and then subjecting these laws to severe tests with a view to refuting them. According to the *verifiability principle* of the logical positivist tradition, a theory is scientific if it can be experimentally confirmed, but for Popper confirmation is a hopeless task, instead a hypothesis is only scientific if it is *falsifiable*. All universal laws have prior probability of zero, and thus will eternally have probability zero of being true, no matter how many tests they pass. The value of a law can only be measured by how well-tested it is. The degree to which a law has been tested is called its degree of *corroboration* by Popper. The $P(e|h)/P(e)$ term in Bayes theorem will be high if a hypothesis h has passed many severe tests.

Popper's critique of inductivism continued throughout his life. In the *Popper–Miller* argument (Popper and Miller 1984), as it became known, it is observed that a hypothesis h is logically equivalent to:

$$(h \leftarrow e) \wedge (h \vee e)$$

for any evidence e. We have that $e \vdash h \vee e$ (where $\vdash$ means "logically implies") and also that (under weak conditions) $p(h \leftarrow e|e) < p(h \leftarrow e)$. From this Popper and Miller argue that

> ... we find that what is left of h once we discard from it everything that is logically implied by e, is a proposition that in general is counterdependent on e (Popper and Miller 1987)

and so.

> Although evidence may raise the probability of a hypothesis above the value it achieves on background knowledge alone, every such increase in probability has to be attributed entirely to the *deductive connections* that exist between the hypothesis and the evidence (Popper and Miller 1987).

In other words if $P(h|e) > P(h)$ this is only because $e \vdash h \vee e$. The Popper–Miller argument found both critics and supporters. Two basic arguments of the critics were that (1) deductive relations only set limits to probabilistic support; infinitely many probability distributions can still be defined on any given fixed system of propositions and (2) Popper–Miller are mischaracterizing induction as the absence of deductive relations, when it actually means *ampliative inference*: concluding more than the premises entail (Cussens 1996).

Causality and Hempel's Paradox

The branch of philosophy concerned with how evidence can confirm scientific hypotheses is known as ▸ *confirmation theory*. Inductivists take the position (against Popper) that observing data which follows from a hypothesis not only fails to refute the hypothesis, but also *confirms* it to some degree: seeing a white swan confirms the hypothesis that all swans are white, because

$$\begin{aligned}\forall x:\ \mathrm{swan}(x) \to \mathrm{white}(x), \mathrm{swan}(\mathrm{white\_swan})\\ \vdash \mathrm{swan}(\mathrm{white\_swan}).\end{aligned}$$

But, by the same argument it follows that observing any nonwhite, nonswan (say a black raven) also confirms that all swans are white, since:

$$\begin{aligned}\forall x:\ \mathrm{swan}(x) \to \mathrm{white}(x), \neg\mathrm{white}(\mathrm{black\_reven})\\ \vdash \neg(\mathrm{black\_reven}).\end{aligned}$$

This is Hempel's paradox to which there are a number of possible responses. One option is to accept that the black raven is a confirming instance, as one object in the universe has been ruled out as a potential refuter. The *degree* of confirmation is however of "a miniscule and negligible degree" (Howson and Urbach 1989, p. 90). Another option is to reject the formulation of the hypothesis as a material implication where $\forall x:\ \mathrm{swan}(x) \to \mathrm{white}(x)$ is just another way of writing $\forall x:\ \neg\mathrm{swan}(x) \vee \mathrm{white}(x)$. Instead, to be a scientific hypothesis of any interest the statement must be interpreted *causally*. This is the view of Imre Lakatos (1922–1974), and since any causal statement has a (perhaps implicit) *ceteris paribus* ("all other things being equal") clause this has implications for refutation also.

> . . . "all swans are white," if true, would be a mere curiosity unless it asserted that swanness *causes* whiteness. But then a black swan would not refute this proposition, since it may only indicate *other causes* operating simultaneously. Thus "all swans are white" is either an oddity and easily disprovable or a scientific proposition with a ceteris paribus clause and therefore easily undisprovable (Lakatos 1970, p. 102).

Inductive Bias

Synonyms

Learning bias; Variance hint

Definition

Most ML algorithms make predictions concerning future data which cannot be deduced from already observed data. The inductive bias of an algorithm is what choses between different possible future predictions. A strong form of inductive bias is the learner’s choice of hypothesis/model space which is sometimes called *declarative bias*. In the case of Bayesian analysis, the inductive bias is encapsulated in the prior distribution.

Inductive Database Approach to Graphmining

Stefan Kramer
Technische Universität München, Garching b. München, Germany

Overview

The inductive database approach to graph mining can be characterized by (1) the concept of querying for (subgraph) patterns in databases of graphs, and (2) the use of specific data structures representing the space of solutions. For the former, a query language for the specification of the patterns of interest is necessary. The latter aims at a compact representation of the solution patterns.

Pattern Domain

In contrast to other graph mining approaches, the inductive database approach to graph mining (De Raedt and Kramer 2001; Kramer et al. 2001) focuses on simple patterns (paths and trees) and complex queries (see below), not on complex patterns (general subgraphs) and simple queries (minimum frequency only). While the first approaches were restricted to paths as patterns in graph databases, they were later extended toward unrooted trees (Rückert and Kramer 2003, 2004). Most of the applications are dealing with structures of small molecules and structure–activity relationships (SARs), that is, models predicting the biological activity of chemical compounds.

Query Language

The conditions on the patterns of interest are usually called *constraints* on the solution space. Simple constraints are specified by so-called *query primitives*. Query primitives express frequency-related or syntactic constraints. As an example, consider the frequency-related query primitive $f(p, D) \geq t$, meaning that a subgraph pattern p has to occur with a frequency of at least t in the database of graphs D. Analogously, other frequency-related primitives demand a maximum frequency of occurrence, or a minimum agreement with the target class (e.g., in terms of the information gain or the χ^2 statistic). Answering frequency-related queries generally requires database access. In contrast to frequency-related primitives, syntax-related primitives only restrict the syntax of solution (subgraph) patterns, and thus do not require database access. For instance, we may demand that a pattern p is more specific than “*c:c-Cl*” (formally $p \geq$ *c:c-Cl*) or more general than “*C-c:c:c:c:c-Cl*” (formally $p \leq$ *C-c:c:c:c:c-Cl*). The strings in the primitive contain vertex (e.g., “*C*,” “*c*,” “*Cl*”. . .) and edge labels (e.g., “ : ,” “-”. . .) of a path in a graph. Many constraints on patterns can be categorized as either monotonic or anti-monotonic. Minimum frequency constraints, for instance, are anti-monotonic, because all subpatterns (in our case: subgraphs) are frequent as well, if a pattern is frequent (according to some user-defined threshold) in a database. Vice versa, maximum frequency is monotonic, because if a pattern is not too frequent, then all superpatterns (in our case: supergraphs) are not too frequent either. Anti-monotonic or monotonic constraints can be solved by variants of levelwise search and APriori (De Raedt and Kramer 2001; Kramer et al. 2001; Mannila and Toivonen 1997). Other types of constraints involving convex functions, for example, related to the target class, can be solved by branch-and-bound algorithms (Morishita and Sese 2000). Typical query languages offer the possibility to combine query primitives conjunctively or disjunctively.

Data Structures

It is easy to show that solutions to conjunctions of monotonic and anti-monotonic constraints can be represented by *version spaces*, and in particular, borders of the most general and the most specific patterns satisfying the constraints (De Raedt and Kramer 2001; Mannila and Toivonen 1997). Version spaces of patterns can be represented in data structures such as *version space trees* (De Raedt et al. 2002; Rückert and Kramer 2003). For sequences, data structures based on *suffix arrays* are known to be more efficient than data structures based on version spaces (Fischer et al. 2006). Query languages allowing disjunctive normal forms of monotonic or anti-monotonic primitives yield multiple version spaces as solutions, represented by generalizations of version space trees (Lee and De Raedt 2003). The inductive database approach to graph mining can also be categorized as *constraint-based mining*, as the goal is to find solution patterns satisfying user-defined constraints.

Inductive Inference

Sanjay Jain[1] and Frank Stephan[2]
[1]School of Computing, National University of Singapore, Singapore, Singapore
[2]Department of Mathematics, National University of Singapore, Singapore, Singapore

Definition

Inductive inference is a theoretical framework to model learning in the limit. The typical scenario is that the learner reads successively datum

$d_0, d_1, d_2, \ldots$ about a concept and outputs in parallel hypotheses $e_0, e_1, e_2, \ldots$ such that each hypothesis e_n is based on the preceding data $d_0, d_1, \ldots, d_{n-1}$. The hypotheses are expected to converge to a description for the data observed; here the constraints on how the convergence has to happen depend on the learning paradigm considered. In the most basic case, almost all e_n have to be the same correct index e, which correctly explains the target concept. The learner might have some preknowledge of what the concept might be, that is, there is some class $\mathcal{C}$ of possible target concepts – the learner has only to find out which of the concepts in $\mathcal{C}$ is the target concept; on the other hand, the learner has to be able to learn every concept which is in the class $\mathcal{C}$.

Detail

The above given scenario of learning is essentially the paradigm of inductive inference introduced by Gold (1967) and known as **Ex** (explanatory) learning. Usually one considers learning of recursive functions or recursively enumerable languages. Intuitively, using coding, one can code any natural phenomenon into subsets of $\mathbb{N}$, the set of natural numbers. Thus, recursive functions from $\mathbb{N}$ to $\mathbb{N}$ or recursively enumerable subsets of $\mathbb{N}$ (called languages here) are natural concepts to be considered.

Here we will mainly consider language learning. Paradigms related to function learning can be similarly defined and we refer the reader to Osherson et al. (1986) and Jain et al. (1999).

One normally considers data provided to the learner to be either full positive data (i.e., the learner is told about every element in the target language, one element at a time, but never told anything about elements not in the target language) or full positive data and full negative data (i.e., the learner is told about every element, whether it belongs or does not belong to the target language). Intuitively, the reason for considering only positive data is that in many natural situations, such as language learning by children and scientific exploration (such as in astronomy), one gets essentially only positive data.

A *text* is a sequence of elements over $\mathbb{N} \cup \{\#\}$. Content of a text T, denoted $\mathrm{ctnt}(T)$, is the set of natural numbers in the range of T. For a finite sequence σ over $\mathbb{N} \cup \{\#\}$, one can similarly define $\mathrm{ctnt}(\sigma)$ as the set of natural numbers in the range of σ. A text T is said to be for a language L if $\mathrm{ctnt}(T) = L$. Intuitively, a text T for L represents sequential presentation of all elements of L, with #'s representing pauses in the presentation. For example, the only text for $\emptyset$ is $\#^\infty$. $T[n]$ denotes the initial sequence of T of length n. That is, $T[n] = T(0)T(1)\ldots T(n-1)$. We let SEQ denote the set of all finite sequences over $\mathbb{N} \cup \{\#\}$. An *informant* I is a sequence of elements over $\mathbb{N} \times \{0,1\} \cup \{\#\}$, where for each $x \in \mathbb{N}$, exactly one of $(x,0)$ or $(x,1)$ is in the range of I. An informant I is for L if $\mathrm{range}(I) - \{\#\} = \{(x, \chi_L(x)) : x \in \mathbb{N}\}$, where χ_L denotes the characteristic function of L.

A learner M is a mapping from SEQ to $\mathbb{N} \cup \{?\}$. Intuitively, output of ? denotes that the learner does not wish to make a conjecture on the corresponding input. The output of e denotes that the learner conjectures hypothesis W_e, where $W_0, W_1, \ldots$ is some acceptable numbering of all the recursively enumerable languages. We say that a learner M converges on T to e if, for all but finitely many n, $\mathrm{M}(T[n]) = e$.

Explanatory Learning

A learner M **TxtEx** identifies a language L iff, for all texts T for L, M converges to an index e such that $W_e = L$. Learner M **TxtEx** identifies a class $\mathcal{L}$ of languages if M **TxtEx** identifies each language in the class $\mathcal{L}$. Finally, one says that a class $\mathcal{L}$ is **TxtEx** learnable if some learner **TxtEx** identifies $\mathcal{L}$. **TxtEx** denotes the collection of all **TxtEx**-learnable classes. One can similarly define **InfEx** identification, for learning from informants instead of texts. The following classes are important examples:

$$RE = \{L : L \text{ is recursively enumerable}\};$$

$$FIN = \{L : L \text{ is a finite subset of } \mathbb{N}\};$$

$$KFIN = \{L : L = K \cup H \text{ for some } H \in FIN\};$$

$$SD = \{L : W_{\min(L)} = L\};$$

$$COFIN = \{L : \mathbb{N} - L \text{ is finite}\};$$

$$SDSIZE = \{\{e + x : x = 0 \vee x < |W_e|\} : W_e \text{ is finite}\};$$

$$SDALL = \{\{e + x : x \in \mathbb{N}\} : e \in \mathbb{N}\}.$$

Here, in the definition of *KFIN*, K is the halting problem, a standard example of a set which is recursively enumerable but not recursive. The classes *FIN*, *SD*, *SDSIZE*, and *SDALL* are **TxtEx** learnable (Case and Smith 1983; Gold 1967): The learner for *FIN* always conjectures the set of all data observed so far. The learner for *SD* conjectures the least datum seen so far as, eventually, the least observed datum coincides with the least member of the language to be learned. The learner for *SDSIZE* as well as the learner for *SDALL* also find in the limit the least datum e to occur and translate it into an index for the e-th set to be learned. The class *KFIN* is not **TxtEx** learnable, mainly for computational reasons. It is impossible for the learner to determine if the current input datum belongs to K or not; this forces a supposed learner either to make infinitely many mind changes on some text for K or to make an error on $K \cup \{x\}$, for some $x \notin K$. The union *SDSIZE* ∪ *SDALL* is also not **TxtEx** learnable, although it is the union of two learnable classes; so it is one example of various nonunion theorems. Gold (1967) gave even a more basic example: *FIN* ∪ $\{\mathbb{N}\}$ is not **TxtEx** learnable. Furthermore, the class *COFIN* is also not **TxtEx** learnable. However, except for *RE*, all the classes given above are **InfEx** learnable, so when being fed the characteristic function in place of only an infinite list of all elements, the learners become, in general, more powerful.

Note that the learner never knows when it has converged to its final hypothesis. If the learner is required to know when it has converged to the final hypothesis, then the criterion of learning is the same as finite learning. Here a finite learner is defined as follows: the learner keeps outputting the symbol ? while waiting for enough data to appear and, when the data observed are sufficient, the learner outputs exactly one conjecture different from ?, which then is required to be an index for the input concept in the hypothesis space. The class of singletons $\{\{n\} : n \in \mathbb{N}\}$ is finitely learnable; the learner just waits until the unique element n of $\{n\}$ has appeared and then knows the language. In contrast to this, the classes *FIN* and *SD* are not finitely learnable.

Blum and Blum (1975) obtained the following fundamental result: Whenever M learns L explanatorily from text, then L has a locking sequence for M. Here, a sequence σ is said to be a locking sequence for M on L if (a) $\text{ctnt}(\sigma) \subseteq L$, (b) for all τ such that $\text{ctnt}(\tau) \subseteq L$, $\text{M}(\sigma) = \text{M}(\sigma\tau)$, and (c) $W_{\text{M}(\sigma)} = L$. If only the first two conditions are satisfied, then the sequence is called a *stabilizing sequence* for M on L (Fulk 1990). It was shown by Blum and Blum (1975) that if a learner M **TxtEx** identifies L, then there exists a locking sequence σ for M on L. One can use this result to show that certain classes, such as *FIN* ∪ $\{\mathbb{N}\}$, are not **TxtEx** learnable.

Beyond Explanatory Learning

While **TxtEx** learning requires that the learner syntactically converges to a final hypothesis, which correctly explains the concept, this is no longer required for the more general criterion of behaviorally correct learning (called **TxtBc** learning). Here, the learner may not syntactically converge, but it is still required that all its hypothesis after sometime are correct; see Bārzdiņš (1974b), Case and Lynes (1982), Case and Smith (1983), Osherson et al. (1986), and Osherson and Weinstein (1982). So there is semantic convergence to a final hypothesis. Thus, a learner M **TxtBc** identifies a language L if for all texts T for L, for all but finitely many n, $W_{\text{M}(T[n])} = L$. One can similarly define **TxtBc** learnability of classes of languages and the collection **TxtBc**. Every **TxtEx**-learnable class is **Bc** learnable, but the classes *KFIN* and *SDSIZE* ∪ *SDALL* are **TxtBc** learnable but not **TxtEx** learnable. Furthermore, **InfEx** $\not\subseteq$ **TxtBc**, for example, *FIN* ∪ $\{\mathbb{N}\}$ is **InfEx** learnable but not **TxtBc** learnable. On the other hand, every class that is finitely learnable from informant is also **TxtEx** learnable (Sharma 1998).

An intermediate learning criterion is **TxtFex** learning (Case 1999) or vacillatory learning, which is similar to **TxtBc** learning except that we require that the number of distinct hypotheses output by the learner on any text is finite. Here one says that the learner $\mathbf{TxtFex}_n$ learns the language L if the number of distinct hypotheses that appears infinitely often on any text T for L is bounded by n. Note that $\mathbf{TxtFex}_* = \mathbf{TxtFex}$. Case (1999) showed that

$$\mathbf{TxtEx} = \mathbf{TxtFex}_1 \subset \mathbf{TxtFex}_2 \subset \mathbf{TxtFex}_3 \subset \ldots \subset \mathbf{TxtFex}_* \subset \mathbf{TxtBc}.$$

For example, the class $SD \cup SDALL$ is actually $\mathbf{TxtFex}_2$ learnable and not **TxtEx** learnable. The corresponding notion has also been considered for function learning, but there the paradigms of explanatory and vacillatory learning coincide (Case and Smith 1983).

Blum and Blum (1975), Case and Lynes (1982), and Case and Smith (1983) also considered allowing the final (or final sequence of) hypothesis to be anomalous; Blum and Blum (1975) considered $*$ anomalies, and (Case and Lynes 1982; Case and Smith 1983) considered the general case. Here the final grammar for the input language may not be perfect, but may have up to a anomalies. A grammar n is a anomalous for L (written $W_n =^a L$) iff card $((L - W_n) \cup (W_n - L)) \leq a$. Here one also considers finite anomalies, denoted by $*$-anomalies, where card$(S) \leq *$ just means that S is finite. Thus, a learner M $\mathbf{TxtEx}^a$ identifies a language L iff, for all texts T for all L, M on T converges to a hypothesis e such that $W_e =^a L$. One can similarly define $\mathbf{TxtBc}^a$-learning criteria. It can be shown that

$$\mathbf{TxtEx} = \mathbf{TxtEx}^0 \subset \mathbf{TxtEx}^1 \subset \mathbf{TxtEx}^2 \subset \ldots \subset \mathbf{TxtEx}^*$$

and

$$\mathbf{TxtBc} = \mathbf{TxtBc}^0 \subset \mathbf{TxtBc}^1 \subset \mathbf{TxtBc}^2 \subset \ldots \subset \mathbf{TxtBc}^*.$$

Let $SD_n = \{L : W_{\min(L)} =^n L\}$. Then one can show (Case and Lynes 1982; Case and Smith 1983) that $SD_{n+1} \in \mathbf{TxtEx}^{n+1} - \mathbf{TxtEx}^n$. However, there is a trade-off between behaviorally correct learning and explanatory learning for learning with anomalies. On one hand, $\mathbf{TxtBc} \not\subseteq \mathbf{TxtEx}^*$, but on the other hand $\mathbf{TxtEx}^{2n+1} \not\subseteq \mathbf{TxtBc}^n$ and $\mathbf{TxtEx}^{2n} \subseteq \mathbf{TxtBc}^n$. However, for learning from informants, we have $\mathbf{InfEx}^* \subseteq \mathbf{InfBc}$ (see Case and Lynes (1982) for the above results).

Consistent and Conservative Learning

Besides the above basic criteria of learning, researchers have also considered several properties that are useful for the learner to satisfy.

A learner M is said to be *consistent* on L iff, for all texts T for L, ctnt$(T[n]) \subseteq W_{\mathrm{M}(T[n])}$. That is, the learner's hypothesis is consistent with the data seen so far. There are three notions of consistency considered in the literature: (a) **TCons**, in which the learner is expected to be consistent on all inputs, irrespective of whether they represent some concept from the target class or not (Wiehagen and Liepe 1976); (b) **Cons**, in which the learner is just expected to be consistent on the languages in the target class being learned, though the learner may be inconsistent or even undefined on the input outside the target class (Bārzdiņš 1974a); and (c) **RCons**, in which the learner is expected to be defined on all inputs, but required to be consistent only on the languages in the target class (Jantke and Beick 1981). It can be shown that $\mathbf{TCons} \subset \mathbf{RCons} \subset \mathbf{Cons} \subset \mathbf{TxtEx}$ (Jantke and Beick 1981; Wiehagen and Liepe 1976; Bārzdiņš 1974a; Wiehagen and Zeugmann 1995).

A learner M is said to be *conservative* (Angluin 1980) if it does not change its mind unless the data contradicts its hypothesis. That is, M conservatively learns L iff, for all texts T for L, if $\mathrm{M}(T[n]) \neq \mathrm{M}(T[n+1])$, then ctnt$(T[n+1]) \not\subseteq W_{\mathrm{M}(T[n])}$. It can be shown that conservativeness is restrictive, that is, there are classes of languages, which can be **TxtEx** identified but not conservatively identified. An example of a class that can be identified explanatorily but not conservatively is the class containing all sets from *SDALL*, that is, the sets of the form $\{e, e+1, e+2, \ldots\}$, and all sets with minimum k_s and up to s elements where $k_0, k_1, k_2, \ldots$ is a recursive one-one enumeration of K. The general idea why this class is not conservatively learnable is that when the learner reads the data $e, e+1, e+2, \ldots$, it will, after some finite time based on data $e, e+1, e+2, \ldots, e+s$, output a conjecture which contains these data plus $e+s+1$; but conservative learning would then imply that $e \in K$ iff $e = k_r$ for some $r \leq s$, contradicting the non-recursiveness of K.

Monotonicity

Related notions to conservativeness are the various notions on monotonic learning that impose certain conditions on whether the previous hypothesis is a subset of the next hypothesis or not. The following notions are the three main ones.

- A learner M is said to be strongly monotonic (Jantke 1991) on L iff, for all texts T for L, $W_{\mathrm{M}(T[n])} \subseteq W_{\mathrm{M}(T[n+1]}$. Intuitively, strong monotonicity requires that the hypothesis of the learner grows with time.
- A learner M is said to be monotonic (Wiehagen 1990) on L iff, for all texts T for L, $W_{\mathrm{M}(T[n])} \cap L \subseteq W_{\mathrm{M}(T[n+1])} \cap L$. In monotonicity, the growth of the hypothesis is required only with respect to the language being learned.
- A learner M is said to be weakly monotonic (Jantke 1991) on L iff, for all texts T for L, if $\mathrm{ctnt}(T[n+1]) \subseteq W_{\mathrm{M}(T[n])}$, then $W_{\mathrm{M}(T[n])} \subseteq W_{\mathrm{M}(T[n+1])}$. That is, the learner behaves strongly monotonically, as long as the input data is consistent with the hypothesis.

An example for a strong monotonically learnable class is the class *SDALL*. When the learner currently conjectures $\{e, e+1, e+2, \ldots\}$ and it sees a datum $d < e$, then it makes a mind change to $\{d, d+1, d+2, \ldots\}$ which is a superset of the previous conjecture; it is easy to see that all mind changes are of this type. It can be shown that strong monotonic learning implies monotonic learning and weak monotonic learning, though monotonic learning and weak monotonic learning are incomparable (and thus both are proper restrictions of **TxtEx** learning). For example, consider the class $\mathcal{C}$ consisting of the set $\{0, 2, 4, \ldots\}$ of all even numbers and, for each n, the set $\{0, 2, 4, \ldots, 2n\} \cup \{2n+1\}$ consisting of the even numbers below $2n$ and the odd number $2n+1$. Then, $\mathcal{C}$ is monotonically but not strong monotonically learnable.

Lange et al. (1992) also considered the dual version of the above criteria, where dual strong monotonicity learning of L requires that, for all texts T for L, $W_{\mathrm{M}(T[n])} \supseteq W_{\mathrm{M}(T[n+1])}$; dual monotonicity requires that, for all texts T for L, $W_{\mathrm{M}(T[n])} \cap (\mathbb{N} - L) \supseteq W_{\mathrm{M}(T[n+1])} \cap (\mathbb{N} - L)$, and dual weak monotonicity requires that, if $\mathrm{ctnt}(T[n+s]) \subseteq W_{\mathrm{M}(T[n])}$, then $W_{\mathrm{M}(T[n])} \supseteq W_{\mathrm{M}(T[n+s])}$.

In a similar fashion, various other properties of learners have been considered. For example, reliability (Blum and Blum 1975; Minicozzi 1976) postulates that the learner does not converge on the input text unless it learns it; prudence (Fulk 1990; Osherson et al. 1986) postulates that the learner outputs only indices of languages, which it also learns; and confidence (Osherson et al. 1986) postulates that the learner converges on every text to some index, even if the text is for some language outside the class of languages to be learned.

Indexed Families

Angluin (1980) initiated a study of learning indexed families of recursive languages. A class of languages (along with its indexing) $L_0, L_1, \ldots$ is an indexed family if membership questions for the languages are uniformly decidable, that is, $x \in L_i$ can be recursively decided in x and i. Angluin gave an important characterization of indexed families that are **TxtEx** learnable.

Suppose a class $\mathcal{L} = \{L_0, L_1, \ldots\}$ (along with the indexing) is given. Then, S is said to be a *tell-tale set* (Angluin 1980) of L_i iff S is finite, and for all j, if $S \subseteq L_j$ and $L_j \subseteq L_i$, then $L_i = L_j$. It can be shown that for any class of languages that are learnable (in **TxtEx** or **TxtBc** sense), there exists a tell-tale set for each language in the class. Moreover, Angluin showed that for indexed families, $\mathcal{L} = L_0, L_1, \ldots$, one can **TxtEx** learn $\mathcal{L}$ iff one can recursively enumerate a tell-tale set for each L_i, effectively from i. Within the framework of learning indexed families, a special emphasis is given to the hypothesis space used; so the following criteria are considered for defining the learnability of a class $\mathcal{L}$ in dependence of the hypothesis space $\mathcal{H} = H_0, H_1, \ldots$. The class $\mathcal{L}$ is

- *Exactly learnable* iff there is a learner using the same hypothesis space as the given class, that is, $H_n = L_n$ for all n;
- *Class-preservingly learnable* iff there is a learner using a hypothesis space $\mathcal{H}$ with $\{L_0, L_1, \ldots\} = \{H_0, H_1, \ldots\}$ – here the order and the number of occurrences in the hypothesis space can differ, but the hypothesis space must consist of the same languages as the class to be learned, and no other languages are allowed in the hypothesis space;
- *Class-comprisingly learnable* iff there is a learner using a hypothesis space $\mathcal{H}$ with $\{L_0, L_1, \ldots\} \subseteq \{H_0, H_1, \ldots\}$ – here the hypothesis space can also contain some further languages not in the class to be learned and the learner does not need to identify these additional languages;
- *Prescribed learnable* iff for every hypothesis space $\mathcal{H}$ containing all the languages from $\mathcal{L}$, there is a learner for $\mathcal{L}$ using this hypothesis space;
- *Uniformly learnable* iff for every hypothesis space $\mathcal{H}$ with index e containing all the languages from $\mathcal{L}$ one can synthesize a learner M_e which succeeds to learn $\mathcal{L}$ using the hypothesis space $\mathcal{H}$.

Note that in all five cases $\mathcal{H}$ only ranges over indexed families. This differs from the standard case where $\mathcal{H}$ is an acceptable numbering of all recursively enumerable sets. We refer the reader to the survey of Lange et al. (2008) for an overview on work done on learning indexed families (**TxtEx** learning, learning under various properties of learners, as well as characterizations of such learning criteria) and to (Jain et al. 2008; Lange and Zeugmann 1993). While for explanatory learning and every class $\mathcal{L}$, all these five notions coincide, these notions turn out to be different for other learning notions like those of conservative learning, monotonic learning, and strong monotonic learning. For example, the class of all finite sets is not prescribed conservatively learnable: one can make an adversary hypothesis space where some indices contain large spurious elements, so that a learner is forced to do nonconservative mind change to obtain correct indices for the finite sets. The same example as above works for showing the limitations of prescribed learning for monotonic and strong monotonic learning.

The interested reader is referred to the textbook *Systems that Learn* (Jain et al. 1999; Osherson et al. 1986) and the papers below as well as the references found in these papers for further reading. Complexity issues in inductive inference like the number of mind changes necessary to learn a class or oracles needed to learn some class can be found under the entries *Computational Complexity of Learning* and *Query-Based Learning*. The entry *Connections between Inductive Inference and Machine Learning* provides further information on this topic.

Definition

Inductive learning is a subclass of machine learning that studies algorithms for learning knowledge based on statistical regularities. The learned knowledge typically has no deductive guarantees of correctness, though there may be statistical forms of guarantees.

Inductive Logic Programming

Abstract

Inductive logic programming is the subfield of machine learning that uses ▶ First-Order Logic to represent hypotheses and data.

Because first-order logic is expressive and declarative, inductive logic programming specifically targets problems involving structured data and background knowledge. Inductive logic programming tackles a wide variety of problems in machine learning, including classification, regression, clustering, and reinforcement learning, often using "upgrades" of existing propositional machine learning systems. It relies on logic for knowledge representation and reasoning purposes. Notions of coverage, generality, and operators for traversing the space of hypotheses are grounded in logic; see also ▸ Logic of Generality. Inductive logic programming systems have been applied to important applications in bio- and chemoinformatics, natural language processing, and web mining.

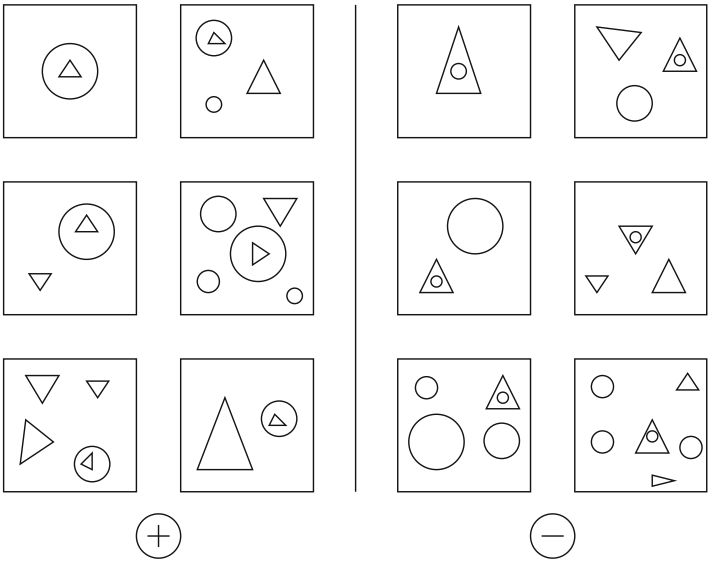
Motivation

The first motivation and most important motivation for using inductive logic programming is that it overcomes the representational limitations of attribute-value learning systems. Such systems employ a table-based representations where the instances correspond to rows in the table, the attributes to columns, and for each instance, a single value is assigned to each of the attributes. This is sometimes called the *single-table single-tuple* assumption. Many problems, such as the Bongard problem shown in Fig. 1, cannot elegantly be described in this format. Bongard (1970) introduced about a hundred concept learning or pattern recognition problems, each containing six positive and six negative examples. Even though Bongard problems are toy problems, they are similar to real-life problems such as structure–activity relationship prediction, where the goal is to learn to predict whether a given molecule (as represented by its 2D graph structure) is active or not. It is hard – if not, impossible – to squeeze this type of problem into the single-table single-tuple format for various reasons. Attribute-value learning systems employ a fixed number of attributes and also assume that these attributes are present in all of the examples. This assumption does not hold for the Bongard problems as the examples possess a variable number of objects (shapes). The singe-table single-tuple representation imposes an implicit order on the attributes, whereas there is no natural order on the objects in the Bongard problem. Finally, the relationships between the objects in the Bongard problem are essential and must be encoded as well. It is unclear how to do this within the single-table single-tuple assumption. First-order logic and relational representations allow one to encode problems involving multiple objects (or entities) as well as the relationships that hold them in a natural way.

The second motivation for using inductive logic programming is that it employs logic, a declarative representation. This implies that hypotheses are understandable and interpretable. By using logic, inductive logic programming systems are also able to employ background knowledge in the induction process. Background knowledge can be provided in the form of definitions of auxiliary relations or predicates that may be used by the learner. Finally, logic provides a well-understood theoretical framework for knowledge representation and reasoning. This framework is also useful for machine learning, in particular, for defining and developing notions such as the covers relation, generality, and refinement operators; see also ▸ Logic of Generality.

Theory

Inductive logic programming is usually defined as concept learning using logical representations. It aims at finding a hypothesis (a set of rules) that covers all positive examples and none of the negatives, while taking into account a background theory. This is typically realized by searching a



Inductive Logic Programming, Fig. 1 A complex classification problem: Bongard problem 47, developed by the Russian scientist Bongard (1970). It consists of 12 scenes (or examples), 6 of class ⊕ and 6 of class ⊖. The goal is to discriminate between the two classes

space of possible hypotheses. More formally, the traditional inductive logic programming definition reads as follows:

Given

- A language describing hypotheses $\mathcal{L}_h$
- A language describing instances $\mathcal{L}_i$
- Possibly a background theory B, usually in the form of a set of (definite) clauses
- The *covers* relation that specifies the relation between $\mathcal{L}_h$ and $\mathcal{L}_i$, that is, when an example e is covered (considered positive) by a hypothesis h, possibly taking into account the background theory B
- A set of positive and negative examples $E = P \cup N$

Find a hypothesis $h \in \mathcal{L}_h$ such that for all $p \in P : covers(B, h, p) = true$ and for all $n \in N : covers(B, h, n) = false$.

This definition can, as for ▶ Concept-Learning in general, be extended to cope with noisy data by relaxing the requirement that all examples be classified correctly.

There exist different ways to represent learning problems in logic, resulting in different learning settings. They typically use definite clause logic as the hypothesis language $\mathcal{L}_i$ but differ in the notion of an example. One can learn from entailment, from interpretations, or from proofs, cf. ▶ Logic of Generality. The most popular setting is *learning from entailment*, where each example is a clause and $covers(B, h, e) = true$ if and only if $B \cup h \models e$.

The top leftmost scene in the Bongard problem of Fig. 1 can be represented by the clause:

```
positive :- object(o1),
            object(o2),
            circle(o1),
            triangle(o2),
            in(o1, o2),
            large(o2).
```

The other scenes can be encoded in the same way. The following hypothesis then forms a solution to the learning problem:

```
positive :- object(X),
            object(Y),
            circle(X),
            triangle(Y),
            in(X,Y).
```

It states that those scenes having a circle inside a triangle are positive. For some more complex Bongard problems, it could be useful to employ background knowledge. It could, for instance, state that triangles are polygons.

```
polygon(X) :- triangle(X).
```

Using this clause as background theory, an alternative hypothesis covering all positives and none of the negatives is

```
positive :- object(X),
            object(Y),
            circle(X),
            polygon(Y),
            in(X,Y).
```

An alternative for using long clauses as examples is to provide an identifier for each example and to add the corresponding facts from the condition part of the clause to the background theory. For the above example, the facts such as

```
object(e1,o1).
object(e1,o2).
circle(e1,o1).
triangle(e1,o2).
in(e1,o1,o2).
large(e1,o2).
```

would be added to the background theory, and the positive example itself would then be represented through the fact `positive(e1)`, where `e1` is the identifier. The inductive logic programming literature typically employs this format for examples and hypotheses.

Whereas inductive logic programming originally focused on concept learning – as did the whole field of machine learning – it is now being applied to virtually all types of machine learning problems, including regression, clustering, distance-based learning, frequent pattern mining, reinforcement learning, and even kernel methods and graphical models.

A Methodology

Many of the more recently developed inductive logic programming systems have started from an existing attribute-value learner and have upgraded it toward the use of first-order logic (Van Laer and De Raedt 2001). By examining state-of-the-art inductive logic programming systems, one can identify a methodology for realizing this (Van Laer and De Raedt 2001). It starts from an attribute-value learning problem and system of interest and takes the following two steps. First, the problem setting is upgraded by changing the representation of the examples, the hypotheses as well as the covers relation toward first-order logic. This step is essentially concerned with defining the learning setting, and possible settings to be considered include the already mentioned learning from *entailment*, *interpretations*, and *proofs* settings. Once the problem is clearly defined, one can attempt to formulate a solution. Thus, the second step adapts the original algorithm to deal with the upgraded representations. While doing so, it is advisable to keep the changes as minimal as possible. This step often involves the modification of the operators used to traverse the search space. Different operators for realizing this are introduced in the entry on the ▶ Logic of Generality.

There are many reasons why following the methodology is advantageous. First, by upgrading a learner that is already effective for attribute-value representations, one can benefit from the experiences and results obtained in the propositional setting. In many cases, for instance, decision trees, this implies that one can rely on well-established methods and findings, which are the outcomes of several decades of machine learning research. It will be hard to do better starting from scratch. Second, upgrading an existing learner is also easier than starting from scratch as many of the components (such as heuristics and search strategy) can be recycled. It is therefore also economic in terms of man power. Third, the upgraded system will be able to emulate the original one, which provides guarantees that the output hypotheses will perform well on attribute-value learning problems. Even more important is that it will often also be able to emulate extensions of the original systems. For instance, many systems that extend frequent item-set mining toward using richer representations, such as sequences, intervals, the use of taxonomies, graphs, and so on, have been developed over the past decade. Many of them can be emulated using the inductive logic programming upgrade of Apriori (Agrawal et al. 1996) called Warmr (Dehaspe and Toivonen 2001). The upgraded inductive logic programming systems will typically be more flexible than the systems it can emulate but typically also less efficient because there is a price to be paid for expressiveness. Finally, it may be possible to incorporate new features in the attribute-value learner by following the methodology. One feature that is often absent from propositional learners and may be easy to incorporate is the use of a background theory.

It should be mentioned that the methodology is not universal, that is, there exist also approaches, such as Muggleton's Progol (1995), which have directly been developed in first-order logic and for which no propositional counterpart exists. In such cases, however, it can be interesting to follow the inverse methodology, which would specialize the inductive logic programming system.

FOIL: An Illustration

One of the simplest and best-known inductive logic programming systems is FOIL (Quinlan 1990). It can be regarded as an upgrade of a rule learner such as CN2 (Clark and Niblett 1989). FOIL's problem setting is an instance of the learning from entailment setting introduced above (though it restricts the background theory to ground facts only and does not allow functors).

Like most rule-learning systems, FOIL employs a separate-and-conquer approach. It starts from the empty hypothesis, and then repeatedly searches for one rule that covers as many positive examples as possible and no negative example, adds it to the hypothesis, removes the positives covered by the rule, and then iterates. This process is continued until all positives are covered. To find one rule, it performs a hill-climbing search through the space of clauses ordered according to generality. The search starts at the most general rule, the one stating that all examples are positive, and then repeatedly specializes it. Among the specializations, it then selects the best one according to a heuristic evaluation based on information gain. A heuristic, based on the minimum description length principle, is then used to decide when to stop specializing clauses.

The key differences between FOIL and its propositional predecessors are the representation and the operators used to compute the specializations of a clause. It employs a refinement operator under θ-subsumption (Plotkin 1970) (see also ▶Logic of Generality). Such an operator essentially refines clauses by adding atoms to the condition part of the clause or applying substitutions to a clause. For instance, the clause

```
positive :- triangle(X),
            in(X,Y),
            color(X,C).
```

can be specialized to

```
positive :- triangle(X),
            in(X,Y),
            color(X,red).

positive :- triangle(X),
            in(X,Y),
            color(X,C),
            large(X).
positive :- triangle(X),
            in(X,Y),
            color(X,C),
            rectangle(Y).
  ...
```

The first specialization is obtained by substituting the variable `C` by the constant `red`, the other two by adding an atom (`large(X)`, `rectangle(Y)`, respectively) to the condition part of the rule. Inductive logic programming systems typically also employ syntactic restrictions – the so-called – that specify which clauses may be used in hypotheses. For instance, in the above example, the second argument of the `color` predicate belongs to the type *Color*, whereas the arguments of `in` are of type *Object* and consist of object identifiers.

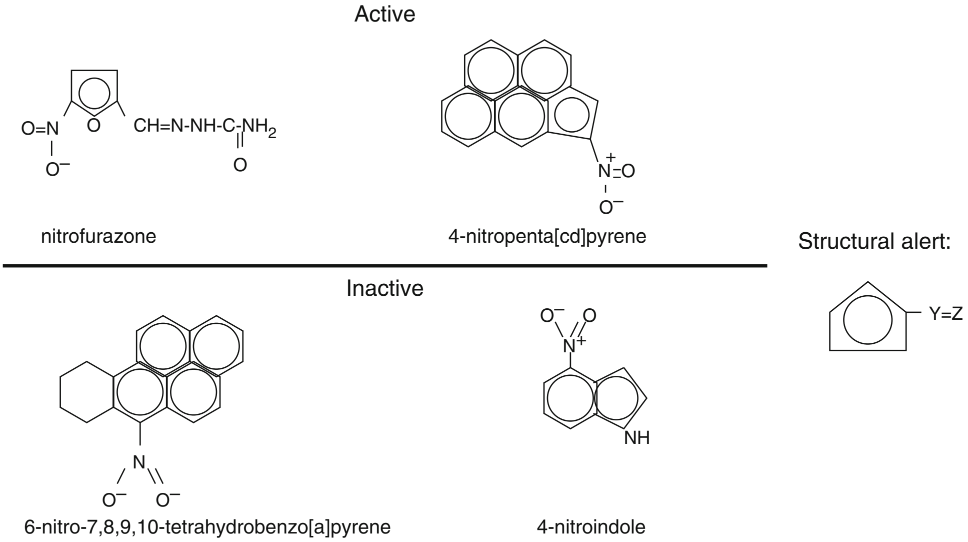
Application

Inductive logic programming has been successfully applied to many application domains, including bio- and chemo-informatics, ecology, network mining, software engineering, information retrieval, music analysis, web mining, natural language processing, toxicology, robotics, program synthesis, design, architecture, and many others. The best-known applications are in scientific domains. For instance, in structure–activity relationship prediction, one is given a set of molecules together with their activities, and background knowledge encoding functional groups, that is particular components of the molecule, and the task is to learn rules stating when a molecule is active or inactive. This is illustrated in Fig. 2 (after Srinivasan et al. 1996), where two molecules are active and two are inactive. One then has to find a pattern that discriminates the actives from the inactives. Structure–activity relationship (SAR) prediction is an essential step in, for instance, drug discovery. Using the general purpose inductive logic programming system Progol (Muggleton 1995) *structural alerts*, such as that shown in Fig. 2, have been discovered. These alerts allow one to distinguish the actives from the inactives – the one shown in the figure matches both of the actives but none of the inactives – and at the same time they are readily interpretable and provide useful insight into the factors determining the activity. To solve structure–activity relationship prediction problems using inductive logic programming, one must represent the molecules and hypotheses using the logical formalisms introduced above. The resulting representation is very similar to that employed in the Bongard problems: the objects are the atoms and relationships the bonds. Particular functional groups are encoded as background predicates.

State-of-the-Art

The upgrading methodology has been applied to a wide variety of machine learning systems and problems. There exist now inductive logic programming systems that:

- Induce logic programs from examples under various learning settings. This is by far the most popular class of inductive logic programming systems. Well-known systems include Aleph (Srinivasan 2007) and Progol (Muggleton 1995) as well as various variants of FOIL (Quinlan 1990). Some of these systems, especially Progol and Aleph, contain many features that are not present in propositional learning systems. Most of these systems focus



Inductive Logic Programming, Fig. 2 Predicting mutagenicity (Srinivasan et al. 1996) on a classification setting and learn the definition of a *single* predicate.

- Induce logical decision trees from examples. These are binary decision trees containing conjunctions of atoms (i.e., queries) as tests. If a query succeeds, then one branch is taken, else the other one. Decision tree methods for both classification and regression exist (see Blockeel and De Raedt 1998; Kramer and Widmer 2001).
- Mine for frequent queries, where queries are conjunctions of atoms. Such queries can be evaluated on an example. For instance, in the Bongard problem, the query `?- triangle (X), in (X, Y)` succeeds on the leftmost scenes and fails on the rightmost ones. Therefore, its frequency would be 6. The goal is then to find all queries that are frequent, that is, whose frequencies exceed a certain threshold. Frequent query mining upgrades the popular local pattern mining setting due to Agrawal et al. (1996) to inductive logic programming (see Dehaspe and Toivonen 2001).
- Learn or revise the definitions of theories, which consist of the definitions of multiple predicates, at the same time (cf. Wrobel 1996), and the entry in this encyclopedia. Several of these systems have their origin in the model inference system by Shapiro (1983) or the work by Angluin (1987).

Current Trends and Challenges

There are two major trends and challenges in inductive logic programming. The first challenge is to extend the inductive logic programming paradigm beyond the purely symbolic one. Important trends in this regard include:

- The combination of inductive logic programming principles with graphical and probabilistic models for reasoning about uncertainty. This is a field known as *statistical relational learning*, *probabilistic logic learning*, or *probabilistic inductive logic programming*. At the time of writing, this is a very popular research stream, attracting a lot of attention in the wider artificial intelligence community, cf. the entry ▶ Statistical Relational Learning in this encyclopedia. It has resulted in many relational or logical upgrades of well-known graphical models including Bayesian networks, Markov networks, hidden Markov models, and stochastic grammars.
- The use of relational distance measures for classification and clustering (Ramon and Bruynooghe 1998; Kirsten et al. 2001). These distances measure the similarity between two examples or clauses, while taking into account the underlying structure of the instances. These distances are then combined with standard classification and clustering methods such as k-nearest neighbor and k-means.
- The integration of relational or logical representations in reinforcement learning, known as ▶ Relational Reinforcement Learning (Dzeroski et al. 2001).

The power of inductive logic programming is also its weakness. The ability to represent complex objects and relations and the ability to make use of background knowledge add to the computational complexity. Therefore, a key challenge of inductive logic programming is tackling this added computational complexity. Even the simplest method for testing whether one hypothesis is more general than another – that is, θ-subsumption (Plotkin 1970) – is NP-complete. Similar tests are used for deciding whether a clause covers a particular example in systems such as FOIL. Therefore, inductive logic programming and relational learning systems are computationally much more expensive than their propositional counterparts. This is an instance of the expressiveness versus efficiency trade-off in computer science. Because of these computational difficulties, inductive logic programming has devoted a lot of attention to efficiency issues. On the theoretical side, there exist various results about the polynomial learnability of certain subclasses of logic programs (cf. Cohen and Page 1995, for an overview). From a practical perspective, there is quite some work on developing efficient methods for searching the hypothesis space and especially for evaluating the quality of hypotheses. Many of these methods employ optimized inference engines based on Prolog or database technology or constraint satisfaction methods (cf. Blockeel and Sebag 2003 for an overview).

Inductive Process Modeling

Ljupčo Todorovski
University of Ljubljana, Ljubljana, Slovenia

Synonyms

Process-based modeling

Definition

Inductive process modeling is a machine learning task that deals with the problem of learning quantitative *process models* from ▸ time series data about the behavior of an observed dynamic system. Process models are models based on ordinary differential equations that add an explanatory layer to the equations. Namely, scientists and engineers use models to both predict and explain the behavior of an observed system. In many domains, models commonly refer to processes that govern system dynamics and entities altered by those processes. Ordinary differential equations, often used to cast models of dynamic systems, offer one way to represent these mechanisms and can be used to simulate and predict the system behavior, but fail to make the processes and entities explicit. In response, process models tie the explanatory information about processes and entities to the mathematical formulation, based on equations, that enables simulation.

Inductive Process Modeling, Table 1 A process model of Predatory–Prey interaction between foxes and rabbits. The notation $d[X,t]$ indicates the time derivative of variable X

model predation;
entities fox{population}, rabbit{population};
process rabbit_growth;
entites rabbit;
*equations d[rabbit.conc,t] = 1.81 * rabbit.conc **
*(1 − 0.0003 * rabbit.conc);*
process fox_death;
entites fox;
*equations d[fox.conc,t] = −1.04 * fox.conc;*
process fox_rabbit_predation;
entities fox, rabbit;
equations
*d[fox.conc,t] = 0.03 * rabbit.conc * fox.conc;*
*d[rabbit.conc,t] = −1 * 0.3 * rabbit.conc * fox.conc;*

Table 1 shows a process model for a predator–prey interaction between foxes and rabbits. The three processes explain the dynamic change of the concentrations of both species (represented in the model as two *population* entities) through time. The *rabbit_growth* process states that the reproduction of rabbit is limited by the fixed environmental capacity. Similarly, the *fox_death* process specifies an unlimited exponential mortality function for the fox population. Finally, the *fox_rabbit_predation* process refers to the predator–prey interaction between foxes and rabbits that states that the prey concentration decreases and the predator one increases proportionally with the sizes of the two populations. The process model makes the structure of the model explicit and transparent to scientists; while at the same time it can be easily transformed in to a system of two differential equations by additively combining the equations for the time derivatives of the system variables *fox.conc* and *rabbit.conc*. Given initial values for these variables, one can simulate the equations to produce trajectories that correspond to the population dynamics through time.

The processes from Table 1 instantiate more general generic processes, that can be used for modeling any ecological system. For example: is a general form of the *fox_rabbit_predation* process from the example model in Table 1. Note that in the generic process, the parameters are replaced with numeric ranges and the entities with identifiers of generic entities (i.e., *Predator* and *Prey* are identifiers that refer to instances of the generic entity *population*).

```
generic process predation;
  entities Predator{population}, Prey{population};
  parameters ar[0.01, 10], ef[0.001, 0.8];
  equations
         d[Predator.conc,t] = ef * ar * Prey.conc *
Predator.conc;
       d[Prey.conc,t] = −1 * ar * Prey.conc * Preda-
tor.conc;
```

Having defined entities and processes on an example, one can define the task of inductive process modeling as: Given

- Time series observations for a set of numeric system variables as they change through time
- A set of entities that the model might include
- Generic processes that specify casual relations among entities
- Constraints that determine plausible relations among processes and entities in the model

Find a specific process model that explains the observed data and the simulation of which closely matches observed time series.

There are two approaches for solving the task of inductive process modeling. The first is the transformational approach that transforms the given knowledge about entities, processes, and constraints to ▸ language bias for equation discovery and uses the Lagramge method for ▸ equation discovery in turn (Todorovski and Džeroski 1997, 2007). The second approach performs search through the space of candidate process models to find the one that matches the given time series data best.

Inductive process modeling methods IPM (Bridewell et al. 2008) and HIPM (Todorovski et al. 2005) follow the second approach. IPM is a naïve method that exhaustively searches the space of candidate process models following the ▸ learning as search paradigm. The search space of candidate process models is defined by the sets of generic processes and of entities in the observed system specified by the user. IPM first matches the type of each entity against the types of entities involved in each generic process and produces a list of all possible instances of that generic process. For example, the generic process *predation*, from the example above, given two *population* entities *fox* and *rabbit*, can be instantiated in four different ways (*fox_fox_predation*, *fox_rabbit_predation*, *rabbit_fox_predation*, and *rabbit_rabbit_predation*). The IPM search procedure collects the set of all possible instances of all the generic processes and uses them as a set of candidate model components. In the search phase, all combinations of these model components are being matched against observed ▸ time series. The matching involves the employment of gradient-descent methods for nonlinear optimization to estimate the optimal values of the process model parameters. As output, IPM reports the process models with the best match.

Trying out all components' combinations is prohibitive in many situations since it obviously leads to combinatorial explosion. HIPM employs constraints that limit the space of combinations by ruling-out implausible or forbidden combinations. Examples of such constraints in the predator–prey example above include rules that a proper process model of population dynamics should include a single growth and a single mortality process per species, the predator–prey process should relate two different species, and different predator–prey interaction should refer to different population pairs. HIPM specifies the rules in a hierarchy of generic processes where each node in the hierarchy specifies a rule for proper combination/selection of process instances.

Computer Science, University of Bamberg,
Bamberg, Germany

Abstract

Inductive programming is introduced as a branch of program synthesis which is based on inductive inferece where recursive, declarative programs are constructed from incomplete specifications, especially from input/output examples. Inductive logic programming as well as inductive functional programming are addressed. Central concepts such as predicate invention and background knowledge are defined. Two worked-out examples are presented to illustrate inductive logic as well as inductive functional programming.

Example-based programming; Inductive program synthesis; Inductive synthesis; Programming by examples; Program synthesis from examples

Definition

Inductive programming is the inference of an algorithm or program featuring recursive calls or repetition control structures, starting from information that is known to be incomplete, called the *evidence*, such as positive and negative input-output examples or clausal constraints. The inferred program must be correct with respect to the provided evidence, in a **generalization** sense: it should be neither equivalent to it nor inconsistent. Inductive programming is guided explicitly or implicitly by a **language bias** and a **search bias**. The inference may draw on background knowledge or query an oracle. In addition to **induction**, **abduction** may be used. The restriction to algorithms and programs featuring recursive calls or repetition control structures distinguishes inductive programming from **concept learning** or **classification**.

We here restrict ourselves to the inference of declarative programs, whether functional or logic, and dispense with repetition control structures in the inferred program in favor of recursive calls.

Motivation and Background

Inductive program synthesis is a branch of the field of *program synthesis*, which addresses a cognitive question as old as computers, namely, the understanding of the human act of computer

Most of the work by this author was done while on leave of absence in 2006/07 as a Visiting Faculty Member and Erasmus Exchange Teacher at Sabancı University, Turkey.

programming, to the point where a computer can be made to help in this task (and ultimately to enhance itself). See Flener (2002) and Gulwani et al. (2014) for surveys; the other main branches of program synthesis are based on deductive inference, namely, *constructive program synthesis* and *transformational program synthesis*. In such *deductive program synthesis*, the provided information, called the *specification*, is assumed to be complete (in contrast to inductive program synthesis where the provided information is known to be incomplete), and the presence of repetitive or recursive control structures in the synthesized program is not imposed.

Research on the inductive synthesis of recursive *functional* programs started in the early 1970s and was brought onto firm theoretical foundations with the seminal THESYS system of Summers (1977) and work of Biermann (1978), where all the evidence is handled non-**incrementally**. Essentially, the idea is first to infer computation *traces* from input-output examples (**instances**) and then to use a **trace-based programming** method to fold these traces into a recursive program. The main results until the mid-1980s were surveyed in Smith (1984). Due to limited progress with respect to the range of programs that could be synthesized, research activities decreased significantly in the next decades. However, a new approach that formalizes functional program synthesis in the term rewriting framework and that allows the synthesis of a broader class of programs than the classical approaches is pursued in Kitzelmann and Schmid (2006).

The advent of *logic* programming brought a new lan but also a new direction in the early 1980s, especially due to the MIS system of Shapiro (1983), eventually spawning the new field of **inductive logic programming** (ILP). Most of this ILP work addresses a wider class of problems, as the focus is *not* only on recursive logic programs: more adequate designations are inductive **theory revision** and *declarative program debugging*, as an additional input is a possibly empty initial theory or program that is **incrementally** revised or debugged according to each newly presented piece of evidence, possibly in the presence of background knowledge or an oracle. The main results on the inductive synthesis of recursive logic programs were surveyed in Flener and Yılmaz (1999).

Structure of Learning System

The core of an inductive programming system is a mechanism for constructing a recursive **generalization** for a set of input/output examples (**instances**). Although we use the vocabulary of logic programming, this method also covers the synthesis of functional programs.

The input, often a set of input/output examples, is called the *evidence*. Further evidence may be queried from an *oracle*. Additional information, in the form of predicate symbols that can be used during the synthesis, can be provided as *background knowledge*. Since the **hypothesis space** – the set of legal recursive programs – is infinite, a **language bias** is introduced. One particularly useful and common approach in inductive programming is to provide a statement bias by means of a *program schema*.

The evidential synthesis of a recursive program starts from the provided evidence for some predicate symbol and works essentially as follows. A program schema is chosen to provide a template for the program structure, where all yet undefined predicate symbols must be instantiated during the synthesis. Predefined predicate symbols of the background knowledge are then chosen for some of these undefined predicate symbols in the template. If it is deemed that the remaining undefined predicate symbols cannot all be instantiated via purely structural generalization by non-recursive definitions, then the method is recursively called to infer recursive definitions for some of them (this is called **predicate invention** and amounts to shifting the *vocabulary bias*); otherwise the synthesis ends successfully right away. This generic method can backtrack to any choice point for synthesizing alternative programs.

In the rest of this section, we discuss this basic terminology of inductive programming more precisely. In the next section, instantiations of this generic method by some well-known methods are presented.

The Evidence and the Oracle

The evidence is often limited to ground positive examples of the predicate symbols that are to be defined. Ground negative examples are convenient to prevent overgeneralization, but should be used constructively and not just to reject candidate programs. A useful generalization of ground examples is evidence in the form of a set of (nonrecursive) clauses, as variables and additional predicate symbols can then be used.

Example 1 The $delOdds(L, R)$ relation, which holds if and only if R is the integer list L without its odd elements, can be incompletely described by the following clausal evidence:

$$\begin{aligned} delOdds([\,],[\,]) &\leftarrow true \\ delOdds([X],[\,]) &\leftarrow odd(X) \\ delOdds([X],[X]) &\leftarrow \neg odd(X) \\ delOdds([X,Y],[Y]) &\leftarrow odd(X),\ \neg odd(Y) \\ delOdds([X,Y],[X,Y]) &\leftarrow \neg odd(X),\ \neg odd(Y) \\ false &\leftarrow delOdds([X],[X]),\ odd(X) \end{aligned} \tag{1}$$

The first clause is a ground positive example, whereas the second and third clauses generalize the infinity of ground positive examples, such as $delOdds([5],[\,])$ and $delOdds([22],[22])$, for handling singleton lists, while the fourth and fifth clauses summarize the infinity of ground positive examples for handling lists of two elements, the second one being even: these clauses make explicit the underlying filtering relation (*odd*) that is *intrinsic* to the problem at hand but cannot be provided via ground examples and would otherwise have to be guessed. The sixth clause summarizes an infinity of ground negative examples for handling singleton lists, namely, where the only element of the list is odd but not filtered.

In some methods, especially for the induction of functional programs, the first *n* positive input-output examples with respect to the underlying data type are presented (e.g., for linear lists, what to do with the empty list, with a one-element list, up to a list with three elements); because of this ordering of examples, no explicit presentation of negative examples is then necessary.

Inductive program synthesis should be monotonic in the evidence (more evidence should never yield a less complete program, and less evidence should not yield a more complete program) and should not be sensitive to the order of presentation of the evidence.

Program Schemas

Informally, a *program schema* contains a template program and a set of axioms. The *template* abstracts a class of actual programs, called *instances*, in the sense that it represents their dataflow and control flow by means of placeholders, but does not make explicit all their actual computations nor all their actual data structures. The *axioms* restrict the possible instances of the placeholders and define their interrelationships. Note that a schema is problem independent. Let us here take a **first-order logic** approach and consider templates as open logic programs (i.e. programs where some placeholder predicate symbols are left undefined or *open*; a program with no open predicate symbols is said to be *closed*) and axioms as first-order specifications of these open predicate symbols.

Example 2 Most methods of inductive synthesis are biased by program schemas whose templates have clauses of the forms in the following generic template:

$$\begin{aligned} r(X,Y,Z) \leftarrow\ & c(X,Y,Z), \\ & p(X,Y,Z) \\ r(X,Y,Z) \leftarrow\ & d(X,H,X_1,\ldots,X_t,Z), \\ & r(X_1,Y_1,Z),\ \ldots,\ r(X_t,Y_t,Z), \\ & q(H,Y_1,\ldots,Y_t,Z,Y) \end{aligned} \tag{2}$$

where c, d, p, q are open predicate symbols, X is a nonempty sequence of terms, and Y, Z are possibly empty sequences of terms. The intended semantics of this generic template can be informally described as follows. For an arbitrary relation r over parameters X, Y, Z, an instance of this generic template is to determine the values of *result parameter* Y corresponding to a given value of *induction parameter* X, considering the value of *auxiliary parameter* Z. Two cases arise: either the c test succeeds and X has a value for which Y can be easily directly computed through p, or X has a value for which Y cannot be so easily directly computed and the *divide-and-conquer principle* is applied:

1. *divide* X through d into a term H and t terms $X_1, \ldots, X_t$ of the same type as X but smaller than X according to some well-founded relation;
2. *conquer* through t recursive calls to r to determine the values of $Y_1, \ldots, Y_t$ corresponding to $X_1, \ldots, X_t$, respectively, considering the value of Z;
3. *combine* through q the terms $H, Y_1, \ldots, Y_t, Z$ to build Y.

Enforcing this intended semantics must be done manually, as any instance template by itself has no semantics, in the sense that any program is an instance of it (it suffices to define c by a program that always succeeds and p by the given program). One way to do this is to attach to a template some axioms (see Smith (1985) for the divide-and-conquer axioms), namely, the set of specifications of its open predicate symbols: these specifications refer to each other, including the one of r, and are generic (because even the specification of r is unknown), but can be manually abduced once and for all according to the informal semantics of the schema.

Predicate Invention

Another important **language bias** is the available vocabulary, which is here the set of predicate symbols mentioned in the evidence set or actually defined in the background knowledge (and possibly mentioned by the oracle). If an inductive synthesis fails, other than backtracking to a different program schema (i.e., shifting the statement bias), one can try and shift the vocabulary bias by inventing new predicate symbols and inducing programs for them in the extended vocabulary; this is also known as performing **constructive induction**. Only the invention of recursively defined predicate symbols is *necessary*, as a non-recursive definition of a predicate symbol can be eliminated by substitution (under **resolution**) for its calls in the induced program (even though that might make the program longer).

In general, it is undecidable whether **predicate invention** is necessary to induce a finite program in the vocabulary of its evidence and background knowledge (as a consequence of Rice's theorem, 1953), but introducing new predicate symbols always allows the induction of a finite program (as a consequence of a result by Kleene), as shown in Stahl (1995). The necessity of shifting the vocabulary bias is only decidable for some restricted languages (but the bias shift attempt might then be unsuccessful), so in practice one often has to resort to heuristics. Note that an inductive synthesizer of recursive algorithms may be recursive itself: it may recursively invoke itself for a necessary new predicate symbol.

Other than the decision problem, the difficulties of predicate invention are as follows. First, adequate formal parameters for a new predicate symbol have to be identified among all the variables in the clause using it. This can be done instantaneously by using precomputations done manually once and for all at the template level. Second, evidence for a new predicate symbol has to be **abduced** from the current program using the evidence for the old predicate symbol. This usually requires an oracle for the old predicate symbol, whose program is still unfinished at that moment and cannot be used. Third, the abduced evidence may be less numerous than for the old predicate symbol (note that if the new predicate symbol is in a recursive clause, then no new evidence might be abduced from the old evidence that is covered by the base clauses) and can be quite sparse, so that the new synthesis is more difficult. This *sparseness problem* can be illustrated by an example.

Example 3 Given the positive ground examples $\mathit{factorial}(0,1)$, $\mathit{factorial}(1,1)$, $\mathit{factorial}(2,2)$, $\mathit{factorial}(3,6)$, and $\mathit{factorial}(4,24)$ and given the still open program:

$$\begin{aligned}
factorial(N,F) &\leftarrow N=0,\ F=1\\
factorial(N,F) &\leftarrow add(M,1,N),\\
&\qquad factorial(M,G),\\
&\qquad product(N,G,F)
\end{aligned}$$

where *add* is known but *product* was just invented (and named so only for the reader's convenience), the abduceable examples are *product*$(1,1,1)$, *product*$(2,1,2)$, *product*$(3,2,6)$, and *product* $(4,6,24)$, which is hardly enough for inducing a recursive program for *product*; note that there is one less example than for *factorial*. Indeed, examples such as *product*$(3,6,18)$, *product*$(2,6,12)$, *product*$(1,6,6)$, etc. are missing, which puts the given examples more than one resolution step apart, if not on different **resolution** paths. This is aggravated by the absence of an oracle for the invented predicate symbol, which is not necessarily intrinsic to the task at hand (although *product* actually is intrinsic to] *factorial*).

Background Knowledge

In an inductive programming context, background knowledge is particularly important, as the inference of recursive programs is more difficult than the inference of **classifiers**. For the efficiency of synthesis, it is crucial that this collection of definitions of the predefined predicate symbols be *annotated* with information about the *types* of their arguments and about whether some *well-founded relation* is being enforced between some of their arguments, so that semantically suitable instances for the open predicate symbols of any chosen program schema can be readily spotted. (This requires in turn that the types of the arguments of the predicate symbols in the provided evidence are declared as well.) The background knowledge should be problem independent, and an inductive programming method should be able to perform *knowledge mobilization*, namely organizing it dynamically according to relevance to the current task.

In data-driven, analytical approaches, background knowledge is used in combination with **explanation-based learning** (EBL) methods, such as **abduction** (see Example 4) or systematic rewriting of input/output examples into computational traces (see Example 5).

Background knowledge can also be given in the form of constraints or an explicit inductive bias as in meta-interpretative learning (Muggleton and Lin 2013) or in using higher-order patterns (Katayama 2006).

Programs and Data

Example 4 The DIALOGS (Dialogue-based Inductive-Abductive LOGic program Synthesizer) method (Flener 1997) is interactive. The main design objective was to take all extra burden from the specifier by having the method ask for exactly and only the information it needs, default answers being provided wherever possible. As a result, no evidence needs to be prepared in advance, as the method invents its own candidate evidence and queries the oracle about it, with an opportunity to declare (at the oracle/specifier's risk) that enough information has been provided. All answers by the oracle are stored as *judgments*, to prevent asking the same query twice. This is suitable for all levels of expertise of human users, as the queries are formulated in the specifier's initially unknown conceptual language, in a way such that the specifier must know the answers if she really feels the need for the wanted program. The method is schema-biased, and the current implementation has two schemas. The template of the *divide-and-conquer* schema has the generality of the generic template (2). The template of the *accumulate* schema extends this by requiring an accumulator in the sequence Z of auxiliary parameters. The evidence language (**observation language**) is (non-recursive) logic programs with negation. Type declarations are provided as a **language bias**. The program language (**hypothesis language**) is recursive logic programs with negation, with possibly multiple base cases and recursive cases.

For instance, starting from the empty program for the relation *delOdds* in Example 1, the algorithm design choices of using the *divide-*

and-conquer schema with R as result parameter and L as induction parameter decomposed (with $t = 1$) through head-tail decomposition by d lead to the following intermediate open program:

$$\begin{aligned} delOdds(L,R) &\leftarrow c(L,R),\ p(L,R) \\ delOdds(L,R) &\leftarrow d(L,H,L_1), \\ &\quad delOdds(L_1,R_1), \\ &\quad q(H,R_1,R) \\ c(\_,\_) &\leftarrow true \\ d(L,H,T) &\leftarrow L = [H|T] \end{aligned} \tag{3}$$

The first five evidential clauses for *delOdds* in (1) are then implicitly interactively acquired from the oracle/specifier by the following question and answer dialogue, leading the specifier to reveal the intrinsic predicate symbol *odd*:

DIALOGS: When does *delOdds*([ ], R) hold?
Specifier: If $R = [\,]$.
DIALOGS: When does *delOdds*([X], R) hold?
Specifier: If ($odd(X)$ *and* $R = [\,]$) *or* ($\neg odd(X)$ *and* $R = [X]$).
DIALOGS: When does *delOdds*([X, Y], R) hold, assuming $odd(Y)$?
Specifier: If ($odd(X)$ *and* $R = [\,]$) *or* ($\neg odd(X)$ *and* $R = [X]$).
DIALOGS: When does *delOdds*([X, Y], R) hold, assuming $\neg odd(Y)$?
Specifier: If ($odd(X)$ *and* $R = [Y]$) *or* ($\neg odd(X)$ *and* $R = [X, Y]$).

Next, **abduction** infers the following evidence set for the still open predicate symbols p and q:

$$\begin{aligned} p([\,],[\,]) &\leftarrow true \\ p([X],[\,]) &\leftarrow odd(X) \\ p([X],[X]) &\leftarrow \neg odd(X) \\ p([X,Y],[Y]) &\leftarrow odd(X),\ \neg odd(Y) \\ p([X,Y],[X,Y]) &\leftarrow \neg odd(X),\ \neg odd(Y) \\ q(X,[\,],[\,]) &\leftarrow odd(X) \\ q(X,[\,],[X]) &\leftarrow \neg odd(X) \\ q(X,[Y],[Y]) &\leftarrow odd(X) \\ q(X,[Y],[X,Y]) &\leftarrow \neg odd(X) \end{aligned}$$

From this, induction infers the following closed programs for p and q:

$$\begin{aligned} p([\,],[\,]) &\leftarrow true \\ q(H,L,[H|L]) &\leftarrow \neg odd(H) \\ q(H,L,L) &\leftarrow odd(H) \end{aligned} \tag{4}$$

The final closed program is the union of the programs (3) and (4), as no predicate invention is deemed necessary. Sample syntheses with predicate invention are presented in Flener (1997) and Flener and Yılmaz (1999).

Example 5 The THESYS method (Summers 1977) was one of the first methods for the inductive synthesis of functional (Lisp) programs. Although it has a rather restricted scope, it can be seen as the methodological foundation of many later methods for inducing functional programs. The noninteractive method is schema biased, and the implementation has two schemas. Upon adaptation to functional programming, the template of the *linear recursion* schema is the instance of the generic template (2) obtained by having X as a sequence of exactly one induction parameter and Z as the empty sequence of auxiliary parameters, and by dividing X into $t = 1$ smaller value X_t, so that there is only $t = 1$ recursive call. The template of the *accumulate* schema extends this by having Z as a sequence of exactly one auxiliary parameter, playing the role of an accumulator. The evidence language (**observation language**) is sets of ground positive examples. The program language (**hypothesis language**) is recursive functional programs, with possibly multiple base cases, but only one recursive case. The only primitive functions are *nil*, *cons*, *head*, *tail*, and *empty*, because the implementation is limited to the list data type, inductively defined by $list \equiv nil \mid cons(x, list)$, under the axioms $empty(nil) = true$, $head(cons(x,y)) = x$, and $tail(cons(x,y)) = y$. There is no function invention.

For instance, from the following examples of a list unpacking function:

$$\begin{aligned}
&unpack(nil) &&= nil\\
&unpack((A)) &&= ((A))\\
&unpack((A\ B)) &&= ((A)\ (B))\\
&unpack((A\ B\ C)) &&= ((A)\ (B)\ (C))
\end{aligned}$$

the **abduced** traces are:

$$\begin{aligned}
&empty(X) &&\rightarrow nil\\
&empty(tail(X)) &&\rightarrow cons(X, nil)\\
&empty(tail(tail(X))) &&\rightarrow cons(cons(head(X), nil), cons(tail(X), nil))\\
&empty(tail(tail(tail(X)))) &&\rightarrow cons(cons(head(X), nil), cons(cons(head(tail(X)), nil),\\
& &&\quad\ cons(tail(tail(X)), nil)))
\end{aligned}$$

and the **induced** program is:

$$\begin{aligned}
unpack(X) = \ &empty(X) &&\rightarrow nil,\\
&empty(tail(X)) &&\rightarrow cons(X, nil),\\
&true &&\rightarrow cons(cons(head(X), nil), unpack(tail(X)))
\end{aligned}$$

A modern extension of THESYS is the IGOR method (Kitzelmann and Schmid 2006). The underlying program template describes the set of all functional programs with the following restrictions: built-in functions can only be first-order, and no nested or mutual recursion is allowed. IGOR adopts the two-step approach of THESYS. Synthesis is still restricted to structural problems, where only the structure of the arguments matters, but not their contents, such as in list reversing. Nevertheless, the scope of synthesizable programs is considerably larger. For instance, tree-recursive functions and functions with hidden parameters can be induced. Most notably, programs consisting of a calling function and an arbitrary set of further recursive functions can be induced. The first step of synthesis (trace construction) is therefore expanded such that traces can contain nestings of conditions. The second step is expanded such that the synthesis of a function can rely on the invention and synthesis of other functions (i.e., IGOR uses a technique of function invention in correspondence to the concept of **predicate invention** introduced above). An extension, IGOR2, relies on constructor term rewriting techniques. The two synthesis steps are merged into one and make use of background knowledge. Therefore, the synthesis of programs for semantic problems, such as list sorting, becomes feasible.

Applications

In the framework of *software engineering*, inductive programming is defined as the inference of information that is pertinent to the construction of a generalized computational system for which the provided evidence is a representative sample (Flener and Partridge 2001). In other words, inductive programming does *not* have to be a panacea for software development in the large and infer a complete software system in order to be useful: it suffices to induce, for instance, a self-contained system module while programming in the small, problem features and decision logic for specification acquisition and enhancement or support for debugging and testing. Inductive programming is then not always limited to programs with repetitive or recursive control structures. There are opportunities for synergy with manual programming and deductive program synthesis, as there are sometimes system modules that no one knows how to specify in a complete way, or that are harder to specify or program in a complete way, and yet where incomplete information such as input-output examples is readily available. More examples and pointers to the literature are given in Flener (2002, Section 5) and Flener and Partridge (2001).

In the context of *end-user programming*, inductive programming methods can be used to enable nonexpert users to take advantage of the more sophisticated functionalities offered by their software. This kind of application is in the focus of **programming by demonstration** (PBD).

Finally, it is worth having an evidential synthesizer of recursive algorithms invoked by a more general-purpose machine learning method when necessary predicate invention is detected or conjectured, as such general methods require a lot of evidence to infer reliably a recursively defined hypothesis.

Future Directions

Inductive programming is still mainly a topic of basic research, exploring how the intellectual ability of humans to infer generalized recursive procedures from incomplete evidence can be captured in the form of synthesis methods. Already a variety of promising methods are available. A necessary step should be to compare and analyze the current methods. A first extensive comparison of different ILP methods for inductive programming was presented some years ago (Flener and Yılmaz 1999). An up-to-date analysis should take into account not only ILP methods but also methods for the synthesis of functional programs, using classical (Kitzelmann and Schmid 2006) as well as evolutionary (Olsson 1995) methods. The methods should be compared with respect to the required quantity of evidence, the kind and amount of background knowledge, the scope of programs that can be synthesized, and the efficiency of synthesis. Such an empirical comparison should result in the definition of characteristics that describe concisely the scope, usefulness, and efficiency of the existing methods in different problem domains. A first step toward such a systematic comparison was presented in Hofmann et al. (2009).

Since only a few inductive programming methods can deal with semantic problems, it should be useful to investigate how inductive programming methods can be combined with other machine learning methods, such as kernel-based **classification**.

Finally, the existing methods should be adapted to a broad variety of application areas in the context of programming assistance, as well as in other domains where recursive data structures or recursive procedures are relevant.

Abstract

We describe different scenarios where a learning mechanism is capable of acquiring experience on a source task, and subsequently exploit such experience on a target task. The core ideas behind this ability to transfer knowledge from one task to another have been studied in the machine learning literature under different titles and perspectives. Here we describe some of them under the names of inductive transfer, transfer learning, multitask learning, metasearching, meta-generalization, and domain adaptation.

Synonyms

Domain adaptation; Multitask learning; Transfer learning; Transfer of knowledge across domains

Definition

Inductive transfer refers to the ability of a learning mechanism to improve performance on the current or *target* task after having learned a different but related concept or skill on a previous *source* task. Transfer may additionally occur between two or more learning tasks that are being undertaken concurrently. The object being transferred may refer to instances, features, a particular form of search bias, an action policy, background knowledge, etc.

Motivation and Background

Learning is not the result of an isolated task that starts from scratch with every new problem. Instead, a learning algorithm should exhibit the ability to adapt through a mechanism dedicated to transfer knowledge gathered from previous experience. The problem of transfer of knowledge is central to the field of machine learning and is also known as *inductive transfer*. In this case, knowledge can be understood as a collection of patterns observed across tasks. One view of the nature of patterns across tasks is that of invariant transformations. For example, image recognition of a target object is simplified if the object is invariant under rotation, translation, scaling, etc. A learning system should be able to recognize a target object on an image even if previous images show the object in different sizes or from different angles. Hence, inductive transfer studies know how to improve learning by detecting, extracting, and exploiting (meta)knowledge in the form of invariant transformations across tasks.

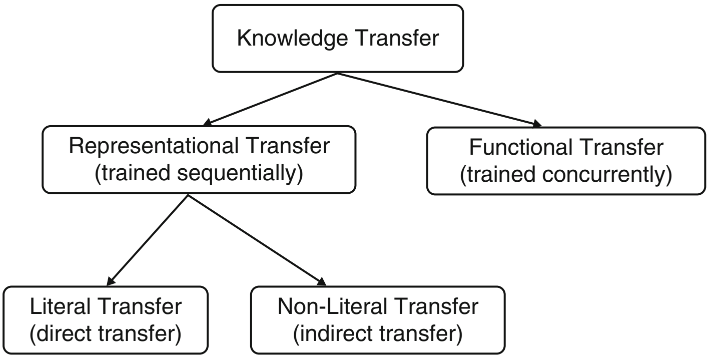
Similarly, in competitive games involving teams of robots (e.g., RoboCup Soccer), transferring knowledge learned from one task to another task is crucial to acquire skills necessary to beat the opponent team. Specifically, imagine a situation where a team of robots has been taught to keep a soccer ball away from the opponent team. To achieve that goal, robots must learn to keep the ball, pass the ball to a close teammate, etc., always trying to remain at a safe distance from the opponents. Now let us assume that we wish to teach the same team of robots to be efficient at scoring against a team of defending robots. Knowledge gained during the first activity can be transferred to the second one. Specifically, a robot can prefer to perform an action learned in the past over actions proposed during the current task, because the past action has a significant higher merit value. For example, a robot under the second task may learn to recognize that it is preferable to shoot than to pass the ball because the goal is very close. This action can be learned from the first task by recognizing that the precision of a pass is contingent upon the proximity of the teammate.

Structure of the Learning System

The main idea behind a learning architecture using knowledge transfer is to produce a source model from which knowledge can be extracted and transferred to a target model. This allows for multiple scenarios (Brazdil et al. 2009; Pratt and Thrun 1997). For example, the target and source models can be trained at different times in such a way that the transfer takes place after the source model has been trained. In this case there is an explicit form of knowledge transfer, also called *representational transfer*. In contrast, we use the term *functional transfer* to denote the case where two or more models are trained simultaneously; in this case the models share (part of) their internal structure during learning (see Neural Networks below). Under representational transfer, we denote as *literal transfer* the case when the source model is left intact and as *nonliteral transfer* the case when the source model is modified before knowledge is transferred to the target model. In nonliteral transfer some processing takes place on the source model before it is used to initialize the target model (see Fig. 1).

Neural Networks. A learning paradigm amenable to test the feasibility of knowledge transfer is that of neural networks (Caruana 1993). A popular form of (functional) knowledge transfer is effected through multitask learning, where the output nodes in the multilayer network represent more than one task. In such a scenario, internal nodes are shared by different tasks dynamically during learning. As an illustration, consider the problem of learning to classify astronomical objects from images mapping

Inductive Transfer, Fig. 1 A taxonomy of inductive transfer



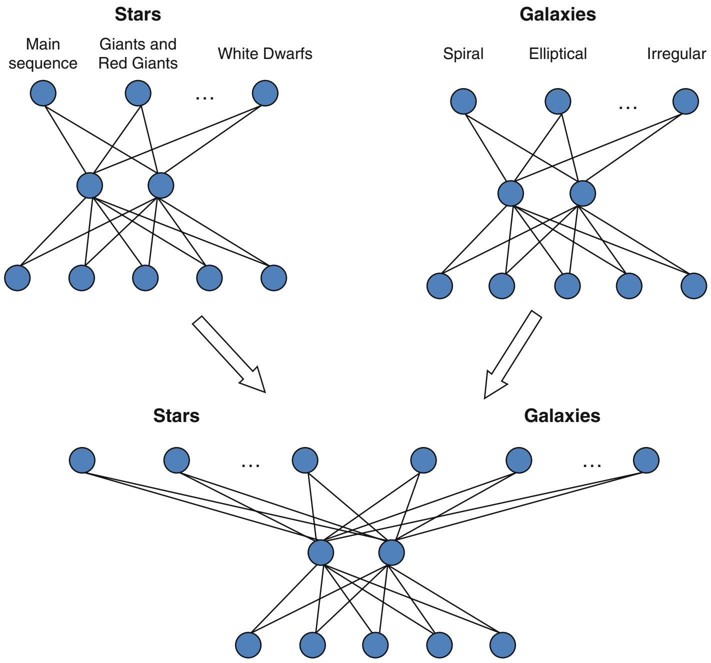
Knowledge Transfer
Representational Transfer (trained sequentially)
Functional Transfer (trained concurrently)
Literal Transfer (direct transfer)
Non-Literal Transfer (indirect transfer)

the sky into multiple classes. One task may be in charge of classifying a star into several classes (e.g., main sequence, dwarf, red giant, neutron, pulsar, etc.). Another task can focus on galaxy classification (e.g., spiral, barred spiral, elliptical, irregular, etc.). Rather than separating the problem into different tasks where each task is in charge of identifying one type of luminous object, one can combine the tasks together into a single parallel multitask problem where the hidden layer of a neural network shares patterns that are common to all classification tasks (see Fig. 2). The reasons explaining why learning often improves in accuracy and speed in this context is that training with many tasks in parallel on a single neural network induces information that accumulates in the training signals; if there exists properties common to several tasks, internal nodes can serve to represent common sub-concepts simultaneously.

Other Paradigms. Knowledge transfer can be performed using other learning and data analysis paradigms –mainly in the form of representational transfer– such as kernel methods, probabilistic methods, clustering, etc. (Raina et al. 2006; Evgeniou et al. 2005). For example, inductive transfer can take place in learning methods that assume a probabilistic distribution of the data by guaranteeing a form of relatedness among the distributions adopted across tasks (Raina et al. 2006). As an illustration, if learning to classify stars and galaxies both assume a mixture of normal densities to model the input-output or example-class distribution, one can force both distributions to have sets of parameters that are as similar as possible while preserving good generalization performance. In that case, shared knowledge can be interpreted as a set of assumptions about the data distribution for all tasks under analysis. The concept of knowledge transfer is also related to the problem of introducing new intermediate concepts during rule induction. In the inductive logic programming (ILP) setting, this is referred to as *predicate invention* (Stahl 1995).

Meta-Searching for Problem Solvers. A different research direction in inductive transfer explores complex scenarios where the software architecture itself evolves with experience (Schmidhuber 1997). The main idea is to divide a program into different components that can be reused during different stages of the learning process. As an illustration, one can work within the space of (self-delimiting binary) programs to propose an optimal ordered problem solver. The goal is to solve a sequence of problems, deriving one solution after the other, as optimally as possible. Ideally the system should be capable of exploiting previous solutions and of incorporating them into the solution to the current problem. This can be done by allocating computing time to the search for previous solutions that, if useful, become transformed into building blocks. We assume the current problem can be solved by copying or invoking previous pieces of code (i.e., building blocks or knowledge). In that case the mechanism will accept those solutions with substantial savings in computational time.

Inductive Transfer, Fig. 2 Example of multitask learning (functional transfer) applied to astronomical images



Domain Adaptation. A recent research direction in representational transfer seeks to adjust the model obtained in a source domain to account for differences exhibited in a new target domain. Unlike traditional studies in classification where both training and testing sets are assumed as realizations of the same joint input-output distribution, this *domain adaptation* approach either weakens or completely disregards such assumption (Ben-David et al. 2007, Daumé, et al. 2006, Storkey 2009). In addition, domain adaptation commonly assumes an abundance of labeled examples in the source domain, but little or no class labels in the target domain.

An example of these concepts lies in light curve classification from star samples obtained from different galaxies. A classification task set to differentiate different types of stars in a nearby source galaxy –where class labels are available– will experience a change in distribution as it moves to a target galaxy lying farther away –where class labels are unavailable. A major reason for such change is that at greater distances, less luminous stars fall below the detection threshold and more luminous stars are preferentially detected. The corresponding dataset shift (Quinonero-Candela et al. 2009) precludes the direct utilization of one single model across galaxies; it calls for a form of model adaptation to compensate for the change in the data distribution.

Domain adaptation has gained much attention recently, mainly due to the pervasive character of problems where distributions change over time. It assumes that the learning task remains constant, but the marginal and class posterior distributions between source and target domain may differ (as opposed to traditional transfer learning where tasks can in addition exhibit different input representations, i.e., different input spaces). Domain adaptation has been attacked from different angles: by searching for a single representation that unifies both source and target domains (Glorot et al. 2011); by proving error bounds as a function of empirical error and the distance between source and target distributions (Ben-David et al. 2010), within a co-training framework where target vectors are incorporated into the source training set based on confidence (Chen et al. 2011), by re-weighting source instances (Mansour et al. 2009), by using regularization terms to learn models that perform well on both source and target domains (Daumé et al. 2010), and several others.

Theoretical Work

Several studies have provided a theoretical analysis of the case where a learner uses experience from previous tasks to learn a new task. This process is often referred to as meta-learning or meta-generalization. The aim is to understand the conditions under which a learning algorithm can provide good generalizations when embedded in an environment made of related tasks. Although the idea of knowledge transfer is normally made implicit in the analysis, it is clear that the meta-learner extracts and exploits knowledge on every task to perform well on future tasks. Theoretical studies fall within a Bayesian model and within a probably approximately correct (PAC) model. The idea is to find not only the right hypothesis in a hypothesis space (base learning), but in addition to find the right hypothesis space in a family of hypothesis spaces (meta-learning).

We briefly review the main ideas behind these studies (Baxter 2000). We begin by assuming that the learner is embedded in a set of related tasks that share certain commonalities. Going back to the problem where a learner is designed for recognition of astronomical objects, the idea is to classify objects (e.g., stars, galaxies, nebulae, and planets) extracted from images mapping certain region of the sky. One way to transfer learning experience from one astronomical center to another is by sharing a meta-learner that carries a bias toward recognition of astronomical objects. In traditional learning, we assume a probability distribution $\mathbf{p}$ that indicates which examples are more likely to be seen in such a task. Now we assume that there is a more general distribution $\mathbf{P}$ over the space of all possible distributions. In essence, the meta-distribution $\mathbf{P}$ indicates which tasks are more likely to be found within the sequence of tasks faced by the meta-learner (distribution $\mathbf{p}$ indicates which examples are more likely to be seen in one task). In our example, the meta-distribution $\mathbf{P}$ peaks over tasks corresponding to classification of astronomical objects. Given a family of hypothesis spaces $\{\mathbf{H}\}$, the goal of the meta-learner is to find a hypothesis space $\mathbf{H}^*$ that minimizes a functional risk corresponding to the expected loss of the best possible hypothesis in each hypothesis space. In practice, since we ignore the form of $\mathbf{P}$, we need to draw samples $\mathbf{T_1}, \mathbf{T_2}, \ldots, \mathbf{T_n}$ to infer how tasks are distributed in our environment. To summarize, in the transfer learning scenario, our input is made of samples $\mathbf{T} = \{\mathbf{T_i}\}$, where each sample $\mathbf{T_i}$ is composed of examples. The goal of the meta-learner is to output a hypothesis space with a learning bias that generates accurate models for a new task.

Future Directions

The research community faces several challenges on how to efficiently transfer knowledge across tasks. One challenge involves devising learning architectures with an explicit representation of knowledge about models and algorithms, i.e., meta-knowledge. Most systems that integrate knowledge transfer mechanisms make an implicit assumption about the type of knowledge being transferred. This is indeed possible when strong assumptions are made on the relationship between the source and target tasks. For example, most approaches to domain adaptation work under strong assumptions about the similarity between the source and target tasks, imposing similar class posterior distributions, marginal distributions, or both. Ideally we would like to track the evolution of the source task to the target task to be able to justify any assumptions about their differences.

From a global perspective, it seems clear that proper treatment of the inductive transfer problem requires more than just statistical or mathematical techniques. Inductive transfer can be embedded in a complex artificial intelligence system that incorporates important components such as knowledge representation, search, planning, reasoning, etc. Without the incorporation of artificial intelligence components, we are forced to work with a large hypothesis space and a set of stringent assumptions about the nature of the discrepancy between the source and target tasks.

Information Retrieval

Information retrieval (IR) is a set of techniques that extract from a collection of documents those that are relevant to a given query. Initially addressing the needs of librarians and specialists, the field has evolved dramatically with the advent of the World Wide Web. It is more general than *data retrieval*, whose purpose is to determine which documents contain occurrences of the keywords that make up a query. Whereas the syntax and semantics of data retrieval frameworks is strictly defined, with queries expressed in a totally formalized language, words from a natural language given no or limited structure are the medium of communication for information retrieval frameworks. A crucial task for an IR system is to index the collection of documents to make their contents efficiently accessible. The documents retrieved by the system are usually ranked by expected relevance, and the user who examines some of them might be able to provide feedback so that the query can be reformulated and the results improved.

In-Sample Evaluation

Synonyms

Within-sample evaluation

Definition

In-sample evaluation is an approach to ▶ algorithm evaluation whereby the learned model is evaluated on the data from which it was learned. This provides a biased estimate of learning performance, in contrast to ▶ holdout evaluation.

Instance Space

Synonyms

Example space; Item space; Object space

Definition

An *instance space* is the space of all possible ▶ instances for some learning task. In ▶ attribute-value learning, the instance space is often depicted as a geometric space, one dimension corresponding to each attribute.

Instance-Based Learning

Eamonn Keogh
University of California-Riverside, Riverside, CA, USA

Synonyms

Analogical reasoning; Case-based learning; Memory-based; Nearest neighbor methods; Non-parametric methods

Definition

Instance-based learning refers to a family of techniques for ▶ classification and ▶ regression, which produce a class label/predication based on the similarity of the query to its nearest neighbor(s) in the training set. In explicit contrast to other methods such as ▶ decision trees and ▶ neural networks, instance-based learning algorithms do not create an abstraction from specific instances. Rather, they simply store all the data, and at query time derive an answer from an examination of the query's ▶ nearest neighbor (s).

Somewhat more generally, instance-based learning can refer to a class of procedures for solving new problems based on the solutions of similar past problems.

Motivation and Background

Most instance-based learning algorithms can be specified by determining the following four items:

1. Distance measure: Since the notion of similarity is being used to produce class label/prediction, we must explicitly state what similarity/distance measure to use. For real-valued data, Euclidean distance is a popular choice and may be optimal under some assumptions.
2. Number of neighbors to consider: It is possible to consider any number from one to all neighbors. This number is typically denoted as k.
3. Weighting function: It is possible to give each neighbor equal weight, or to weight them based on their distance to the query.
4. Mapping from local points: Finally, some method must be specified to use the (possibly weighted) neighbors to produce an answer. For example, for regression the output can be the weighted mean of the k nearest neighbors, or for classification the output can be the majority vote of the k nearest neighbors (with some specified tie-breaking procedure).

Since instance-based learning algorithms defer all the work until a query is submitted, they are sometimes called lazy algorithms (in contrast to eager learning algorithms, such as decision trees). Beyond the setting of parameters/distance measures/mapping noted above, one of the main research issues with instance-based learning algorithms is mitigating their expensive classification time, since a naïve algorithm would require comparing the distance for the query to every point in the database. Two obvious solutions are indexing the data to achieve a sublinear search, and numerosity reduction (data editing) (Wilson and Martinez 2000).

Further Reading

The best distance measure to use with an instance-based learning algorithms is the subject of active research. For the special case of time series data alone, there are at least one hundred methods (Ding et al. 2008). Conferences such as ICML, SIGKDD, etc. typically have several papers each year which introduce new distance measures and/or efficient search techniques.

Kernel-based reinforcement learning

Definition

Traditional reinforcement-learning (RL) algorithms operate on domains with discrete state spaces. They typically represent the value function in a table, indexed by states, or by state–action pairs. However, when applying RL to domains with continuous state, a tabular representation is no longer possible. In these cases, a common approach is to represent the value function by storing the values of a small set of states (or state–action pairs), and interpolating these values to other, unstored, states (or state–action pairs). This approach is known as instance-based reinforcement learning (IBRL). The instances are the explicitly stored values, and the interpolation is typically done using well-known instance-based supervised learning algorithms.

Motivation and Background

Instance-Based Reinforcement Learning (IBRL) is one of a set of value-function approximation techniques that allow standard RL algorithms to deal with problems that have continuous state spaces. Essentially, the tabular representation of the value function is replaced by an instance-based supervised learning algorithm and the rest of the RL algorithm remains unaltered. Instance-based methods are appealing because each stored instance can be viewed as analogous to one cell in the tabular representation. The interpolation method of the instance-based learning algorithm then blends the value between these instances.

IBRL allows generalization of value across the state (or state–action) space. Unlike tabular representations it is capable of returning a value approximation for states (or state–action pairs) that have never been directly experienced by the system. This means that, in theory, fewer experiences are needed to learn a good approximation to the value function and, hence, a good control policy. IBRL also provides a more compact representation of the value function than a table does. This is especially important in problems with multi-dimensional continuous state spaces. A straightforward discretization of such a space results in an exponential number of table cells. This, in turn, leads to an exponential increase in the amount of training experiences needed to obtain a good approximation of the value function.

An additional benefit of IBRL over other value-function approximation techniques, such as artificial neural networks, is the ability to bound the predicted value of the approximation. This is important, since it allow us to retain some of the theoretical non-divergence results for tabular representations.

Structure of Learning System

IBRL can be used to approximate both the state value function and the state–action value function. For problems with discrete actions, it is common to store a separate value function for each action. For continuous actions, the (continuous) state and action vectors are often concatenated, and VFA is done over this combined domain. For clarity, we will discuss only the state value function here, although our comments apply equally well to the state–action value function.

The Basic Approach

IBRL uses an instance-based supervised learning algorithm to replace the tabular value function representation of common RL algorithms. It maintains a set of states, often called basis points, and their associated values, using them to provide a value-function approximation for the entire state space. These exemplar states can be obtained in a variety of ways, depending on the nature of the problem. The simplest approach is to sample, either regularly or randomly, from the state space. However, this approach can result in an unacceptably large number of instances, especially if the state space is large, or has high dimension. A better approach is to use states encountered by the learning agent as it follows trajectories in the state space. This allows the representational power of the approximation algorithm to be focused on areas of the space in which the learning agent is likely to be. This, too, can result in a large number of states, if the agent is long-lived. A final approach combines the previous two by sub-sampling from the observed states.

Each stored instance state has a value associated with it, and an instance-based supervised learning algorithm is used to calculate the value of all other states. While any instance-based algorithm can be used, kernel-based algorithms have proven to be popular. Algorithms such as locally weighted regression (Smart and Kaelbling 2000), and radial basis function networks (Kretchmar and Anderson 1997) are commonly seen in the literature. These algorithms make some implicit assumptions about the form of the value function and the underlying state space, which we discuss below. For a state s, the kernel-based value-function approximation $V(s)$ is

$$V(s) = \frac{1}{\eta} \sum_{i=1}^{n} \phi(s, s_i) V(s_i), \tag{1}$$

where the s_i values are the n stored basis points, η is a normalizer,

$$\eta = \sum_{i=1}^{n} \phi(s, s_i), \tag{2}$$

and ϕ is the kernel function. A common choice for ϕ is an exponential kernel,

$$\phi(s, t) = e^{\frac{(s-t)^2}{\sigma^2}}, \tag{3}$$

where σ is the kernel bandwidth. The use of kernel-based approximation algorithms is well motivated, since they respect Gordon's non-divergence conditions (Gordon 1995), and also Szepesvári and Smart's convergence criteria (Szepesvári and Smart 2004).

As the agent gathers experience, the value approximations at each of the stored states and, optionally, the location and bandwidth of the states must be updated. Several techniques, often based on the temporal difference error, have been proposed, but the problem remains open. An alternative to on-line updates is a batch approach, which relies on storing the experiences generated by the RL agent, composing these into a discrete MDP, solving this MDP exactly, and then using supervised learning techniques on the states and their associated values. This approach is known as fitted value iteration (Szepesvári and Munos 2005).

Examples of IBRL Algorithms

Several IBRL algorithms have been reported in the literature. Kretchmar and Anderson (1997) presented one of the first IBRL algorithms. They used a radial basis function (RBF) network to approximate the state–action value function for the well-known mountain-car test domain. The temporal difference error of the value update is used to modify the weights, centers, and variances of the RBF units, although they noted that it was not particularly effective in producing good control policies.

Smart and Kaelbling (2000) used locally weighted learning algorithms and a set of heuristic rules to approximate the state–action value function. A set of states, sampled from those experienced by the learning agent, were stored along with their associated values. One approximation was stored for each discrete action. Interpolation between these exemplars was done by locally weighted averaging or locally weighted regression, supplemented with heuristics to avoid extrapolation and over-estimation. Learning was done on-line, with new instances being added as the learning agent explored the state space. The algorithm was shown to be effective in practice, but offered no theoretical guarantees.

Ormoneit and Sen (2002) presented an offline kernel-based reinforcement-learning algorithm that stores experiences (s_i, a_i, r_i, s_i') as the instances, and uses these to approximate the state–action value function for problems with discrete actions. For a given state s and action a, the state–action value $Q(s, a)$ is approximated as

$$\hat{Q}(s, a) = \frac{1}{\eta_{s,a}} \sum_{i | a_i = a} \phi\left(\frac{d(s, s_i)}{\sigma}\right) \left[r_i + \gamma \max_{a'} \hat{Q}(s_i', a')\right], \tag{4}$$

where ϕ is a kernel function, σ is the kernel bandwidth, γ is the RL discount factor, and $\eta_{s,a}$ is a normalizing term,

$$\eta_{s,a} = \sum_{i|a_i=a} \phi\left(\frac{d(s, s_i)}{\sigma}\right). \qquad (5)$$

They showed that, with enough basis points, this approximation converges to the true value function, under some reasonable assumptions. However, they provide no bound on the number of basis points needed to provide a good approximation to the value function.

Assumptions

IBRL makes a number of assumptions about the form of the value function, and the underlying state space. The main assumptions are that state similarity is well measure by (weighted) Euclidean distance. This implicity assumes that the underlying state space be metric, and is a topological disk. Essentially, this means that stattes that are close to each other in the state space have similar value. This is clearly not true for states between which the agent cannot move, such as those on the opposite sides of a thin wall. In this case, there is a discontinuity in the state space, introduced by the wall, which is not well modeled by the instance-based algorithm.

Instance-based function approximation algorithms assume that the function they model is smooth and continuous between the basis points. Any discontinuities in the function tend to get "smoothed out" in the approximation. This assumption is especially problematic for value-function approximation, since it allows value on one side of the discontinuity to affect the approximation on the other. If the location of the discontinuity is known, and we are able to allocate an arbitrary number of basis points, we can overcome this problem. However, in practical applications of RL, neither of these is feasible, and the problem of approximating the value function at or near discontinuities remains an open one.

Problems and Drawbacks

Although IBRL has been shown to be effective on a number of problems, it does have a number of drawbacks that remain unaddressed. Instance-based approximation algorithms are often expensive in terms of storage, especially for long-lived agents. Although the literature contains many techniques for editing the basis set of instance-based approximators, these techniques are generally for a supervised learning setting, where the utility of a particular edit can be easily evaluated. In the RL setting, we lack the ground truth available to supervised learning, making the evaluation of edits considerably more difficult. Additionally, as the number of basis points increases, so does the time needed to perform an approximation. This limitation is significant in the RL setting, since many such value predictions are needed on every step of the accompanying RL algorithm.

The value of a particular state, s, is calculated by blending the values from other nearby states, s_i. This is problematic if it is not possible to move from state s to each of the states s_i. The value of s should only be influenced by the value of states reachable from s, but this condition is not enforced by standard instance-based approximation algorithms. This leads to problems when modeling discontinuities in the value function, as noted above, and in situations where the system dynamics constrain the agent's motion, as in the case of a "one-way door" in the state space.

IBRL also suffers badly from the curse of dimen-sionality; the number of points needed to adequately represent the value function is exponential in the dimensionality of the state space. However, by using only states actually experienced by the learning agent, we can lessen the impact of this problem. By using only observed states, we are explicitly modeling the manifold over which the system state moves. This manifold is embedded in the full state space and, for many real-world problems, has a lower dimensionality than the full space. The Euclidean distance metric used by many instance-based algorithms will not accurately measure distance along this manifold. In practice, the manifold over which the system state moves will be locally Euclidean for problems with smooth, continuous dynamics. As a result, the assumptions of instance-based function approximators are valid locally and the approximations are of reasonable quality.

Intelligent Backtracking

Synonyms

Dependency directed backtracking

Definition

Intelligent backtracking is a general class of techniques used to enhance search and constraint satisfaction algorithms. Backtracking is a general mechanism in search where a problem solver encounters an unsolvable search state and backtracks to a previous search state that might be solvable. Intelligent backtracking mechanisms provide various ways of selecting the backtracking point based on past experience in a way that is likely to be fruitful.

Intent Recognition

▶ Inverse Reinforcement Learning

Internal Model Control

Synonyms

Certainty equivalence principle; Model-based control

Definition

Many advanced controllers for nonlinear systems require knowledge of the model of the dynamics of the system to be controlled. The system dynamics is often called an "internal model," and the resulting controller is model-based. If the model is not known, it can be learned with function approximation techniques. The learned model is subsequently used as if it were correct in order to synthesize a controller – the control literature calls this assumption the "certainty equivalence principle."

Interval Scale

An **interval** measurement scale ranks the data, and the differences between units of measure can be calculated by arithmetic. However, *zero* in the interval level of measurement means neither "nil" nor "nothing" as *zero* in arithmetic means. See ▶ Measurement Scales.

Inverse Entailment

Definition

Inverse entailment is a ▶ generality relation in ▶ inductive logic programming. More specifically, when learning from entailment using a background theory B, a hypothesis H covers an example e, relative to the background theory B if and only if $B \wedge H \models e$, that is, the background theory B and the hypothesis H together entail the example (see ▶ entailment). For instance, consider the background theory B:

```
bird :- blackbird.
bird :- ostrich.
```

and the hypothesis H:

```
flies :- bird.
```

Together $B \wedge H$ entail the example e:

```
flies :- blackbird, normal.
```

This can be decided through deductive inference. Now when learning from entailment in inductive logic programming, one starts from the example e and the background theory B, and the aim is to induce a rule H that together with B entails the example. Inverting entailment is based on the observation that $B \wedge H \models e$ is logically equivalent to $B \wedge \neg e \models \neg H$, which in turn can be used to compute a hypothesis H that will cover the example relative to the background theory. Indeed, the negation of the example is $\neg e$:

```
blackbird.
normal.
:-flies.
```

and together with B this entails $\neg H$:

```
bird.
:-flies.
```

The principle of inverse entailment is typically employed to compute the ▶ bottom clause, which is the most specific clause covering the example under entailment. It can be computed by generating the set of all facts (true and false) that are entailed by $B \wedge \neg e$ and negating the resulting formula $\neg H$.

Definition

Inverse reinforcement learning (inverse RL) considers the problem of extracting a reward function from observed (nearly) optimal behavior of an expert acting in an environment.

Motivation and Background

The motivation for inverse RL is twofold:

- For many RL applications, it is difficult to write down an explicit reward function specifying how different desiderata should be traded off exactly. In fact, engineers often spend significant effort tweaking the reward function such that the optimal policy corresponds to performing the task they have in mind. For example, consider the task of driving a car well. Various desiderata have to be traded off, such as speed, following distance, lane preference, frequency of lane changes, distance from the curb, etc. Specifying the reward function for the task of driving requires explicitly writing down the trade-off between these features.

Inverse RL algorithms provide an efficient solution to this problem in the apprenticeship learning setting – when an expert is available to demonstrate the task. Inverse RL algorithms exploit the fact that an expert demonstration implicitly encodes the reward function of the task at hand.

- Reinforcement learning and related frameworks are often used as computational models for animal and human learning (Watkins 1989; Schmajuk and Zanutto 1997; Touretzky and Saksida 1997). Such models are supported both by behavioral studies and by neurophysiological evidence that reinforcement learning occurs in bee foraging (Montague et al. 1995) and in songbird vocalization (Doya and Sejnowski 1995). It seems clear that in examining animal and human behavior, we must consider the reward function as an unknown to be ascertained through empirical investigation, particularly when dealing with multiatttribute reward functions. Consider, for example, that the bee might weigh nectar ingestion against flight distance, time, and risk from wind and predators. It is hard to see how one could determine the relative weights of these terms a priori. Similar considerations apply to human economic behavior, for example. Hence, inverse reinforcement learning is a fundamental problem of theoretical biology, econometrics, and other scientific disciplines that deal with reward-driven behavior.

Structure of the Learning System

Preliminaries and Notation

A Markov decision process (MDP) is a tuple $\langle S, A, T, \gamma, D, R\rangle$, where S is a finite set of states, A is a set of actions, $T = \{P_{sa}\}$ is a set of state-transition probabilities (here, P_{sa} is the state transition distribution upon taking action a in state s), $\gamma \in [0, 1)$ is a discount factor, D is the distribution over states for time zero, and $R : S \mapsto \mathbb{R}$ is the reward function.

A policy π is a mapping from states to probability distributions over actions. We let Π denote the set of all stationary policies (We restrict attention to stationary policies, since it is well known that there exists a stationary policy that is optimal for infinite horizon MDPs.). The value of a policy π is given by

$$V(\pi) = \mathrm{e}\left[\sum_{t=0}^{\infty} \gamma^t R(s_t)|\pi\right].$$

The expectation is taken with respect to the random state sequence $s_0, s_1, s_2, \ldots$ drawn by starting from a state $s_0 \sim D$ and picking actions according to π.

Let $\mu_S(\pi)$ be the discounted distribution over states when acting according to the policy π. In particular, for a discrete state space, we have that $[\mu_S(\pi)](s) = \sum_{t=0}^{\infty} \gamma^t \mathrm{Prob}(s_t = s|\pi)$. (In the case of a continuous state space, we replace $\mathrm{Prob}(s_t = s|\pi)$ by the appropriate probability density function.) Then, we have that

$$V(\pi) = R^\top \mu_S(\pi).$$

Thus, the value of a policy π when starting from a state s_0 is linear in the reward function.

Often the reward function R can be represented more compactly. Let $\phi : S \to \mathbb{R}^n$ be a feature map. A typical assumption in inverse RL is to assume the reward function R is a linear combination of the features ϕ: $R(s) = w^\top \phi(s)$. Then, we have that the value of a policy π is linear in the reward function weights w:

$$\begin{aligned} V(\pi) &= E[\textstyle\sum_{t=0}^{\infty} \gamma^t R(s_t)|\pi] \\ &= E[\textstyle\sum_{t=0}^{\infty} \gamma^t w^\top \phi(s_t)|\pi] \\ &= w^\top E[\textstyle\sum_{t=0}^{\infty} \gamma^t \phi(s_t)|\pi] \\ &= w^\top \mu_\phi(\pi). \end{aligned} \quad (1)$$

Here, we used linearity of expectation to bring w outside of the expectation. The last equality defines the vector of *feature expectations* $\mu_\phi(\pi) = E\big[\sum_{t=0}^{\infty} \gamma^t \phi(s_t)|\pi\big]$.

We assume access to demonstrations by some expert. We denote the expert's policy by π^*. Specifically, we assume the ability to observe trajectories (state sequences) generated by the expert starting from $s_0 \sim D$ and taking actions according to π^*.

Characterization of the Inverse RL Solution Set

A reward function R is consistent with the policy π^* being optimal if and only if the value obtained when acting according to the policy π^* is at least as high as the value obtained when acting according to any other policy π, or equivalently:

$$U(\pi^*) \geq U(\pi) \ \ \forall \pi \in \Pi. \tag{2}$$

Using the fact that $U(\pi) = R^\top \mu_S(\pi)$, we can equivalently write the conditions of Eq. (2) as a set of linear constraints on the reward function R:

$$R^\top \mu_S(\pi^*) \geq R^\top \mu_S(\pi) \ \ \forall \pi \in \Pi. \tag{3}$$

The state distribution $\mu_S(\pi)$ does not depend on the reward function R. Thus, Eq. (3) is a set of linear constraints in the reward function, and we can use a linear program (LP) solver to find a reward function consistent with the policy π^* being optimal. Strictly speaking, Eq. (3) solves the inverse RL problem. However, to apply inverse RL in practice, the following three issues need to be addressed:

1. **Reward function ambiguity.** Typically a large set of reward functions satisfy all the constraints of Eq. (3). One such a reward function that satisfies all the constraints for any MDP is the all-zeros reward function (it is consistent with any policy being optimal). Clearly, the all-zeros reward function is not a desirable answer to the inverse RL problem. More generally, this observation suggests not all reward functions satisfying Eq. (3) are of equal interest and raises the question of how to recover reward functions that are of interest to the inverse RL problem.
2. **Statistical efficiency.** Often the state space is very large (or even infinite), and we do not have sufficiently many expert demonstrations available to accurately estimate $\mu(\cdot\,; \pi^*)$ from data.
3. **Computational efficiency.** The number of constraints in Eq. (3) is equal to the number of stationary policies $|\Pi|$ and grows quickly with the number of states and actions of the MDP. For finite-state-action MDPs, we have $|A|^{|S|}$ constraints. So, even for small state and action spaces, feeding all the constraints of Eq. (3) into an LP solver becomes quickly impractical. For continuous state-action spaces, the formulation of Eq. (3) has an infinite number of constraints, and thus using a standard LP solver to find a feasible reward function R is impossible.

In the following sections, we address these three issues.

Reward Function Ambiguity

As observed above, typically a large set of reward functions satisfy all the constraints of Eq. (3). To obtain a single reward function, it is natural to reformulate the inverse RL problem as an optimization problem. We describe one standard approach for disambiguation. Of course many other formulations as an optimization problem are possible.

Similar to common practice in support vector machines research, one can maximize the (soft) margin by which the policy π^* outperforms all other policies. As is common in structured prediction tasks ((see, e.g., Taskar et al. (2003)), one can require the margin by which the policy π^* outperforms another policy π to be larger when π differs more from π^*, as measured according to some function $h(\pi^*, \pi)$. The resulting formulation (Ratliff et al. 2006) is

$$\begin{aligned} \min_{R,\xi} \quad & \|R\|_2^2 + C\xi \\ \text{s.t. } & R^\top \mu_S(\pi^*) \geq R^\top \mu_S(\pi) + h(\pi^*, \pi) - \xi \\ & \forall \pi \in \Pi. \end{aligned} \tag{4}$$

For the resulting optimal reward function to correspond to a desirable solution to the inverse RL problem, it is important that the objective and the margin scaling encode the proper prior knowledge. If a sparse reward function is suggested by prior knowledge, then a 1-norm might be more appropriate in the objective. An example of a margin scaling function for a discrete MDP is the number of states in which the action prescribed by the policy π differs from the action prescribed by the expert policy π^*. If the expert has only been observed in a small number of states, then one could restrict attention to these states when evaluating this margin scaling function.

Another way of encoding prior knowledge is by restricting the reward function to belong to a certain functional class, for example, the set of functions linear in a specified set of features. This approach is very common and is also important for statistical efficiency. It will be explained in the next section.

Remark When using inverse RL to help us specify a reward function for a given task based on an expert demonstration, it is not necessary to explicitly resolve the ambiguities in the reward function. In particular, one can probably perform as well as the expert without matching the expert's reward function. More details are given in Sect. "A Generative Approach to Inverse RL".

Statistical Efficiency

As formulated thus far, solving the inverse RL problem requires the knowledge (or accurate statistical estimates) of $\mu_S(\pi^*)$. For most practical problems, the number of states is large (or even infinite), and thus accurately estimating $\mu_S(\pi^*)$ requires a very large number of expert demonstrations. This (statistical) problem can be resolved by restricting the reward function to belong to a prespecified class of functions. The common approach is to assume the reward function R can be expressed as a linear combination of a known set of features. In particular, we have $R(s) = w^\top \phi(s)$. Using this assumption, we can use the expression for the value of the policy π from Eq. (1).

Rewriting Eq. (4), we now have the following constraints in the reward weights w:

$$\begin{aligned} \min_{w,\xi} \quad & \|w\|_2^2 + C\xi \\ \text{s.t. } & w^\top \mu_\phi(\pi^*) \geq w^\top \mu_\phi(\pi) + h(\pi^*, \pi) - \xi \\ & \forall \pi \in \Pi. \end{aligned} \tag{5}$$

This new formulation only requires estimates of the expected feature counts $\mu_\phi(\pi^*)$, rather than estimates of the distribution over the state space $\mu_S(\pi^*)$. Assuming the number of features is smaller than the number of states, this significantly reduces the number of expert demonstrations required.

Computational Efficiency

For concreteness, we will consider the formulation of Eq. (6). Although the number of variables is only equal to the number of features in the reward function, the number of constraints is very large (equal to the number of stationary policies). As a consequence, feeding the problem into a standard quadratic programming (QP) solver will not work.

Ratliff et al. (2006) suggested a formal computational approach to solving the inverse RL problem, using standard techniques from convex optimization, which provide convergence guarantees. More specifically, they used a subgradient method to optimize the following equivalent problem:

$$\begin{aligned} \min_{w,\xi} \|w\|_2^2 + C \max_{\pi \in \Pi} \Big(& w^\top \mu_\phi(\pi) + h(\pi^*, \pi) \\ & - w^\top \mu_\phi(\pi^*) \Big) . \end{aligned} \tag{6}$$

In each iteration, to compute the subgradient, it is sufficient to find the optimal policy with respect to a reward function that is easily determined from the current reward weights w and the margin scaling function $h(\pi^*, \cdot)$. In more recent work, Ratliff et al. (2007) proposed a boosting algorithm to solve a formulation similar to Eq. (6), which also includes feature selection.

A Generative Approach to Inverse RL

Abbeel and Ng (2004) made the following observation, which resolves the ambiguity problem in a completely different way: if, for a policy π, we have that $\mu_\phi(\pi) = \mu_\phi(\pi^*)$, then the following holds:

$$U(\pi) = w^\top \mu_\phi(\pi) = w^\top \mu_\phi(\pi^*) = U(\pi^*),$$

no matter what the value of w is. Thus, to perform as well as the expert, it is sufficient to find a policy that attains the same expected feature counts μ_ϕ as the expert.

Abbeel and Ng provide an algorithm that finds a policy π satisfying $\mu_\phi(\pi) = \mu_\phi(\pi^*)$. The algorithm iterates over two steps: (i) Generate a reward function by solving a QP. (ii) Solve the MDP for the current reward function.

In contrast to the previously described inverse RL methods, which focus on merely recovering a reward function that could explain the expert's behavior, this inverse RL algorithm is shown to find a policy that performs at least as well as the expert. The algorithm is shown to converge in a polynomial number of iterations.

Apprenticeship Learning: Inverse RL Versus Imitation Learning

Inverse RL alleviates the need to specify a reward function for a given task when expert demonstrations are available. Alternatively, one could directly estimate the policy of the expert using standard a machine-learning algorithm, since it is simply a mapping from state to action. The latter approach, often referred to as imitation learning or behavioral cloning (links), has been successfully tested on a variety of tasks, including learning to fly in a fixed-wing flight simulator (Sammut et al. 1992) and learning to drive a car (Pomerleau 1989; Abbeel and Ng 2004).

The imitation learning approach can be expected to be successful whenever the policy class to be considered can be learned efficiently from data. In contrast, the inverse RL approach relies on having a reward function that can be estimated efficiently from data.

Inverse Resolution

Definition

Inverse resolution is, as the name indicates, a rule that inverts resolution. This follows the idea of induction as the inverse of deduction formulated in the ▶ logic of generality. The resolution rule is the best-known deductive inference rule, used in many theorem provers and logic programming systems. ▶ Resolution starts from two ▶ clauses and derives the resolvent, a clause that is entailed by the two clauses. This can be graphically represented using the following schema (for propositional logic).

$$\frac{h \leftarrow g, a_1, \ldots, a_n \text{ and } g \leftarrow b_1, \ldots, b_m}{h \leftarrow b_1, \ldots, b_m, a_1, \ldots, a_n}.$$

Inverse resolution operators, such as *absorption* (17) and *identification* (17), invert this process.

To this aim, they typically assume the resolvent is given together with *one* of the original clauses and then derive the missing clause. This leads to the following two operators, which start from the clauses below and induce the clause above the line.

$$\frac{h \leftarrow g, a_1, \ldots, a_n \text{ and } g \leftarrow b_1, \ldots, b_m}{h \leftarrow b_1, \ldots, b_m, a_1, \ldots, a_n \text{ and } g \leftarrow b_1, \ldots, b_m},$$

$$\frac{h \leftarrow g, a_1, \ldots, a_n \text{ and } g \leftarrow b_1, \ldots, b_m}{h \leftarrow b_1, \ldots, b_m, a_1, \ldots, a_n \text{ and } h \leftarrow g, a_1, \ldots, a_n}$$

The operators are shown here only for the propositional case, as the first order case is more involved as it requires one to deal with substitutions as well as inverse substitutions.

As one example, consider the clauses

1. flies :- bird, normal.
2. bird :- blackbird.
3. flies :- blackbird, normal.

Here, (3) is the resolvent of (1) and (2). Furthermore, starting from (3) and (2), the absorption operator would generate (1), and starting from (3) and (1), the identification operator would generate (2).

k-Armed Bandit

Shie Mannor
Israel Institute of Technology, Haifa, Israel

Synonyms

Multi-armed bandit; Multi-armed bandit problem

Definition

In the classical k-armed bandit problem, there are k alternative arms, each with a stochastic reward whose probability distribution is initially unknown. A decision maker can try these arms in some order, which may depend on the rewards that have been observed so far. A common objective in this context is to find a policy for choosing the next arm to be tried, under which the sum of the expected rewards comes as close as possible to the ideal reward, that is, the expected reward that would be obtained if it were to try the "best" arm at all times. There are many variants of the k-armed bandit problem that are distinguished by the objective of the decision maker, the process governing the reward of each arm, and the information available to the decision maker at the end of every trial.

Motivation and Background

k-Armed bandit problems are a family of sequential decision problems that are among the most studied problems in statistics, control, decision theory, and machine learning. In spite of their simplicity, they encompass many of the basic problems of sequential decision making in uncertain environments such as the tradeoff between exploration and exploitation.

There are many variants of bandit problems including Bayesian, Markovian, adversarial, budgeted, and exploratory variants. Bandit formulations arise naturally in multiple fields and disciplines including communication networks, clinical trials, search theory, scheduling, supply chain automation, finance, control, information technology, etc. (Berry and Fristedt 1985; Cesa-Bianchi and Lugosi 2006; Gittins 1989).

The term "multi-armed bandit" is borrowed from the slang term for a slot machine (the one-armed bandit), where a decision maker has to decide whether to insert a coin into the gambling machine and pull a lever possibly getting a significant reward, or to quit without spending any money.

Theory

We briefly review some of the most popular bandit variants.

C. Sammut, G.I. Webb (eds.), *Encyclopedia of Machine Learning and Data Mining*,
DOI 10.1007/978-1-4899-7687-1

The Stochastic *k*-Armed Bandit Problem

The classical stochastic bandit problem is described as follows. There are k arms (or machines or actions) and a single decision maker (or controller or agent). Each arm corresponds to a discrete time Markov process. At each timestep, the decision maker observes the current state of each arm's process and selects one of the arms. As a result, the decision maker obtains a reward from the process of the selected arm and the state of the corresponding process changes. Arms that are not selected are "frozen" and their processes remain in the same state. The objective of the decision maker is to maximize her (discounted) reward.

More formally, let the state of arm n's process at stage t be $x_n(t)$. Then, if the decision maker selects arm $m(t)$ at time t we have that:

$$x_n(t+1) = \begin{cases} x_n(t) & n \neq m(t) \\ f_n(x_n(t), \omega) & n = m(t) \end{cases},$$

where $f_n(x, \omega)$ is a function that describes the (possibly stochastic) transition probability of the n-th process and accepts the state of the n-th process and a random disturbance ω.

The reward the decision maker receives at time t is a function of the current state and a random element: $r(x_{m(t)}(t), \omega)$. The objective of the decision maker is to maximize her cumulative discounted reward. That is, she wishes to maximize

$$V = \mathbf{E}^{\pi}\left[\sum_{t=1}^{\infty} \gamma^t r(x_{m(t)}(t), \omega_t)\right],$$

where $\mathbf{E}^{\pi}$ is the expectation obtained when following policy π and γ is a discount factor ($0 < \gamma < 1$). A policy is a decision rule for selected arms as a function of the state of the processes.

This problem can be solved using ▶ dynamic programming, but the state space of the joint Markov decision process is exponential in the number of arms. Moreover, the dynamic programming solution does not reveal the important structural properties of the solution.

Gittins and Jones (1972) showed that there exists an optimal index policy. That is, there is a function that maps the state of each arm to real number (the "index") such that the optimal policy is to choose the arm with the highest index at any given time. Therefore, the stochastic bandit problem reduces to the problem of computing the index, which can be easily done in many important cases.

Regret Minimization for the Stochastic *k*-Armed Bandit Problem

A different flavor of the bandit problem focuses on the notion of regret, or learning loss. In this formulation, there are k arms as before and when selecting arm m a reward that is independent and identically distributed is given (the reward depends only on the identity of the arm and not on some internal state or the results of previous trials). The decision maker's objective is to obtain high expected reward. Of course, if the decision maker had known the statistical properties of each arm, she would have always chosen the arm with the highest expected reward. However, the decision maker does not know the statistical properties of the arms in advance, in this setting.

More formally, if the reward when choosing arm m has expectation r_m, the regret is defined as:

$$r(t) = t \cdot \max_{1 \le m \le k} r_m - \mathbf{E}^{\pi}\left[\sum_{\tau=1}^{t} r(\tau)\right], \qquad (1)$$

where $r(t)$ is sampled from the arm $m(t)$. This quantity represents the expected loss for not choosing the arm with the highest expected reward on every timestep.

This variant of the bandit problem highlights the tension between acquiring information (exploration) and using the available information (exploitation). The decision maker should carefully balance between the two since if she chooses to only try the arm with the highest estimated reward she might regret not exploring other arms whose reward is underestimated but is actually higher than the reward of the arm with highest estimated reward.

A basic question in this context is whether $R(t)$ can be made to grow sub-linearly. Robbins (1952) answered this question in the affirmative. It was later proved (Lai and Robbins 1985) that it is possible in fact to obtain logarithmic regret (the growth of the regret is logarithmic in the number of timesteps). Matching lower bounds (and constants) were also derived.

The Non-stochastic *k*-Armed Bandit Problem

A third popular variant of the bandit problem is the non-stochastic one. In this problem, it is assumed that the sequence of rewards each arm produces is deterministic (possibly adversarial). The decision maker, as in the stochastic bandit problem, wants to minimize her regret, where the regret is measured with respect to the best fixed arm (this best arm might change with time, however). Letting the reward of arm m at time t be $r_m(t)$, we redefine the regret as:

$$r(t) = \max_{1 \le m \le k} \sum_{\tau=1}^{t} r_m(\tau) - \mathbf{E}^{\pi}\left[\sum_{\tau=1}^{t} r(\tau)\right], \quad (2)$$

where the expectation is now taken with respect to randomness in the arm selection. The basic question here is if the regret can be made to grow sub-linearly. The case where the reward of each arm is observed was addressed in the 1950s (see Cesa-Bianchi and Lugosi (2006), for a discussion), where it was shown that there are algorithms that guarantee that the regret grows like $\sqrt{t}$. For the more difficult case, where only the reward of the selected arm is observed and that the rewards of the other arms may not be observed it was shown (Auer et al. 2002) that the same conclusion still holds.

It should be noticed that the optimal policy of the decision maker in this adversarial setting is generally randomized. That is, the decision maker has to select an action at random by following some distribution. The reason is that if the action the decision maker takes is deterministic and can be predicted by Nature, then Nature can consistently "give" the decision maker a low reward for the selected arm while "giving" a high reward to all other arms, leading to a linear regret.

There are some interesting relationships between the non-stochastic bandit problem and prediction with expert advice, universal prediction, and learning in games (Cesa-Bianchi and Lugosi 2006).

The Exploratory *k*-Armed Bandit Problem

This bandit variant emphasizes efficient exploration rather than on the exploration–exploitation tradeoff. As in the stochastic bandit problem, the decision maker is given access to k arms where each arm is associated with an independent and identically distributed random variable with unknown statistics. The decision maker's goal is to identify the "best" arm. That is, the decision maker wishes to find the arm with the highest expected reward as quickly as possible.

The exploratory bandit problem is a sequential hypothesis testing problem but with the added complication that the decision maker can choose where to sample next, making it among the simplest active learning problems. In the context of the probably approximate correct (PAC) setup, it was shown (Mannor and Tsitsiklis 2004) that finding the ε-optimal arm (that is, an arm whose expected reward is lower than that of the best arm by at most ε) with probability of at least $1 - \delta$ requires

$$O\left(\frac{k}{\varepsilon^2}\log\left(\frac{1}{\delta}\right)\right)$$

samples on expectation. Moreover, this bound can be obtained (up to multiplicative constants) via an algorithm known as median elimination.

Bandit analyses such as these have played a key role in understanding the efficiency of ▸ reinforcement-learning algorithm as well.

Kernel Matrix

Synonyms

Gram matrix

Definition

Given a kernel function $k\colon X \times X \to$ and patterns $x_1, \ldots, x_m \in X$, the $m \times m$ matrix K with elements $K_{ij} := k(x_i, x_j)$ is called the kernel matrix of k with respect to $x_1, \ldots, x_m$.

Kernel Methods

Abstract

Over the past decade, kernel methods have gained much popularity in machine learning. Linear estimators have been popular due to their convenience in analysis and computation. However, nonlinear dependencies exist intrinsically in many real applications and are indispensable for effective modeling. Kernel methods can sometimes offer the best of both aspects. The reproducing kernel Hilbert space provides a convenient way to model nonlinearity, while the estimation is kept linear. Kernels also offer significant flexibility in analyzing generic non-Euclidean objects such as graphs, sets, and dynamic systems. Moreover, kernels induce a rich function space where functional optimization can be performed efficiently. Furthermore, kernels have also been used to define statistical models via exponential families or Gaussian processes and can be factorized by graphical models. Indeed, kernel methods have been widely used in almost all tasks in machine learning.

Definition

Kernel methods refer to a class of techniques that employ positive definite kernels. At an algorithmic level, its basic idea is quite intuitive: implicitly map objects to high-dimensional feature spaces and then directly specify the inner product there. As a more principled interpretation, it formulates learning and estimation problems in a reproducing kernel Hilbert space, which is advantageous in a number of ways:

- It induces a rich feature space and admits a large class of (nonlinear) functions.
- It can be flexibly applied to a wide range of domains including both Euclidean and non-Euclidean spaces.
- Searching in this infinite-dimensional space of functions can be performed efficiently, and one only needs to consider the finite subspace expanded by the data.
- Working in the linear spaces of function lends significant convenience to the construction and analysis of learning algorithms.

Motivation and Background

The reproducing kernel was first studied by Aronszajn (1950). Poggio and Girosi (1990) and Wahba (1990) used kernels for data analysis, and Boser et al. (1992) incorporated kernel functions into maximum margin models. Schölkopf et al. (1998) first used kernels for principal component analysis.

Theory

Positive semi-definite (psd) kernels are the most commonly used type of kernels, and its motivation is as follows. Given two objects x_1, x_2 from a space $\mathcal{X}$ which is not necessarily Euclidean, we map them to a high-dimensional feature space via $\phi(x_1)$ and $\phi(x_2)$, and then compute the inner products there by $k(x_1, x_2) = \langle \phi(x_1)\phi(x_2)\rangle$. In many algorithms, the set $\{x_i\}$ influences learning only via inner products between x_i and x_j; hence it is sufficient to specify $k(x_1, x_2)$ directly without explicitly defining ϕ. This leads to considerable savings in computation, when ϕ ranges in high-dimensional spaces or even infinite-dimensional spaces. Clearly, the function k must satisfy some conditions. For example, as a necessary condition, for any finite number of examples $x_1, \ldots, x_n$ from $\mathcal{X}$, the matrix

$$\begin{aligned} K &:= (k(x_i, x_j))_{i,j} \\ &= (\phi(x_1), \ldots, \phi(x_n))^\top (\phi(x_1), \ldots, \phi(x_n)) \end{aligned}$$

must be positive semi-definite. Surprisingly, this turns out to be a sufficient condition as well, and hence we define the positive semi-definite kernels.

Definition 1 (positive semi-definite kernels) Let $\mathcal{X}$ be a nonempty set. A function $k : \mathcal{X} \times \mathcal{X} \mapsto \mathbb{R}$ is called a positive semi-definite kernel if for any $n \in \mathbb{N}$ and $x_1, \ldots, x_n \in \mathcal{X}$, the Gram matrix $K := (k(x_i, x_j))_{i,j}$ is symmetric and positive semi-definite (psd).

Reproducing Kernel Hilbert Space

Given a psd kernel k, we are able to construct a map ϕ from $\mathcal{X}$ to an inner product space $\mathcal{H}$, such that $\langle \phi(x_1)\phi(x_2)\rangle = k(x_1, x_2)$. The image of x under ϕ is just a function $\phi(x) := k(x, \cdot)$, where $k(x, \cdot)$ is a function of $\cdot$, assigning the value $k(x, x')$ for any $x' \in \mathcal{X}$. To define inner products between functions, we need to construct an inner product space $\mathcal{H}$ which contains $\{k(x, \cdot) : x \in \mathcal{X}\}$. First, $\mathcal{H}$ must contain the linear combinations $\left\{\sum_{i=1}^{n} \alpha_i k(x_i, \cdot) : n \in \mathbb{N}, x_i \in \mathcal{X}, \alpha_i \in \mathbb{R}\right\}$. Then we endow it with an inner product as follows. For any $f, g \in \mathcal{H}$ and $f = \sum_{i=1}^{n} \alpha_i k(x_i, \cdot)$, $g = \sum_{j=1}^{m} \beta_j k(x'_j, \cdot)$, define

$$\langle fg\rangle := \sum_{i=1}^{n} \sum_{j=1}^{m} \alpha_i \beta_j k(x_i, x'_j),$$

and it is easy to show that this is well defined (independent of the expansion of f and g). Using the induced norm, we can complete the space and thus get a Hilbert space $\mathcal{H}$, which is called reproducing kernel Hilbert space (RKHS). The term "reproducing" is because for any function $f \in \mathcal{H}$, $\langle f k(x, \cdot)\rangle = f(x)$.

Properties of psd Kernels

Let $\mathcal{X}$ be a nonempty set and $k_1, k_2, \ldots$ be arbitrary psd kernels on $\mathcal{X} \times \mathcal{X}$. Then

- The set of psd kernels is a closed convex cone, *i.e.*, (a) if $\alpha_1, \alpha_2 \geq 0$, then $\alpha_1 k_1 + \alpha_2 k_2$ is psd and (b) if $k(x, x') := \lim_{n \to \infty} k_n(x, x')$ exists for all x, x', then k is psd.
- The pointwise product $k_1 k_2$ is psd.

- Assume for $i = 1, 2$, k_i is a psd kernel on $\mathcal{X}_i \times \mathcal{X}_i$, where $\mathcal{X}_i$ is a nonempty set. Then the tensor product $k_1 \otimes k_2$ and the direct sum $k_1 \oplus k_2$ are psd kernels on $(\mathcal{X}_1 \times \mathcal{X}_2) \times (\mathcal{X}_1 \times \mathcal{X}_2)$.

Example Kernels

One of the key advantages of kernels lies in its applicability to a wide range of objects.

Euclidean Spaces In $\mathbb{R}^n$, popular kernels include linear kernel $k(x_1, x_2) = \langle x_1 x_2 \rangle$, polynomial kernels $k(x_1, x_2) = (\langle x_1 x_2 \rangle + c)^d$ where $d \in \mathbb{N}$ and $c \geq 0$, Gaussian RBF kernels $k(x_1, x_2) = \exp(-\gamma \|x_1 - x_2\|^2)$ where $\gamma > 0$, and Laplacian RBF kernels $k(x_1, x_2) = \exp(-\gamma \|x_1 - x_2\|)$. Another useful type of kernels on Euclidean spaces is the spline kernels.

Convolution Kernels Haussler (1999) investigated how to define a kernel between composite objects by building on the similarity measures that assess their respective parts. It needs to enumerate all possible ways to decompose the objects; hence efficient algorithms like dynamic programming are needed.

Graph Kernels Graph kernels are available in two categories: between graphs and on a graph. The first type is similar to convolution kernels, which measures the similarity between two graphs. The second type defines a metric between the vertices and is generally based on the graph Laplacian. By applying various transform functions to the eigenvalue of the graph Laplacian, various smoothing and regularization effects can be achieved.

Fisher Kernels Kernels can also be defined between probability densities $p(x|\theta)$. Let $U_\theta(x) = -\partial_\theta \log p(x|\theta)$ and $I = \mathbb{E}_x[U_\theta(x) U_\theta^\top(x)]$ be the Fisher score and Fisher information matrix, respectively. Then the normalized and unnormalized Fisher kernels are defined by

$$k(x, x') = U_\theta^\top(x) I^{-1} U_\theta(x')$$
$$\text{and} \quad k(x, x') = U_\theta^\top(x) U_\theta(x'),$$

respectively. In theory, estimation using normalized Fisher kernels corresponds to regularization on the $L_2(p(\cdot|\theta))$ norm. And in the context of exponential families, the unnormalized Fisher kernels are identical to the inner product of sufficient statistics.

Kernel Function Classes

Many machine learning algorithms can be posed as functional minimization problems, and the candidate function set is chosen as the RKHS. The main advantage of optimizing over an RKHS originates from the representer theorem.

Theorem 2 (representer theorem) *Denote by $\Omega : [0, \infty) \mapsto \mathbb{R}$ a strictly monotonic increasing function, by $\mathcal{X}$ a set, and by $c : (\mathcal{X} \times \mathbb{R}^2)^n \mapsto \mathbb{R} \cup \{\infty\}$ an arbitrary loss function. Then each minimizer $f \in \mathcal{H}$ of the regularized risk functional*

$$c((x_1, y_1, f(x_1)), \ldots, (x_n, y_n, f(x_n))) + \Omega(\|f\|_{\mathcal{H}}^2) \quad (1)$$

admits a representation of the form

$$f(x) = \sum_{i=1}^{n} \alpha_i k(x_i, x).$$

The representer theorem is important in that although the optimization problem is in an infinite-dimensional space $\mathcal{H}$, the solution is guaranteed to lie in the span of n particular kernels centered on the training points.

The objective (1) is composed of two parts: the first part measures the loss on the training set $\{x_i, y_i\}_{i=1}^n$ which depends on f only via its value at x_i. The second part is the regularizer, which encourages small RKHS norm of f. Intuitively, this regularizer penalizes the complexity of f and prefers smooth f. When the kernel k is translation invariant, *i.e.*, $k(x_1, x_2) = h(x_1 - x_2)$, Smola et al. (1998) showed that $\|f\|^2$ is related to the Fourier transform of h, with more penalty imposed on the high-frequency components of f.

Applications

Kernels have been applied to almost all branches of machine learning.

Supervised Learning

One of the most well-known applications of kernel method is the SVM for binary classification. Its primal form can be written as

$$\underset{w,b,\xi}{\text{minimize}} \frac{\lambda}{2}\,\|w\|^2 + \frac{1}{n}\sum_{i=1}^{n}\xi_i,$$

$$s.t.\ y_i(\langle w x_i\rangle + b) \geq 1 - \xi_i,\ \text{and}\ \xi_i \geq 0,\ \forall i.$$

Its dual form can be written as

$$\underset{\alpha_i}{\text{minimize}} \frac{1}{2\lambda}\sum_{i,j} y_i y_j \left\langle x_i x_j\right\rangle \alpha_i \alpha_j - \sum_i \alpha_i,$$

$$s.t.\ \sum_i y_i \alpha_i = 0,\ \alpha_i \in [0, n^{-1}],\ \forall i.$$

Clearly, this can be extended to feature maps and kernels by setting $k(x_i, x_j) = \left\langle x_i x_j\right\rangle$. The same trick can be applied to other algorithms like ν-SVM, regression, density estimation, etc. For multi-class classification and structured output classification where the possible label set $\mathcal{Y}$ can be large, kernel maximum margin machines can be formulated by introducing a joint kernel on pairs of (x_i, y) $(y \in \mathcal{Y})$, i.e., the feature map takes the tuple (x_i, y). Letting $\Delta(y_i, y)$ be the discrepancy between the true label y_i and the candidate label y, the primal form is

$$\underset{w,\xi_i}{\text{minimize}} \frac{\lambda}{2}\,\|w\|^2 + \frac{1}{n}\sum_{i=1}^{n}\xi_i, \quad s.t.\ \big\langle w\phi(x_i, y_i) - \phi(x_i, y)\big\rangle \geq \Delta(y_i, y) - \xi_i,\ \forall\ i, y,$$

and the dual form is

$$\underset{\alpha_{i,y}}{\text{minimize}} \frac{1}{2\lambda}\sum_{(i,y),(i',y')} \alpha_{i,y}\alpha_{i',y'}\big\langle \phi(x_i, y_i) - \phi(x_i, y)\phi(x_{i'}, y_{i'}) - \phi(x_{i'}, y')\big\rangle - \sum_{i,y}\Delta(y_i, y)\alpha_{i,y}$$

$$s.t.\quad \alpha_{i,y} \geq 0,\ \forall\ i, y;\quad \sum_y \alpha_{i,y} = \frac{1}{n},\ \forall i.$$

Again all the inner products $\langle \phi(x_i, y)\phi(x_{i'}, y')\rangle$ can be replaced by the joint kernel $k((x_i, y), (x_{i'}, y'))$. Further factorization using graphical models is possible; see Taskar et al. (2004). Notice when $\mathcal{Y} = \{1, -1\}$, setting $\phi(x_i, y) = y\phi(x_i)$ recovers the binary SVM formulation. Effective methods to optimize the dual objective include sequential minimal optimization, exponentiated gradient (Collins et al. 2008), mirror descent, cutting plane, or bundle methods (Smola et al. 2007a).

Unsupervised Learning

Data analysis can benefit from modeling the distribution of data in feature space. There we can still use the rather simple linear methods, which give rise to nonlinear methods on the original data space. For example, the principal components analysis (PCA) can be extended to Hilbert spaces (Schölkopf et al. 1998), which allows for image denoising, clustering, and nonlinear dimensionality reduction.

Given a set of data points $\{x_i\}_{i=1}^{n}$, PCA tries to find a direction d such that the projection of $\{x_i\}$ to d has the maximal variance. Mathematically, one solves

$$\max_{d:\|d\|=1} \operatorname{Var}\{\langle x_i d\rangle\} \iff \max_{d:\|d\|=1} d^\top \times \left(\frac{1}{n}\sum_i x_i x_i^\top - \frac{1}{n^2}\sum_{ij} x_i x_j^\top\right) d,$$

which can be solved by finding the maximum eigenvalue of the variance of $\{x_i\}$. Along the same line, we can map the examples to the RKHS and find the maximum variance projection direction again. Here we first center the data, i.e., let the feature map be $\tilde{\phi}(x_i) = \phi(x_i) - \frac{1}{n}\sum_j \phi(x_j)$, and define a kernel $\tilde{k}$ based on the centered feature. So we have $\sum_{j=1}^{n}\tilde{K}_{ij} = 0$ for all i. Now the objective can be written as

$$\max_{f:\|f\|_{\tilde{\mathcal{H}}}=1} \operatorname{Var}\left\{\big\langle \tilde{\phi}(x_i) f\big\rangle_{\tilde{\mathcal{H}}}\right\} \iff \max_{f:\|f\|=1} \operatorname{Var}\{f(x_i)\} \iff \max_{f:\|f\|\leq 1} \operatorname{Var}\{f(x_i)\}. \quad (2)$$

Treat the constraint $\|f\| \leq 1$ as an indicator function $\Omega(\|f\|^2)$ where $\Omega(x) = 0$ if $x \leq 1$ and ∞ otherwise. Then the representer theorem can be invoked to guarantee that the optimal solution is $f = \sum_i \alpha_i \tilde{k}(x_i, \cdot)$ for some $\alpha_i \in \mathbb{R}$. Plugging it into (2), the problem becomes $\max_{\boldsymbol{\alpha}:\boldsymbol{\alpha}^\top \tilde{K}\boldsymbol{\alpha}=1} \boldsymbol{\alpha}^\top \tilde{K}^2\boldsymbol{\alpha}$. To get necessary conditions for optimality, we write out the Lagrangian $L = \boldsymbol{\alpha}\tilde{K}^2\boldsymbol{\alpha} - \lambda(\boldsymbol{\alpha}\tilde{K}\boldsymbol{\alpha} - 1)$. Setting to 0 the derivative over $\boldsymbol{\alpha}$, we get

$$\tilde{K}^2\boldsymbol{\alpha} = \lambda\tilde{K}\boldsymbol{\alpha}. \tag{3}$$

Therefore $\boldsymbol{\alpha}^\top \tilde{K}^2\boldsymbol{\alpha} = \lambda$. Although (3) does not guarantee that $\boldsymbol{\alpha}$ is an eigenvector of $\tilde{K}$, one can show that for each λ satisfying (3), there exists an eigenvector $\boldsymbol{\alpha}$ of $\tilde{K}$ such that $\tilde{K}\boldsymbol{\alpha} = \lambda\boldsymbol{\alpha}$. Hence, it is sufficient to study the eigensystem of $\tilde{K}$ just like in the vanilla PCA. Once the optimal α_i^* is obtained, any data point x can be projected to $\sum_i \alpha_i^* \tilde{k}(x_i, x)$.

More applications of kernels in unsupervised learning can be found in canonical correlation analysis, independent component analysis (Bach and Jordan 2002), kernelized independence criteria via Hilbert space embeddings of distributions (Smola et al. 2007b), etc.

K-Means Clustering

Xin Jin[1] and Jiawei Han[2]
[1]PayPal Inc., San Jose, CA, USA
[2]University of Illinois at Urbana-Champaign, Urbana, IL, USA

Abstract

K-Means Clustering is a popular clustering algorithm with local optimization. In order to improve its performance, researchers have proposed methods for better initialization and faster computation.

Synonyms

Cluster initialization; Iterative computation

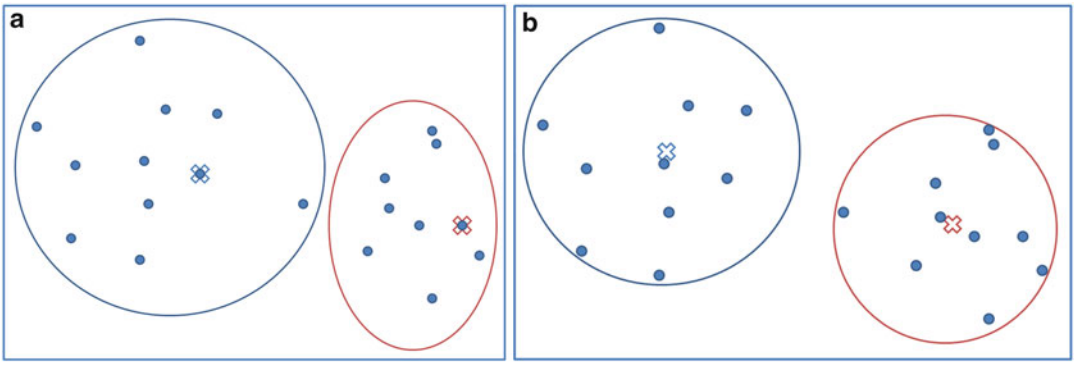
Definition

K-means (Lloyd 1957; MacQueen 1967) is a popular data clustering method, widely used in many applications. Algorithm 1 shows the procedure of K-means clustering. The basic idea of the K-means clustering is that given an initial but not optimal clustering, relocate each point to its new nearest center, update the clustering centers by calculating the mean of the member points, and repeat the relocating-and-updating process until converge criteria (such as predefined number of iterations, difference on the value of the distortion function) are satisfied.

The task of initialization is to form the initial K clusters. Many initializing techniques have been proposed, from simple methods, such as choosing the first K data points, Forgy initialization (randomly choosing K data points in the dataset), and random partitions (dividing the data points randomly into K subsets), to more sophisticated methods, such as density-based initialization, intelligent initialization, furthest-first initialization (FF for short, it works by picking first center point randomly and then adding more center points which are furthest from existing ones), and subset furthest-first (SFF) initialization. For more details, refer to paper Steinley and Brusco (2007) which provides a survey and comparison of over 12 initialization methods.

Algorithm 1 K-means clustering algorithm

```
Input: $K$, number of clusters; $D$, a data set of $N$ points
Output: A set of $K$ clusters
Initialization.
repeat
    for each point $p$ in $D$ do
        find the nearest center and assign $p$ to the corresponding cluster.
    end for
    update clusters by calculating new centers using mean of the members.
until stop-iteration criteria satisfied
return clustering result.
```



***K*-Means Clustering, Fig. 1** K-means clustering example ($K = 2$). The center of each cluster is marked by "x." (**a**) Initialization. (**b**) Re-assignment

Figure 1 shows an example of K-means clustering on a set of points, with $K = 2$. The clusters are initialized by randomly selecting two points as centers.

Complexity analysis. Let N be the number of points, D the number of dimensions, and K the number of centers. Suppose the algorithm runs I iterations to converge. The space complexity of K-means clustering algorithm is $O(N(D + K))$. Based on the number of distance calculations, the time complexity of K-means is $O(NKI)$.

Fast Computation for Large-Scale Data

For large-scale data clustering, K-means algorithm spends the majority of the time on the numerous distance calculations between the points and the centers. Many algorithms have been proposed to handle this problem, such as PDS (Bei and Gray 1985), TIE (Chen and Hsieh 1991), Elkan (Beil et al. 2003), MPS (Ra and Kim 1993), kd-tree K-means (Pelleg and Moore 1999), HKM (Nister and Stewenius 2006), GT (Kaukoranta et al. 2000), CGAUDC (Lai et al. 2008), and GAD (Jin et al. 2011).

PDS (partial distortion search) (Bei and Gray 1985) cumulatively computes the distance between the point and a candidate center by summing up the differences at each dimension. TIE (triangular inequality elimination) (Chen and Hsieh 1991) prunes candidate centers based on the triangle inequality of metric distance. MPS (mean-distance-ordered partial search) (Ra and Kim 1993) uses sorting to initially guess the center whose mean value is closest to that of the current point and prune candidates via an inequality based on an Euclidean distance property.

In many large-scale applications, we need to perform large K clustering, and HKM (Nister and Stewenius 2006) and kd-tree K-means (Pelleg and Moore 1999) are fast algorithms which work for this *large cluster* problem because their time complexity on K is reduced from the original $O(K)$ in K-means to $O(\log(K))$.

HKM (Nister and Stewenius 2006) performs fast hierarchical K-means clustering. Instead of directly performing clustering on large clusters, HKM uses K-means for a small number of clusters at each node of a hierarchical tree.

The kd-tree K-means (Pelleg and Moore 1999) algorithm utilizes kd-tree to find the approximate nearest center in a way that is faster than brute force searching. Centers were split hierarchically from the root to the leaf nodes of the kd-tree; leaf nodes will contain similar centers. When searching for the nearest center, we only need to check leaf nodes which are most similar to the point.

Many fast algorithms are based on a strategy that filters out unnecessary distance calculations using metric properties and thus only work for metric distances. Another strategy called *activity* *detection* avoids the metric properties and works for both metric and non-metric distances. GT (Kaukoranta et al. 2000) utilizes point activity for fast clustering. CGAUDC (Lai et al. 2008) is an extension of GT and gets further improvement on performance. GAD (Jin et al. 2011) provides a general solution for utilizing activity detection for fast clustering.

Software

The following software have implementations of the K-means clustering algorithm:

K-Medoids Clustering

Xin Jin[1] and Jiawei Han[2]
[1]PayPal Inc., San Jose, CA, USA
[2]University of Illinios at Urbana-Champaign, Urbana, IL, USA

Abstract

K-Medoids Clustering is a clustering method more robust to outliers than K-Means. Representative algorithms include Partitioning Around Medoids (PAM), CLARA, CLARANS, etc.

Synonyms

Iterative algorithm

Definition

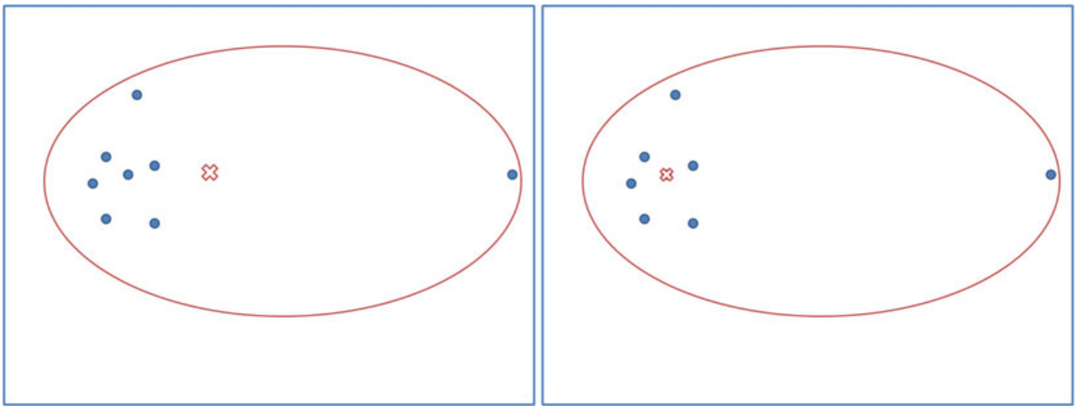
The K-means clustering algorithm is sensitive to outliers, because a mean is easily influenced by extreme values. K-medoids clustering is a variance of K-means but more robust to noises and outliers (Han et al. 2011). Instead of using the mean point as the center of a cluster, K-medoids use an actual point in the cluster to represent it. Medoid is the most centrally located object of the cluster, with minimum sum of distances to other points. Figure 1 shows the difference between mean and medoid in a 2D example. The group of points in the right form a cluster, while the rightmost point is an outlier. Mean is greatly influenced by the outlier and thus cannot represent the correct cluster center, while medoid is robust to the outlier and correctly represents the cluster center.

Partitioning Around Medoids (PAM) (Kaufman and Rousseeuw 2005) is a representative K-medoids clustering method. The basic idea is as follows: select K representative points to form initial clusters and then repeatedly move to better cluster representatives. All possible combinations of representative and nonrepresentative points are analyzed, and the quality of the resulting clustering is calculated for each pair. An original representative point is replaced with the new point which causes the greatest reduction in distortion function. At each iteration, the set of best points for each cluster form the new respective medoids.

When calculating the cost of swapping a nonrepresentative point p_{rand} with a representative point p_i, there are four cases that need to be examined for each of the nonrepresentative point p.

1. Case 1: p originally belongs to representative point p_i. If, after replacement, p is closest to one of the other representative point p_j, then p is reassigned to p_j.
2. Case 2: p originally belongs to representative point p_i. If after replacement, p is closest to p_{rand}, then p is reassigned to p_{rand}.
3. Case 3: p originally belongs to one of the other representative point p_j. If after replacement, p is still closest to p_j, then there is no reassignment of p.
4. Case 4: p originally belongs to one of the other representative point p_j. If after replacement, p is closest to p_{rand}, then p is reassigned to p_{rand}.

The cost function is defined as the change in the value of the distortion function when a representative point is replaced by a nonrepresentative point. The total cost C of replacing is the sum of costs incurred by all nonrepresentative points.



K-Medoids Clustering, Fig. 1 Mean vs. medoid in 2D space. In both figures (**a**) and (**b**), the group of points in the right forms a cluster and the rightmost point is an outlier. *The red point* represents the center found by mean or medoid

If C is negative, then the replacement is allowed since the distortion function would be reduced.

Algorithm 1 K-medoids clustering algorithm (PAM)

```
Require: $K$, number of clusters; $D$, a data set of $N$ points
Ensure: A set of $K$ clusters
Arbitarily choose $K$ points in $D$ as initial representative points.
repeat
    for each non-representative point $p$ in $D$ do
        find the nearest representative point and assign $p$ to the corresponding cluster.
    end for
    randomly select a non-representative point $p_{\text{rand}}$;
    compute the overall cost $C$ of swapping a representative point $p_i$ with $p_{\text{rand}}$;
    if $C < 0$ then
        swap $p_j$ with $p_{\text{rand}}$ to form a new set of $K$ representative points.
    end if
until stop-iteration criteria satisfied
return clustering result.
```

The time complexity of the PAM algorithm is $O(K(N - K)^2 I)$.

Fast Computation for Large Data

PAM is not scalable for large data set; some algorithms have been proposed to improve the efficiency, such as CLARA (clustering large applications) (Kaufman and Rousseeuw 2005) and CLARANS (clustering large applications based upon randomized search) (Ng and Han 2002).

CLARA takes the sampling strategy: randomly sample a small portion of the actual data as a representative of the whole data and perform PAM from the sampled data set to find the K medoids. If the sample can closely represent the original data set, the representative medoids found will be a good approximation of those that found from using the whole data set. To improve clustering quality, CLARA takes multiple random samples, applies PAM on each sample, and outputs the best clustering. Suppose the size of the sample is M, which is much smaller than the original data size N; the time complexity of CLARA is $O((KM^2 + K(N - K))I)$. CLARA is more efficient than PAM; however, it cannot find the best clustering if any medoid found from the sample is not among the best K-medoids.

CLARANS is able to improve the quality of CLARA. It can be modeled as searching through a graph where a node is a set of K-medoids and neighbor nodes differ by one medoid, so each node has $K(N - K)$ neighbors. A node is evaluated by the distortion function to measure its clustering quality. CLARANS starts with a randomly selected node and randomly selects its neighbor; if the neighbor has better clustering quality, move to the neighbor node and continue iteration. If the node is a local minimum, i.e., no tested neighbor gets better clustering, restart with a new randomly selected node and repeat the procedure. Iteration stops at some criteria, for example, finding a predefined number of local minima. Some improvements (Chu et al. 2008) have been proposed for CLARANS. There are two categories, conceptual/algorithmic and implementational improvements, including the revisiting of the accepted cases for swap comparison and the application of partial distance searching and previous medoid indexing to clustering.

Softwares

The following softwares have implementations of the K-medoids clustering algorithm:

- Flexclust: flexible cluster algorithms. R package. It provides a general framework for k-centroids cluster analysis supporting arbitrary distance measures and centroid computation. http://cran.r-project.org/web/packages/flexclust/index.html
- Julia. Clustering package: https://github.com/JuliaStats/Clustering.jl
- ELKI (for environment for developing KDD-applications supported by index structures). A Java-based data mining software framework developed at the Ludwig Maximilian University of Munich, Germany. http://elki.dbs.ifi.lmu.de

- Java-ML. Java Machine Learning Library: http://java-ml.sourceforge.net

Abstract

K-Way Spectral Clustering is the technology to discover k clusters using spectral clustering.

Synonyms

Diagonal matrix; Eigenvector; Laplacian matrix; Spectral clustering

Definition

In spectral clustering (Luxburg 2007; Zha et al. 2001; Dhillon et al. 2004), the dataset is represented as a similarity graph $G = (V, E)$. The vertices represent the data points. Two vertices are connected if the similarity between the corresponding data points is larger than a certain threshold, and the edge is weighted by the similarity value. Clustering is achieved by choosing a suitable partition of the graph that each group corresponds to one cluster.

A good partition (i.e., a good clustering) is that the edges between different groups have an overall low weight and the edges within a group have high weight, which indicates that points in different clusters are dissimilar from each other and points within the same cluster are similar to each other. One basic spectral clustering algorithm finds a good partition in the following way:

Given a set of data points P and the similarity matrix S where S_{ij} measures the similarity between points $i, j \in P$, form a graph. Build Laplacian matrix L of the graph,

$$L = I - D^{-1/2} S D^{-1/2} \qquad (1)$$

where D is the diagonal matrix:

$$D_{ii} = \sum_j S_{ij} \qquad (2)$$

Find eigenvalues and eigenvectors of the matrix L, map vertices to corresponding components, and form clusters based on the embedding space.

The methods to find K clusters include recursive bi-partitioning and clustering multiple eigenvectors. The former technique is inefficient and unstable. The latter approach is more preferable because it is able to prevent instability due to information loss.

Latent Factor Models and Matrix Factorizations

Definition

Latent Factor models are a state of the art methodology for model-based ▶ collaborative filtering. The basic assumption is that there exist an unknown low-dimensional representation of users and items where user-item affinity can be modeled accurately. For example, the rating that a user gives to a movie might be assumed to depend on few implicit factors such as the user's taste across various movie genres. Matrix

C. Sammut, G.I. Webb (eds.), *Encyclopedia of Machine Learning and Data Mining*,
DOI 10.1007/978-1-4899-7687-1

factorization techniques are a class of widely successful Latent Factor models that attempt to find weighted low-rank approximations to the user-item matrix, where weights are used to hold out missing entries. There is a large family of matrix factorization models based on choice of loss function to measure approximation quality, regularization terms to avoid overfitting, and other domain-dependent formulations.

Lazy Learning

Geoffrey I. Webb
Faculty of Information Technology, Monash
University, Victoria, Australia

Abstract

Lazy learning is a machine learning strategy whereby learning is delayed until consultation time.

Definition

The computation undertaken by a learning system can be viewed as occurring at two distinct times, *training time* and *consultation* or *testing time*. Consultation time is the time between when an object is presented to a system for an inference to be made and the time when the inference is completed. Training time is time prior to consultation time during which the system makes inferences from training data in preparation for consultation time. *Lazy learning* refers to any machine learning process that defers the majority of computation to consultation time. Two typical examples of lazy learning are ▶ instance-based learning and Lazy Bayesian Rules.

Lazy learning stands in contrast to *eager learning*, in which the majority of computation occurs at training time.

Discussion

Lazy learning can be computationally advantageous when predictions using a single training set will only be made for few objects. This is because it is only necessary to model the immediate areas of the ▶ instance space that are occupied by objects to be classified. In consequence, no computation is expended modeling areas of the instance space that are irrelevant to the predictions that need to be made. This can also be an advantage when a training set is frequently updated, as can be the case in ▶ online learning, as it is not necessary to create a complete global model before making a prediction subsequent to new training examples becoming available.

Lazy learning can help improve prediction ▶ accuracy, by allowing a system to concentrate on deriving the best possible decision for the exact points of the instance space for which predictions are to be made. In contrast, eager learning can sometimes result in suboptimal predictions for some specific areas of the instance space as a result of trade-offs during the process of deriving a single model that seeks to minimize average error over the entire instance space.

However, lazy learning must store the entire training set for use in classification. In contrast, eager learning need only store a model, which may be must more compact than the original data.

Learning as Search

Claude Sammut
The University of New South Wales, Sydney,
NSW, Australia

Definition

Learning can be viewed as a search through the space of all sentences in a concept description language for a sentence that best describes the data. Alternatively, it can be viewed as a search through all hypotheses in a ▶ hypothesis space. In either case, a generality relation usually determines the structure of the search space.

Background

The input to a learning program consists of descriptions of objects from the universe (the ▶ training set) and, in the case of ▶ supervised learning, an output value associated with the example. A program is limited in the concepts that it can learn by the representational capabilities of both the ▶ observation language (i.e., the language used to describe the training examples) and ▶ hypothesis language (the language used to describe the concept). For example, if an attribute/value list is used to represent examples for an induction program, the measurement of certain attributes and not others places limits on the kinds of patterns that the learner can find. The learner is said to be *biased* by its observation language. The hypothesis language also places constraints on what may and may not be learned. For example, in the language of attributes and values, relationships between objects are difficult to represent. Whereas, a more expressive language, such as first-order logic, can easily be used to describe relationships. These biases are collectively referred to as *representation bias*.

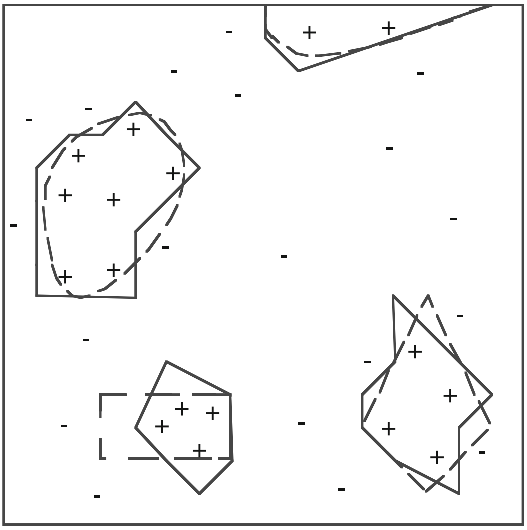
Representational power comes at a price. Learning can be viewed as a search through the space of all sentences in a language for a sentence that best describes the data. The richer the language, the larger the search space. When the search space is small, it is possible to use "brute force" search methods. If the search space is very large, additional knowledge is required to reduce the search. Notions of generality and specificity are important for ordering the search (see ▶ Generalization and ▶ Specialization).

Representation

The representation of instances and concepts affects the way a learning system searches for concept representations.

The input to a learning program may take many forms, for example, records in a database, pages of text, images, audio, and other signals of continuous data. Very often, the raw data are transformed into *feature vectors* or *attribute/value lists*. The values of the attributes or features may be continuous or discrete. These representation by attribute/value lists is the observation language.

The representation of the concept varies considerably, depending on the approach taken for learning. In ▶ instance-based learning, concepts are represented by a set of prototypical instances of the concept, so abstract representations are not constructed at all. This kind of representation is said to be *extensional*. Instance-based learning is also called ▶ lazy learning because the learner does little work at the time that training instances are presented. Rather, at classification time, the system must find the most similar instances to the new example. See Fig. 1.

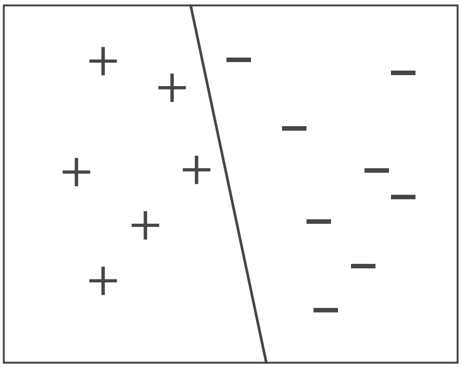


Learning as Search, Fig. 1 The extension of an instance-based Learning concept is shown in *solid lines*. The *dashed lines* represent the target concept. A sample of positive and negative examples is shown (Adapted from Aha et al. 1991)

When instances are represented as feature vectors, we can treat each feature or attribute as one dimension in a multi-dimensional space. The supervised learning problem can then be characterized as the problem of finding a surface that separates objects that belong to different classes into different regions. In the case of unsupervised learning, the problem becomes one of the finding clusters of instances in the multi-dimensional space.

Learning methods differ in the way they represent and create the discrimination surfaces. In *function approximation*, the learner searches for functions that describes the surface (Fig. 2). Function approximation methods can often produce accurate classifiers because they are capable of construction complex decision surfaces. However, the concept description is stored as a set of coefficients. Thus, the results of learning are not easily available for inspection by a human reader.

Rather than searching for discriminant functions, symbolic learning systems find expressions equivalent to sentences in some form of logic. For example, we may distinguish objects according to two attributes: size and color. We may say that an object belongs to class 3 if its color is red and its size is very small to medium. Following the notation of Michalski (1983), the classes in Fig. 3 may be written as:



Learning as Search, Fig. 2 A linear discrimination between two classes

$$\text{class1} \leftarrow \text{size} = \text{large} \wedge \text{color} \in \{\text{red, orange}\}$$

$$\text{class2} \leftarrow \text{size} \in \{\text{small, medium}\} \wedge \text{color} \in \{\text{orange, yellow}\}$$

$$\text{class3} \leftarrow \text{size} \in \{v\_\text{small} \ldots \text{medium}\} \wedge \text{color} = \text{blue}$$

Note that this kind of description partitions the universe with axis-orthogonal surfaces, unlike the function approximation methods that find smooth surfaces to discriminate classes (Fig. 4).

Useful insights into induction can be gained by visualizing it as searching for a discrimination surface in a multi-dimensional space. However, there are limits to this geometric interpretation of learning. If we wish to learn concepts that describe complex objects and relationships between the objects, it is often useful to rely on reasoning about the concept description language itself.

As we saw, the concepts in Fig. 3 can be expressed as clauses in propositional logic. We can establish a correspondence between sentences in the concept description language (the hypothesis language) and a diagrammatic representation of the concept. More importantly, we can create a correspondence between generalization and spe-

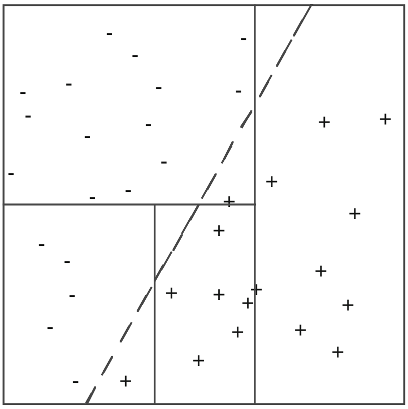
V_large						



Learning as Search, Fig. 4 The *dashed line* shows the real division of objects in the universe. The *solid lines* show a decision tree approximation

cialization operations on the sets of objects and generalization and specialization operations on the sentences of the language.

Once we have established the correspondence between sets of objects and their descriptions, it is often convenient to forget about the objects and only consider that we are working with expressions in a language. For example, the clause

$$\text{class2} \leftarrow \text{size} = \text{large} \wedge \text{color} = \text{red} \qquad (1)$$

can be generalized to

$$\text{class} \leftarrow \text{size} = \text{large} \qquad (2)$$

by dropping one of the conditions. Thus, we can view learning as search through a generalization lattice that is created by applying different syntactic transformations on sentences in the hypothesis language.

Version Spaces and Subsumption

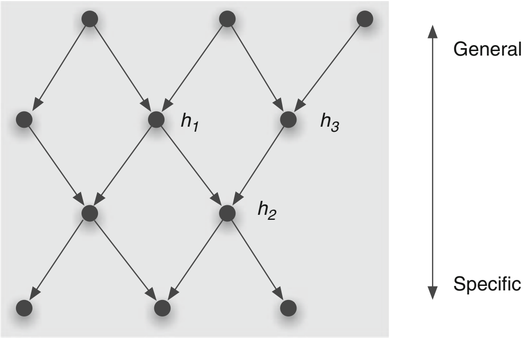
Mitchell (1977, 1982) defines the *version space* for a learning algorithm as the subset of hypotheses consistent with the training examples. That is, the hypothesis language is capable of describing a large, possibly infinite, number of concepts. When searching for the target concept, we are only interested in the subset of sentences in the hypothesis language that are consistent with the training examples, where consistent means that the examples are correctly classified. We can used the *generality* of concepts to help us limit our search to only those hypotheses in the version space.

In the above example, we stated that clause (2) is more general than clause (1). In doing so, we assumed that there is a general-to-specific ordering on the sentences in the hypothesis language. We can formalize the generality relation as follows. A hypothesis, h, is a predicate that maps an instance to *true* or *false*. That is, if $h(x)$ is true then x is hypothesized to belong to the concept being learned, the *target*. Hypothesis, h_1, is more general than or equal to h_2, if h_1 covers at least as many examples as h_2 (Mitchell 1997). That is, $h_1 \geq h_2$ if and only if

$$(\forall x)[h_1(x) \rightarrow h_2(x)]$$

A hypothesis, h_1, is strictly more general than h_2, if $h_1 \geq h_2$ and $h_2 \not\leq h_1$.

Note that the *more general than* ordering is strongly related to *subsumption* (see ▸ subsumption and the ▸ Logic of Generality). Where the above definition of the generality relation is given in terms of the cover of a



Learning as Search, Fig. 5 Generalization lattice

hypothesis, subsumption defines a generality ordering on expressions in the hypothesis language.

Learning algorithms can use the *more general than* relation to order their search for the best hypothesis. Because generalizations and specializations may not be unique, this relation forms a lattice over the sentences in the hypothesis language, as illustrated in Fig. 5. A search may start from the set of most specific hypotheses that fit the training data and perform a *specific-to-general* search or it may start from the set of most general hypotheses and perform a *general-to-specific* search. The search algorithm may also be bidirectional, combining both.

In Fig. 5, each node represents a hypothesis. The learning algorithm searches this lattice in an attempt to find the hypothesis that best fits the training data. Like searching in any domain, the algorithm may keep track of one node at a time, as in *depth first* or *best first* searches, or it may create a frontier of nodes as in *breadth first* or *beam searches*.

Suppose we have single-hypothesis search. A specific-to-general search may begin by randomly selecting a positive training example and creating a hypothesis that the target concept is exactly that example. Each time a new positive example is seen that is not covered by the hypothesis, the hypothesis must be *generalized*. That is, a new hypothesis is constructed that is general enough to cover all the examples covered by the previous hypothesis, as well as covering the new example. If the algorithm sees a negative example that is incorrectly covered by the current hypothesis, then the hypothesis must be *specialized*. That is, a new hypothesis is construct that is more specific than the current hypothesis such that all the positive examples that were previously covered are still covered by the new negative example is excluded.

A similar method can be used for a general-to-specific search. In this case, the initial hypothesis is that the target concept covers every object in the universe. In both cases, the algorithm must choose how to construct either generalizations or specializations. That is, a method is needed to choose which nodes in the search to expand next. Here, the ▸ least general generalization (Plotkin 1970) or the ▸ most general specialization are useful. These define the smallest steps that can be taken in expanding the search. For example, in Fig. 5, h_2 is the minimal specialization that can be made from h_1 or h_3 in a general-to-specific search that starts from the top of the lattice. Similarly, h_1 and h_3 are the least general generalizations of h_2. A search for the target concept can begin with an initial hypothesis and make minimal generalizations or specializations in expanding the next node in the search.

Rather than maintaining on a single current hypothesis, a search strategy may keep a set of candidate hypotheses. For example, a breadth first search generalizing from hypothesis h_2 will create a frontier for the search that is the set $\{h_1, h_3\}$. When there are many ways in which an hypothesis can be generalized or specialized, the size of the frontier set may be large. In algorithms such as Aq (Michalski 1983) and CN2 (Clark and Niblett 1989), a *beam search* is used. Rather than storing all possible hypotheses, the n best are kept are stored, where "best" can be defined in several ways. One metric for comparing hypotheses is given by

$$\frac{P_c + N_{\bar{c}}}{P + N}$$

where P and N are the number of positive and negative instances, respectively; P_c is the number of positive instances covered by the hypothesis;

and $N_{\bar{c}}$ is the number of negative instances not covered.

Algorithm 1 The candidate-elimination algorithm, after Mitchell (1997)

```
Initialize G to the set of maximally general hypotheses in the hypothesis space
Initialize S to the maximally specific hypotheses in the hypothesis space
For each training example, $d$,
  if $d$ is a positive example
    remove from $G$ any hypothesis inconsistent with $d$
    For each hypothesis, $s$, in S that is not consistent with $d$
      remove $s$ from $S$
        add all minimal generalizations, $h$, of s such that
          $h$ is consistent with $d$ and some member of $G$ is more general than $h$
remove from $S$ any hypothesis that is more general than another hypothesis in $S$
  if $d$ is a negative example
    remove from $S$ any hypothesis inconsistent with $d$
    For each hypothesis, $g$, in $G$ that is not consistent with $d$
      remove $g$ from $G$
        add all minimal specializations, $h$, of $g$ such that
          $h$ is consistent with $d$ and some member of $S$ is more general than $h$
      remove from $G$ any hypothesis that is less general than another hypothesis in $G$
```

Mitchell's (1997) candidate-elimination algorithm performs a bidirectional search in the hypothesis space. It maintains a set, S, of most specific hypotheses that are consistent with the training data and a set, G, of most general hypotheses consistent with the training data. These two sets form two boundaries on the version space. As new training examples are seen, the boundaries are generalized or specialized to maintain consistency. If a new positive example is not covered by a hypothesis in S, then it must be generalized. If a new negative example is not rejected by an hypotheses in G, then it must be specialized. Any hypothesis in G not consistent with a positive example is removed and any hypothesis in S not consistent with a negative example is also removed. See Algorithm 1.

Noisy Data

Up to this point, we have assumed that the training data are free of noise. That is, all the examples are correctly classified and all the attribute values are correct. Once we relax this assumption, the algorithms described above must be modified to use approximate measures of consistency. The danger presented by noisy data is that the learning algorithm will *over fit* the training data by creating concept descriptions that try to cover the bad data as well as the good. For methods to handle noisy data see the entries in ▶ pruning.

Several standard texts give good introductions to search in learning, including Langley (1996), Mitchell (1997), Bratko (2000), and Russell and Norvig (2009).

Learning Control

Learning control refers to the process of acquiring a control strategy for a particular control system and a particular task by trial and error. Learning control is usually distinguished from adaptive control in that the learning system is permitted to fail during the process of learning. In contrast, adaptive control emphasizes single trial convergence without failure. Thus, learning control resembles the way that humans and animals acquire new movement strategies, while adaptive control is a special case of learning control that fulfills stringent performance constraints, e.g., as needed in life-critical systems like airplanes and industrial robots. In general, the control system can be any system that changes its state in response to a control signal, e.g., a web page with a hyperlink, a car, or a robot.

Learning Curves in Machine Learning

Claudia Perlich
IBM T.J. Watson Research Center, Yorktown Heights, NY, USA

Synonyms

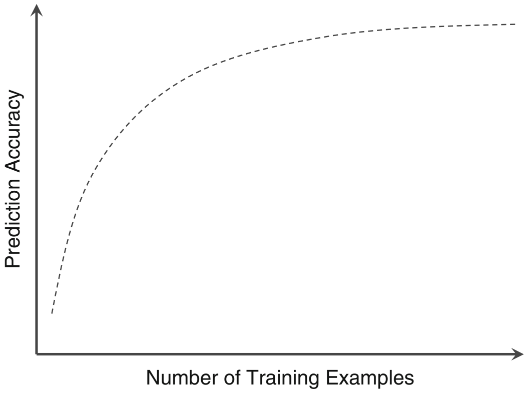
Error curve; Experience curve; Improvement curve; Training curve

Definition

A learning curve shows a measure of predictive performance on a given domain as a function of some measure of varying amounts of learning effort. The most common form of learning curves in the general field of machine learning shows predictive accuracy on the test examples as a function of the number of training examples as in Fig. 1.

Motivation and Background

Learning curves were initially introduced in educational and behavioral/cognitive psychology. The first person to describe the learning curve was Hermann Ebbinghaus in 1885 (Wozniak



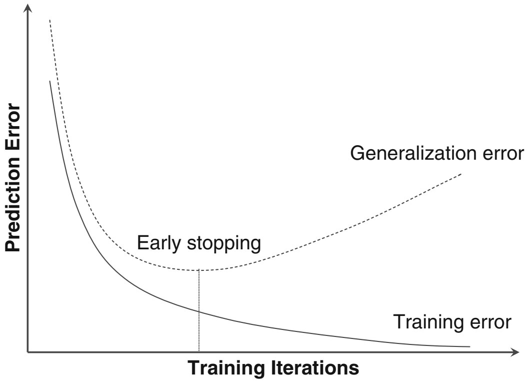
Learning Curves in Machine Learning, Fig. 1 Stylized learning curve showing the model accuracy on test examples as a function of the number of training examples

1999). He found that the time required to memorize a nonsense syllable increased sharply as the number of syllables increased. Wright (1936) described the effect of learning on labor productivity in the aircraft industry and proposed a mathematical model of the learning curve. Over time, the term has acquired related interpretation in many different fields including the above definition in machine learning and statistics.

Use of Learning Curves in Machine Learning

In the area of machine learning, the term "learning curve" is used in two different contexts, the main difference being the variable on the x-axis of the curve.

- The ▶ artificial neural network (ANN) literature has used the term to show the diverging behavior of in and out-of-sample performance as a function of the *number of training iterations* for a given number of training examples. Figure 2 shows this stylized effect.
- General machine learning uses learning curves to show the predictive ▶ generalization performance as a function of the *number of training examples*. Both the graphs in Fig. 3 are examples of such learning curves.



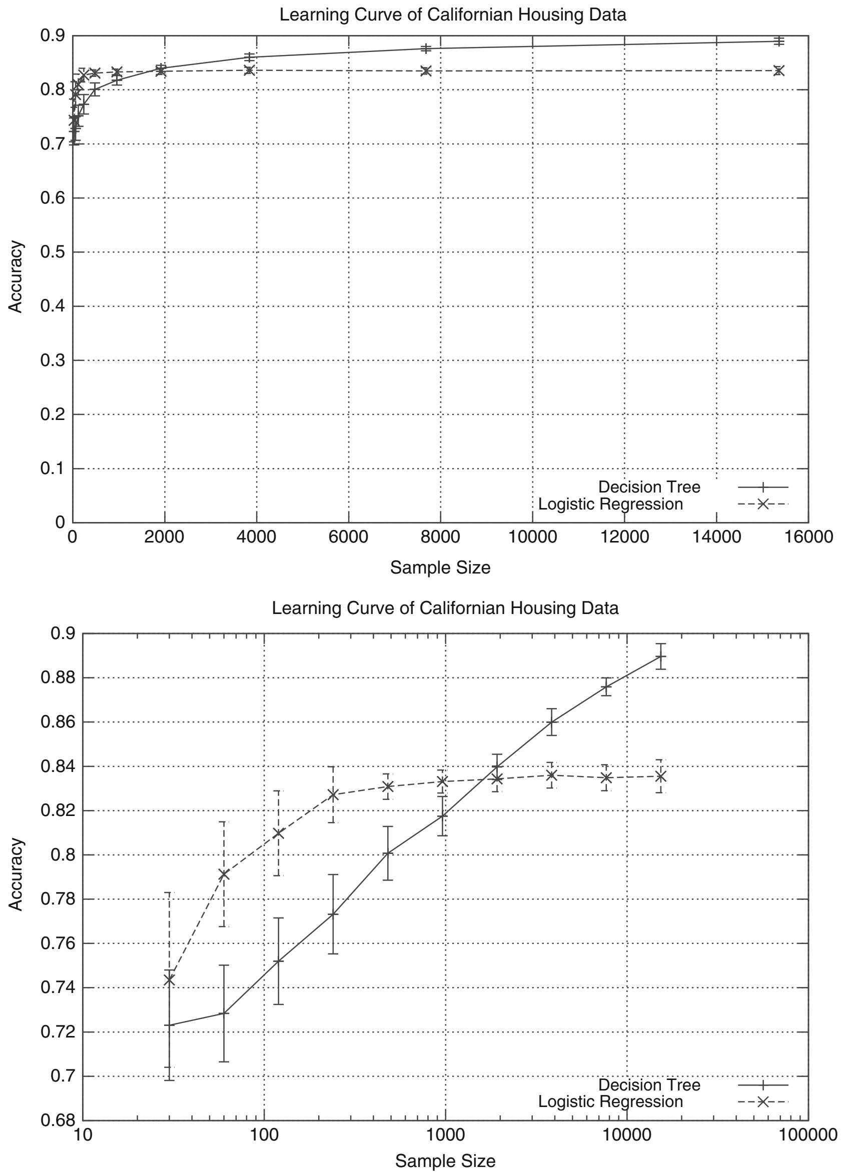
Learning Curves in Machine Learning, Fig. 2 Learning curve for an artificial neural network

Artificial Neural Networks

The origins of ANNs are heavily inspired by the social sciences and the goal of recreating the learning behavior of the brain. The original model of the "perceptron" mirrored closely the biological foundations of neural sciences. It is likely that the notion of learning curves was to some extent carried over from the social sciences of human learning into the field of ANNs. It shows the model error as a function of the training time measured in terms of the number of iterations. One iteration denotes in the context of neural network learning one single pass over the training data and the corresponding update of the network parameters (also called weights). The algorithm uses gradient descent minimizing the model error on the training data.

The learning curve in Fig. 2 shows the stylized effect of the relative training and generalization error on a test set as a function of the number of iterations. After initial decrease of both types of error, the generalization error reaches a minimum and starts to increase again while the training error continues to decrease.

This effect of increasing generalization error is closely related to the more general machine learning issue of ▶ overfitting and variance error for models with high expressive power (or capacity). One of the initial solutions to this problem for neural networks was early stopping – some form of early regularization technique that picked the model at the minimum of the error curve on a



Learning Curves in Machine Learning, Fig. 3 Typical learning curves in original and log scale

validation subset of the data that was not used for training.

General Machine Learning

In the more general machine learning setting and statistics (Flury and Schmid 1994), learning curves represent the generalization performance of the model as a function of the size of the training set.

Figure 3 was taken from Perlich et al. (2003) and shows two typical learning curves for two different modeling algorithms (▶ decision tree and ▶ logistic regression) on a fairly large domain. For smaller training-set sizes the curves are steep, but the increase in accuracy lessens for larger training-set sizes. Often for very large training-set sizes the standard representation in the upper graph obscures small, but non-trivial, gains. Therefore, to visualize the curves it is often useful to use a log scale on the horizontal axis and start the graph at the accuracy of the smallest training-set size (rather than at zero). In addition, one can include error bars that capture the estimated variance of the error over multiple experiments and provide some impression of the relevance of the differences between two learning curves as shown in the graphs.

The figure also highlights a very important issue in comparative analysis of different modeling techniques: learning curves for the same domain and different models can cross. This implies an important pitfall as pointed out by Kibler and Langley (1988): "Typical empirical papers report results on training sets of fixed size, which tells one nothing about how the methods would fare given more or less data, rather than collecting learning curves ⋯". A corollary on the above observation is the dangers of selecting an algorithm on a smaller subset of the ultimately available training data either in the context of a proof of concept pre-study or some form of cross-validation.

Aside from its empirical relevance there has been significant theoretical work on learning curves – notably by Cortes et al. (1994). They are addressing the question of predicting the expected generalization error from the training error of a model. Their analysis provides many additional insights about the generalization performance of different models as a function of not only training size but in addition the model capacity.

University of Bonn, Sankt Augustin, Germany

Synonyms

Learning from complex data; Learning from non-propositional data; Learning from nonvectorial data

Definition

Learning from structured data refers to all those learning tasks where the objects to be considered as inputs and/or outputs can usefully be thought of as possessing internal structure and/or as being interrelated and dependent on each other, thus forming a structured space. Typical instances of data in structured learning tasks are sequences as they arise, e.g., in speech processing or bioinformatics, and trees or general graphs such as syntax trees in natural language processing and document analysis, molecule graphs in chemistry, relationship networks in social analysis, and link graphs in the World Wide Web. Learning from structured data presents special challenges, since the commonly used feature vector representation and/or the i.i.d. (independently and identically distributed data) assumption are no longer applicable. Different flavors of learning from structured data are represented by (overlapping) areas such as ▶ Inductive Logic Programming, ▶ Statistical Relational Learning, probabilistic relational and logical learning, learning with structured outputs, sequence learning, learning with trees and graphs, ▶ graph mining, and ▶ collective classification.

Motivation and Background

For a long time, learning algorithms had almost exclusively considered data represented in rectangular tables defined by a fixed set of columns and a number of rows corresponding to the number of objects to be described. In this representation, each row independently and completely describes one object, each column containing the value of one particular property or feature of the object. Correspondingly, this representation is also known as feature vector representation, propositional representation, or vectorial data representation. Statistically, in such a representation, the values in each row (i.e., the objects) are assumed to be drawn i.i.d. from a fixed (but unknown) distribution.

However, when working with objects that are interrelated and/or have internal structure, this representation is no longer adequate. Consider representing chemical molecules with varying numbers of atoms and bonds in a table with a fixed number of columns. If we wanted each molecule to correspond to one row, we would have to fit the atoms and bonds into the columns, e.g., by reserving a certain number of columns for each one of them and their respective properties. To do that however, we would have to make the table wide enough to contain the largest possible molecule, resulting in many empty columns for smaller molecules, and by mapping the component atoms and bonds to columns, we would assign an order to them that would not be justified by the underlying problem and that would consequently mislead any feature vector learning algorithm.

The second issue with structured data arises from objects that are interrelated. Consider, e.g., the task of speech recognition, i.e., learning to map an acoustic unit into the corresponding lexical unit. Clearly, to solve this task, one must consider the sequence of such units, since both on the input and the output sides the probability of observing a particular unit will strongly depend on the preceding or subsequent units. The same is true, e.g., in classifying pages in the World Wide Web, where it is quite likely that the classification of the page will correlate with the classifications of neighboring pages. Therefore, any learning algorithm that would regard acoustic units or pages as independent and identically distributed objects is destined to fail, since for a successful solution the interdependencies must be modeled and exploited.

In machine learning, even though there has been interest in structured representation from the very beginning of the 1970s (cf. the systems Arch (Winston 1975) or INDUCE (Michalski 1983)), it was only in the 1990s, triggered by the popularity of logic programming and Horn clause representation, that learning from structured data was more intensively considered for logical representations in the subfield of Inductive Logic Programming. Outside of (what was then) machine learning, due to important applications such as speech processing, probabilistic models for sequence data such as ▸ Hidden Markov Models have been considered much earlier. Toward the end of the 1990s, given an enormous surge of interest in applications in bioinformatics and the World Wide Web, and technical advances resulting from the integration of probabilistic and statistical approaches into machine learning (e.g., ▸ Graphical Models and ▸ kernel methods), work on learning from structured data has taken off and now represents a significant part of machine learning research in overlapping subareas such as Inductive Logic Programming, Statistical Relational Learning, probabilistic relational and logical learning, learning with structured outputs, sequence learning, learning with trees and graphs, graph mining, and collective inference.

Main Tasks and Solution Approaches

A particular problem setting for learning from structured data is given by specifying, among others, (1) the language representing the input and output of the learning algorithms, (2) the type of the input and/or output data, and (3) the learning task.

1. Beyond attribute-value representation, the most intensively investigated representation languages used in learning are ▸ First-Order Logic, in particular, the fragment of first-order Horn clauses, and labeled graphs. Although labeled graphs can be considered as special relational structures and thus form a special fragment of first-order logic, these two representation languages are handled separately in machine learning. As an example of first-order representation of labeled graphs, the molecular graph of a benzene ring can be represented as follows:

   atom(a_1,carbon).,$\ldots$,atom(a_6,carbon).,
   atom(a_7,hydrogen).,$\ldots$,atom(a_{12},hydrogen).,
   edge(a_1,a_2,aromatic).,$\ldots$,edge(a_6,a_1,aromatic).,
   edge(a_1,a_7,single).,$\ldots$,edge(a_6,a_{12},single).,
   edge(X,Y) $\leftarrow$ edge(Y,X).

   
   The molecular graph of benzene rings (carbon atoms are unmarked)

   Besides complexity reasons, the above two representation languages are motivated also by the difference in the matching operators typically used for these two representations. While in case of first-order logic, the matching operator is defined by logical implication or by relational homomorphism (often referred to as subsumption), which is a decidable, but thus, incomplete variant of logical implication, in case of labeled graphs it is defined by subgraph isomorphism (i.e., by injective homomorphism).
2. Another component defining a task for learning from structured data is the type of the input and/or output data (see ▸ Observation Language and ▸ Hypothesis Language). For the input, two main types can be distinguished: the instances are disjoint structures (structured instances) or substructures of some global structure (structured instance space). Molecular graphs formed by the atom-bond structure of chemical compounds are a common example of structured instances. For structured instance spaces, the web graph provides an example of a global structure; for this case, the set of instances corresponds to the set of vertices formed by the web sites. The primary goal of traditional discriminative learning

is to approximate unknown target functions mapping the underlying instance space to some subset of the set of real numbers. In some of the applications, however, the elements of the range of the target function must also be structured. Such problems are referred to as learning in structured output spaces. As an example of structured output, we mention the protein secondary structure prediction problem, where the goal is to approximate the function mapping the primary structures of proteins to their secondary structures. Notice that primary and secondary structures can be represented by strings, which in turn can be considered as labeled directed paths.

3. Finally, the third component defining a problem setting is the learning task. Besides the classical learning tasks (e.g., supervised, semisupervised, unsupervised, transductive learning etc.), recent tasks include new problems such as, e.g., learning preferences (i.e., a directed graph, where an edge from vertex u to vertex v denotes that v is preferred to u), learning rankings (i.e., when the target preference relation must be a total order), etc.

Several classes of algorithms have been developed for the problem settings defined by the above components. ▸ Propositionalization techniques (e.g., as in LINUS (Lavrac et al. 1991)) first transform the structured data into a single table of fixed width by extracting a large number of propositional features and then use some propositional learner.

Non-propositionalization rule-based approaches follow mainly general-to-specific (top–down) or specific-to-general (bottom-up) search strategies. For top–down search (e.g., as in FOIL (Quinlan 1990)), the crucial step of the algorithms is the definition of the refinement operators. While for graph structured data the specialization relation on the hypothesis space is usually defined by subgraph isomorphism and is therefore a partial order, for First-Order Logic it is typically defined by subsumption and is therefore only a preorder (i.e., antisymmetry does not hold), leading to undesirable algorithmic properties (e.g., incompleteness). For bottom–up search (e.g., as in GOLEM (Muggleton and Feng 1992)), which is less common for graph structured data, the generalization of hypotheses is usually defined by some variant of Plotkin's Least General Generalization operator for first-order clauses. While this generalization operator has nice algebraic properties, its application raises severe complexity issues, as the size of the hypotheses may exponentially grow in the number of examples.

Recent research in structural learning has been focusing very strongly on distance- and kernel-based approaches which in terms of accuracy have often turned out superior to rule-based approaches (e.g., in virtual screening of molecules). In such approaches, the basic algorithms carry over unchanged from the propositional case; instead, special distance (e.g., as in RIBL (Emde and Wettschereck 1996)) or kernel functions for structural data are developed. Since even for graphs, computing any complete kernel (i.e., for which the underlying embedding function into the feature space is injective) is at least as hard as the graph isomorphism problem, most practical and efficient kernels are based on examining the structure for the occurrence of simpler parts (e.g., trees, walks, paths, and cycles) which are then counted and effectively used as feature vectors in an intersection kernel.

Finally, as a recent class of approaches, we also mention Statistical Relational Learning which extends probabilistic Graphical Models (e.g., Bayesian networks or Markov networks) with relational and logic elements (e.g., as in Alchemy (Domingos and Richardson 2007), ICL (Poole 2008), PRISM (Sato and Kameya 2008)).

Applications

Virtual compound screening is a representative application example of learning from structured data. This computational problem in pharmaceutical research is concerned with the identification of chemical compounds that can be developed into drug candidates. Since current pharmaceutical compound repositories contain millions of molecules, the design of efficient algorithms for virtual compound screening has become an integral part of computer-aided drug design. One of the branches of the learning algorithms concerned with this prediction problem is based on using the compounds' 2D graph structures formed by their atoms and bonds. Depending on the representation of chemical graphs, this branch of algorithms can further be classified into logic and graph-based approaches. The first class of algorithms, developed mostly in Inductive Logic Programming, treats chemical graphs as relational structures addressing the problem to the context of learning in logic; the second class of algorithms regards them as labeled graphs addressing the problem to ▶ Graph Mining.

Learning Graphical Models

Kevin B. Korb
Clayton School of Information Technology,
Monash University, Clayton, VIC, Australia

Abstract

Learning graphical models has become an important part of data mining and data science. Here we survey some of the more important techniques and concepts, including causal models and causal discovery, statistical equivalence, Markov Blanket discovery and knowledge engineering.

Synonyms

Bayesian model averaging; Causal discovery; Dynamic Bayesian network; Learning Bayesian networks

Definition

Learning graphical models (see Graphical Models) means to learn a graphical representation of either a causal or probabilistic model containing the variables $X_j \in \{X_i\}$. Although graphical models include more than directed acyclic graphs (DAGs), we shall focus here on learning DAGs, as that is where the majority of research and application is taking place.

Definition 1 (Directed acyclic graph (DAG)) A directed acyclic graph (DAG) is a set of variables (nodes, vertices) $\{X_i\}$ and a set of directed arcs (edges) between them such that following the arcs in their given direction can never lead from a variable back to itself.

DAGs parameterized to represent probability distributions are otherwise known as *Bayesian networks*. Some necessary concepts and notation for discussing the learning of graphical models is given in Table 1.

A key characteristic of multivariate probability distributions is the conditional independence structure they give rise to, i.e., the complete list of statements of the form

$$X_A \perp\!\!\!\perp X_B | X_C$$

true of the distribution. The goal of learning DAGs is to learn a minimal DAG representation of the conditional independence structure for a distribution satisfying the Markov condition:

Definition 2 (Markov condition) A DAG satisfies the Markov condition relative to a probability distribution if and only if for all X_i and $X_j \notin \pi_{X_i}$ in the DAG $X_i \perp\!\!\!\perp X_j | \pi_{X_i}$ so long as X_j is not a descendant of X_i (i.e., X_j is not in the transitive closure of the parent relation starting from X_i).

DAGs which violate the Markov condition are not capable of fully representing the relevant probability distribution. Upon discovering such a violation, the normal response is to fix the model by adding missing arcs. In the causal discovery literature, this condition is often referred to as the *causal Markov condition*, which simply means the arcs are being interpreted as representing causal relationships and not merely as probabilistic dependencies.

Definition 3 (Markov blanket) The Markov blanket (MB) of a node X_i is the minimal set $\mathbf{X_{MB}}$ such that for all other nodes X_j in the model $X_i \perp\!\!\!\perp X_j | \mathbf{X_{MB}}$.

The Markov blanket consists of a node's parents, children, and its children's other parents.

Motivation and Background

Bayesian networks have enjoyed a substantial success in thousands of diverse modeling, prediction, and control applications, including medical diagnosis, epidemiology, software engineering, ecology and environmental management, agriculture, intelligence and security, finance, and

Learning Graphical Models, Table 1 Notation

Notation	Description
X_i	A random variable
$\mathbf{X}$	A set of random variables
$\{X_i\}$	A set of random variables indexed by $i \in I$
$X = x_j$ (or, x_j)	A random variable taking the value x_j
$p(x)$	The probability that $X = x$
$X_A \models X_B$	X_A and X_B are *independent* (i.e., $p(X_A) = p(X_A \vert X_B)$)
$X_A \models X_B \vert X_C$	X_A and X_B are *conditionally independent* given X_C (i.e., $p(X_A \vert X_C) = p(X_A \vert X_B, X_C)$)
$X_A \not\models X_B$	X_A and X_B are *dependent* (i.e., $p(X_A) \neq p(X_A \vert X_B)$)
$X_A \not\models X_B \vert X_C$	X_A and X_B are *conditionally dependent* given X_C (i.e., $p(X_A \vert X_C) \neq p(X_A \vert X_B, X_C)$)
π_{X_i}	The set of parents of X_i in a DAG (i.e., nodes Y such that $Y \rightarrow X_i$)

marketing (see, e.g., http://www.norsys.com for customers implementing such applications and more). Many of these networks have been built by the traditional process of "knowledge engineering," that is, by eliciting both structure and conditional probabilities from human domain experts. That process is limited by the availability of expertise and also by the time and cost of performing such elicitation and subsequent model validation. In domains where significant quantities of data are available, it is pertinent to consider whether automated learning of Bayesian networks might either replace or compliment knowledge engineering. A variety of techniques for doing so have been developed, and the causal discovery of Bayesian networks is by now an important subindustry of data mining.

Theory

Probability and Causality

The key to learning Bayesian networks from the sample data is the relation between causal dependence and probabilistic dependence. This is most easily understood in reference to undirected chains of variables, as in Fig. 1.

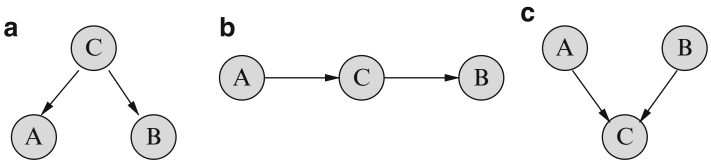
Where the arcs in Fig. 1 represent causal dependencies, then the probabilistic dependencies are as the caption describes, that is, in common causes and chains, the end nodes A and B are rendered probabilistically independent of each other given the knowledge of the state of C. Contrariwise, when A and B are parents of a common effect, and otherwise unrelated, they are probabilistically independent given no information (i.e., marginally independent), but *become* dependent given the knowledge of C. This last relationship is often called "explaining away," because it corresponds to situations where, when already knowing the presence of, say, some symptom C, the learning of the presence of a disease A reduces our belief in some alternative explanation B of the symptom.

These relationships between probabilistic dependence and causal dependence are the key for learning the causal structure of Bayesian networks because the sample data allow us to estimate probabilistic dependencies directly, and the difference between conditional dependency structures in Fig. 1a, b versus its opposite in Fig. 1c allows automated learners to distinguish between these different underlying causal patterns. (This is related to *d-separation* in graphical models.) This distinction is explicitly made use of in constraint learners, but also implicitly used by metric learners.

In addition to structure learning, parameter learning is necessary, i.e., learning the conditional probabilities of nodes given their parent values (conditional probability tables). Straightforward counting methods are frequently employed, although expectation maximization, Gibbs sampling, and other techniques may come into play when the available data are noisy.

Statistical Equivalence

Two DAGs are said to be statistically equivalent (or Markov equivalent) when they contain the same variables, and each can be parameterized so as to represent any probability distribution that the other can represent. Verma and Pearl (1990) proved that DAGs are statistically equivalent just in case they have the same undirected arc structures and the identical set of uncovered common



Learning Graphical Models, Fig. 1 Causality and probabilistic dependence: (**a**) common cause with $A \perp\!\!\!\perp B|C$; (**b**) causal chain with $A \perp\!\!\!\perp B|C$; (**c**) common effect with $A \not\perp\!\!\!\perp B|C$

effects, i.e., common effects such as in Fig. 1c where the two parents are not themselves directly connected. They dubbed the set of statistically equivalent models *patterns*; these can be represented using partially directed acyclic graphs (PDAGs), i.e., graphs with some arcs left undirected. Chickering (1995) showed that statistically equivalent models have identical maximum likelihoods relative to any given set of data. This latter result has suggested to many that causal learning programs can have no reasonable ambition to learn anything other than patterns, that is, any learner's discrimination between DAGs within a common pattern can only be based upon prior probability (e.g., prejudice). This is suggested, for example, by the fact that Bayesian learning combines (by multiplying) prior probabilities and likelihoods, so identical likelihoods will always lead to identical conclusions should the priors also be the same. We shall note some reason to doubt this supposed limit to causal discovery below.

Applications

Constraint Learners

The most direct application of the above ideas to learning Bayesian networks is exhibited in what may be called constraint learners. These programs assess conditional independencies between paired sets of variables given some other set of observed variables using statistical tests on the data, eliminating all DAGs that are incompatible with the independencies and dependencies asserted by the statistical test. (For this reason these programs are often called "conditional independence learners"; however that tag is misleading, as is explained below.) The original such algorithm, the IC algorithm of Verma and Pearl (1990), can be described in simplified form as three rules for constructing a network from Yes or No answers to questions of the form "Is it the case that $X \perp\!\!\!\perp Y \mid \mathbf{W}$?"

Rule I: Put an undirected link between any two variables X and Y if and only if for every set of variables $\mathbf{W}$ s.t. $X, Y \notin \mathbf{W}$

$$X \not\perp\!\!\!\perp Y \mid \mathbf{W},$$

> i.e., X and Y are directly connected if and only if they are dependent under every conditioning set (including Ø).

Rule II: For every undirected structure $X - Y - Z$, orient the arcs $X \rightarrow Y \leftarrow Z$ if and only if

$$X \not\perp\!\!\!\perp Z \mid \mathbf{W}$$

for **every W** s.t. $X, Z \notin \mathbf{W}$ and $Y \in \mathbf{Z}$,

> i.e., Y is an uncovered common effect if and only if the end variables X and Z are dependent under every conditioning set that includes Y.

Rule I is justified by the need to express the probabilistic dependency between X and Y under all possible circumstances. Rule II is justified by the asymmetry in probabilistic dependencies illustrated in Fig. 1.

Application of these two rules is then followed by applying a Rule III, which just checks for any arc directions that are forced by further considerations, such as avoiding the introduction of cycles or any uncovered common effects not already identified in Rule II, and so not supported by the conditional independence tests.

This algorithm was first put into practice in the PC algorithm distributed as a part of the TETRAD program (Spirtes et al. 1993). Aside from introducing some algorithmic efficiencies, PC adds orthodox statistical tests to answer the conditional independence questions. In the case of linear models, it uses a statistical significance test for vanishing partial correlations, accepting a dependence when and only when the test is statistically significant. For discrete networks a χ^2 test replaces the correlation test. Margaritis and Thrun further improve the algorithm's efficiency by limiting conditioning sets to the Markov blankets of the variable under test (Margaritis and Thrun 2000). The PC algorithm has become the most widely used Bayesian network learner, available in `weka` and many Bayesian network modeling tools.

Metric Learners

Constraint learners attempt to build up a network using a sequence of independent statistical tests. One problem with them is that when one such test gives an incorrect result, subsequent tests will assume that result, with the potential for errors to cascade. Metric learners, by contrast, use some score applied to a network as a whole to assess it relative to the data. The earliest of this kind, by Cooper and Herskovits, turned the computation of a Bayesian measure into a counting problem. Under a number of fairly strong assumptions, such as that children variable states are always uniformly distributed given their parent states, they derived the measure

$$P(d,e) = P(d)\prod_{k=1}^{n}\prod_{j=1}^{s_{\pi(k)}}\frac{(s_k-1)!}{(S_{kj}+s_k-1)!}\prod_{l=1}^{s_k}\alpha_{kjl}!$$

where d is the DAG being scored, e the data, n the number of variables, s_k the number of values X_k may take, $s_{\pi(k)}$ the number of values the parents of X_k may take, S_{kj} the number of cases in the data where π_k takes its j-th value, and α_{kjl} is the number of cases where X_k takes its l-th value and π_k takes its j-th value. Cooper and Herskovits proved that this measure can be computed in polynomial time. Assuming the adequacy of this probability distribution, computation of the joint probability suffices for Bayesian learning, since by Bayes' theorem, maximizing $P(d,e)$ is equivalent to maximizing the posterior probability of d. Cooper and Herskovits applied this measure in the program K2, which required as inputs both the data and a total ordering of the variables. The latter input eliminates all problems about discovering arc orientations, which could be considered a cheat since, as the discussion of the IC algorithm showed, this is a part of the causal learning problem. Subsequently, Chow and Liu's (1968) maximum-weighted spanning tree algorithm (MWST) has been used as a preprocessor to K2, doing a reasonable job of finding an ordering based upon the mutual information between pairs of variables.

A wide variety of alternative metrics for DAGs have been developed since K2. Heckerman et al. (1994) generalized the K2 metric to incorporate prior information, yielding BD (Bayesian metric with Dirichlet priors). Other alternatives include minimum description length (MDL) scores (Bouckaert 1993; Suzuki 1996, 1999), Bayesian information criterion (BIC) (Cruz-Ramírez et al. 2006), and minimum message length (MML) (Wallace et al. 1996; Korb and Nicholson 2011). Although all of these measures score the DAG as a whole relative to some data set, they are just as (or more) sensitive to the individual dependencies and independencies between variables as are the constraint learners. The difference between the two types of learners is not whether they attend to the sets of conditional independencies expressed in the data, but whether do so serially (which the constraint learners do) or collectively (as do the metric learners).

The question naturally arises whether constraint learners as a class are superior to metric learners or vice versa or, indeed, in which individual learner might be best. There is no settled answer to such questions, nor, in fact, is there any agreement about *how* such questions are best settled, even for fixed domains or data sets. Perhaps the issue is more general than that of learning Bayesian networks, since the fundamental theory of machine learning evaluation seems to be massively underdeveloped (see Algorithm Evaluation). In consequence, while nearly every new publication claims superiority in some sense for its preferred algorithm, the evidential basis for such claims remains a suspect. It is clear nonetheless that many of the programs available are helpful with data analysis and are being so applied.

Search and Complexity

The space of DAGs is superexponential in the number of variables, making the learning process hard; it is NP-hard to be exact (Chickering et al. 2004). In practice there are limits to the effectiveness of each algorithm, imposed by the number of variables (see Dimensionality Reduction), the number of joint states the variables may take, and the amount of data. The known limitations for different algorithms are scattered throughout the literature. This and the next section introduce some ideas for scaling up causal discovery.

Greedy search has frequently been used with both constraint-based and metric-based learning. The PC algorithm, searching the space of patterns, is an example, as it starts with a fully connected graph and searches greedily for arcs to remove. Chickering and Meek's greedy equivalence search (GES) is another greedy algorithm operating in the pattern space (Chickering and Meek 2002). Cooper and Herskovits' K2 is also a greedy searcher, adding arcs so long as single arc additions increase the probability score for the network. Bouckaert adopted this approach with his MDL score (Bouckaert 1993). Greedy searches, of course, tend to get lost in local maxima, and Suzuki loosened the search method for his MDL scoring, using branch and bound (Suzuki 1999).

Genetic algorithms (GAs) have been successfully applied to learning Bayesian networks. Larrañaga et al. used GAs over the space of total orderings to maximize the K2 score (Larrañaga et al. 1996); Neil and Korb developed a GA searching the DAG space to maximize the MML score (Neil and Korb 1999). A similar approach using MDL is found in Wong et al. (1999).

Markov chain Monte Carlo (MCMC) searches perform stochastic sampling over the model space and have become a popular technique for Bayesian network learning. Gibbs sampling is used in Chickering and Heckerman (1997), where they compare a number of different metrics (and incorrectly conflate BIC and MDL scores; see Cruz-Ramírez et al. 2006) for learning a restricted class of Bayesian networks. Another MCMC approach, the Metropolis-Hastings algorithm, has been to estimate the posterior probability distribution over the space of total orderings, using the MML score (Korb and Nicholson 2011, Chap 8).

An approach to coping with search complexity is to use an anytime algorithm, that is, one which at any given time can be stopped to yield a best-so-far result. Yuan and Malone describe an anytime version of A^* search using metrics for BN discovery (Yuan and Malone 2013). The same authors show that a heuristic window A^* has reasonable efficiency; optimality is not guaranteed, but the algorithm can report a maximum distance from the optimal BN (Malone and Yuan 2013).

An alternative to model selection – searching for the single best model – is Bayesian model averaging, that is, searching for a set of models and weights for each of them Chickering and Heckerman (1997). And an alternative to *that* is to find a single Bayesian network that is equivalent to an averaged selection of networks (Dash and Cooper 2004).

Markov Blanket Discovery

Recently interest has grown in algorithms to learn, specifically, the Markov blankets around individual variables, which is a special kind of feature selection problem (see Feature Selection). This approach can help deal with "Big Data": whether the "curse of dimensionality" (too many variables) or extremely large data sets.

One use for this is in prediction: since the MB renders all other variables conditionally independent of a target variable, finding the MB means having all the variables required for an optimal predictor. Koller and Sahami developed an approximate Markov blanket filtering approach for prediction (Koller and Sahami 1996); Saeed improved the efficiency of this approach (Saeed 2008). Tsamardinos et al. describe the max-min hill climbing (MMHC) algorithm for MB discovery (Tsamardinos et al. 2006). Nägele et al. apply this to learning in very high-dimensional spaces (Nägele et al. 2007). Given the MB for a target variable, one can simply apply regression techniques (or any predictive technique) to the discovered variables. This works fine for standard prediction, but does not generalize to situations where some of the predictor variables are externally modified rather than observed. For an interesting collection of papers mostly applying some kind of Markov blanket discovery approach to prediction, see the collection (Guyon et al. 2008).

One can also apply MB discovery to causal learning, employing causal discovery within the reduced set of variables in the Markov blanket. Iterating this will yield multiple causal subnetworks, when a global causal network might be stitched together from them, as Aliferis et al. do with their HHC algorithm (Aliferis et al. 2010b), completing the whole causal discovery process while evading complexity problems. A current review of the issues and techniques can be found in two companion articles by Aliferis et al. (2010a, b).

Knowledge Engineering with Bayesian Networks

Another approach to dealing with the complexity and tribulations of global causal discovery is to aid the discovery process with prior information. Bayesian inference is, after all, done by combining priors with likelihoods, and the priors need not always be perfectly flavorless, such as uniform priors over the DAG space. In almost all applications where data threaten to overwhelm automated discovery, there is also at least some expertise, if only the ability to say, for example, that the sex of a patient is determined before adult lifestyle practices are adopted. Such temporal information provided to a discovery algorithm can provide a huge boost to the discovery process.

This quite simple kind of prior information, the temporal tiers within which the variables may be allocated, has been available in many of the discovery programs for a long time. PC, for example, allows tiers to be specified. K2 more restrictively required a total ordering of the variables. The methods described by Heckerman et al. (1994) go beyond tiers. They provide for the specification of a network or subnetwork; the prior probability of any network in the search space can be computed according to its distance from the network provided. They also introduced the idea of equivalent sample size, i.e., the weight to be given the prior information relative to the data, meaning that their priors are soft (probabilistic) rather than hard constraints. O'Donnell et al. (2006) adapted their MML score to allow soft priors for tiers, dependencies, direct and indirect causal relations, and networks or subnetworks, with variable degrees of confidence.

The flexible combination of prior information (expertise) with data in the causal discovery process allows for a fully fledged knowledge engineering process in the construction of Bayesian networks. Experts may be consulted for structural or parametric information, data may be gathered, and these different contributions may be weighted or reweighted according to the results of sensitivity analyses or other tests. The result can be a much faster and more useful approach to building and applying Bayesian networks. Research continues in this useful area of incorporating prior information, e.g., in Borboudakis et al. (2011).

Causal discovery with meaningful priors, by the way, shows that limiting discovery to patterns is insufficient: better priors, or better use of priors, can make a significant difference *within* patterns of DAGs.

Abstract

The field of bioinformatics developed in the 1980s and 1990s, largely focusing on the computational analysis of newly available collections of DNA and protein sequences. In this context, a wide variety of machine learning analysis methods have been developed to understand the evolutionary history and molecular biology function of such sequences.

Definition

Hereditary information is stored in the nucleus of every living cell as biopolymers of deoxyribonucleic acids (DNA). DNA thus encodes the blueprint for all known forms of life. A DNA sequence can be expressed as a finite string over an alphabet of {A, C, G, T}, corresponding to the four DNA bases. The human genome consists of approximately three billion bases, divided among 23 chromosomes.

During its life, each cell makes temporary copies of short segments of DNA. These short-lived copies are comprised of ribonucleic acid (RNA). Each 3-mer of RNA can subsequently be translated, via the universal genetic code, into one of 20 amino acids. The resulting amino acid sequence is called a protein, and the DNA sequence that encodes the protein is called a gene.

Machine learning has been used to build models of many different types of biological sequences. These include models of short, functional elements within DNA or protein sequences, as well as models of genes, RNAs, and proteins.

Motivation and Background

Fundamentally, the motivation for building models of biological sequences is to understand the molecular mechanisms of the cell and the molecular basis for human disease. Each subheading below describes a different type of model, each of which attempts to capture a different facet of the underlying biology. All of these models, ultimately, aim to uncover either evolutionary or functional relationships among sequences.

Although DNA and protein sequences were available in small numbers as early as the 1950s, a significant number of sequences were not available until the 1980s. Most of the advances in model development started in the 1990s, with the exception of phylogenetic models, which were already being developed in the 1970s.

Structure of Learning System

Motifs

In the context of biological sequences, a "motif" is a short (typically 6–20 letters) subsequence that is functionally significant. A motif may correspond to, e.g., the location along the DNA strand where a particular protein binds or conversely the location along the protein that binds to the DNA. The motif can arise either via convergent evolution (when two sequences evolve to look similar to one another) or via evolutionary conservation (if sequences that lack the motif are likely to be eliminated via natural selection).

Motif discovery is the problem of identifying a previously unknown motif within a given collection of sequences, by finding patterns that occur more often than one would expect by chance. The problem is challenging in part because two occurrences of a given motif may not resemble each other exactly.

Work on motif discovery falls into two camps, based upon how the motifs themselves are represented. One camp uses position-specific scoring matrices (PSSMs), in which a motif of width w over an alphabet of size A is represented as a w-by-A probability matrix. In this matrix, each entry represents the probability that a given letter occurs at the given position. Early work in this area used expectation-maximization to identify protein motifs (Lawrence and Reilly 1990). This effort was significantly extended in the MEME algorithm (Bailey and Elkan 1994), which continues to be widely used today. A complementary approach uses Gibbs sampling (Lawrence et al. 1993), which offers several benefits, including avoiding local minima and the ability to sample multiple motifs simultaneously.

The other motif discovery camp uses a discrete motif representation, in which each motif is represented as a consensus sequence plus a specified maximum number of mismatches. In this formalism, enumerative methods can guarantee solving a given problem to optimality. For realistic problem sizes, this approach is most applicable to DNA, because of its much smaller alphabet size. One popular method of this kind is Weeder (Pavesi et al. 2004), which performed well in a comparison of motif discovery algorithms (Tompa et al. 2005).

More recently, the generation of large-scale in vitro binding data sets for DNA-binding proteins, for example, using protein binding microarray experiments, has renewed interest in algorithms for learning transcription factor binding motifs (Weirauch et al. 2013). These motifs may be represented either as PSSMs or by more general models based on k-length subsequences ("k-mers"). Meanwhile, experimental data on in vivo genomic binding of transcription factors based on chromatin immunoprecipitation followed by sequencing (ChIP-seq) has also been modeled using k-mer based learning methods (Arvey et al. 2012).

Proteins

A central problem in computational biology is the classification of proteins into functional and structural classes given their amino acid sequences. The 3D structure that a protein assumes after folding largely determines its function in the cell. However, directly obtaining a protein's 3D structure involves difficult experimental techniques such as X-ray crystallography or nuclear magnetic resonance, whereas it is relatively easy to determine a protein's sequence. Through evolution, structure is more conserved than sequence, so that detecting even very subtle sequence similarities, or remote homology, is important for predicting function.

Since the early 1980s, researchers have developed a battery of successively more powerful methods for detecting protein sequence similarities. This development can be broken into three main stages. Early methods focused on the *pairwise comparison* problem and assessed the statistical significance of similarities between two proteins based on pairwise alignment. These methods are only capable of recognizing relatively close homologies. The BLAST algorithm (Altschul et al. 1990), based on heuristic alignment, and related tools are the most widely used methods for pairwise sequence comparison and database search today.

In the second stage, further accuracy was achieved by collecting aggregate statistics from a set of similar sequences and comparing the resulting statistics to a single, unlabeled protein of interest. One important example of *family-based models* are profile hidden Markov models (HMMs) (Krogh et al. 1994), probabilistic generative models estimated from a multiple alignment of sequences from a protein family. Profile HMMs generate variable length sequences by allowing insertions and deletions relative to the core residues of the alignment.

The third stage introduced *discriminative algorithms* based on classifiers like support vector machines for protein classification and remote homology detection. Such methods train both on positive sequences belonging to a protein family as well as negative examples consisting of sequences unrelated to the family. They require protein sequences to be represented using an explicit feature mapping or a kernel function in order to train the classifier. The first discriminative protein classification algorithm was the SVM-Fisher method (Jaakkola et al. 2000), which uses a profile HMM to extract a feature vector of Fisher scores for each input sequence x, defined by the gradient vector

$$\nabla_\theta \log P(x|\theta)|_{\theta=\theta_0},$$

where $\log P(x|\theta)$ is the log likelihood function the sequence relative to the HMM and θ_0 is the maximum likelihood estimate for the model parameters. Another feature representation that has been used is the empirical kernel map:

$$\Phi(x) = \langle s(x_1, x), \ldots, s(x_m, x) \rangle,$$

where $s(x, y)$ is a function depending on a pairwise similarity score between x and y and x_i, $i = 1 \ldots m$, are the training sequences (Liao and Noble 2002). In addition, it is possible to construct useful kernels directly without explicitly depending on generative models by using subsequence-based string kernels. For example, the mismatch kernel (Leslie et al. 2003) is defined by a histogram-like feature map The feature space is indexed by all possible k-length subsequences $\alpha = a_1 a_2 \ldots a_k$, where each a_i is a character in the alphabet $\mathcal{A}$ of amino acids. The feature map is defined on k-gram α by $\Phi(\alpha) = (\phi_\beta(\alpha))_{\mathcal{A}^k}$ where $\phi_\beta(\alpha) = 1$ if α is within m mismatches of β, 0 otherwise, and is extended additively to longer sequences: $\Phi(x) = \sum_{k-\text{grams} \in x} \Phi(\alpha)$.

One challenge in using the k-gram representations is that computing sequence similarity using this feature map can quickly become computationally intractable (Leslie et al. 2003), particularly when the number of mismatches m is large or if the sequence alphabet grows beyond the 20 basic amino acids to encode, for instance, additional physical or chemical properties of the protein sequence. To handle this problem, Kuksa et al. (2008) introduced linear time algorithms with alphabet-independent complexity applicable to computation of a large class of existing string kernels. The approach relies on the ability to precompute, in closed form, the number of k-grams that are at most m mismatches away from two short strings α and β. These methods have been subsequently extended from Hamming (i.e., match or no match) to arbitrary measures of similarity $\mathcal{S}(a, b)$ between elements a,b of each k-gram (Kuksa et al. 2012).

Genes

After a genome (or a portion of a genome) has been sequenced, a biologist's first question is usually, "Where are the genes?" In simple organisms, most of the genome is translated into proteins, and so the gene-finding problem reduces, essentially, to identifying the boundaries between genes. In more complex organisms, a large proportion of the genome is comprised of nonprotein coding DNA. The human genome, for example, is comprised of approximately 98 % noncoding DNA. This noncoding DNA is interspersed between coding regions and even in the midst of a single coding region. The gene-finding problem, canonically, is to identify the regions of a given DNA sequence that encode proteins.

Initial methods for gene finding combined scores produced by different types of detectors. A *signal* detector attempts to recognize local, fixed-length features, such as characterize the boundaries between coding and noncoding regions within a single gene. A *content* detector attempted to recognize larger patterns on the basis of compositional statistics. Early gene-finding algorithms combined these various scores in an ad hoc fashion to identify gene-like regions.

In the mid-1990s, several research groups began using HMMs for gene finding. HMMs provide a coherent, fully probabilistic method that is capable of capturing many of the complexities of real genes. An early, widely used method was Genscan (Burge and Karlin 1997), which uses fifth-order Markov statistics along with variable duration HMMs. Next-generation gene finders used conditional random field models (Bernal et al. 2007) and large-margin structured output techniques (Rätsch et al. 2007).

A more recent, unsupervised variant of the gene-finding problem is *semiautomated genome annotation* (Day et al. 2007). In this case, the input is not the DNA sequence per se but a collection of sequence-based measurements arrayed along the genome, representing local DNA conformation as well as properties of proteins bound to the DNA. The task is to simultaneously partition the genome and assign an integer label to each segment in such a way that segments with the same label have similar data. The process is semiautomated because the semantics of the labels – corresponding to genes, regulatory elements, etc. – must be inferred manually in a post-processing step.

RNAs

Most RNA molecules are so-called messenger RNAs, which are used in the production of a corresponding protein molecule. Some RNAs, however, do not code for proteins but instead function on their own. These RNAs fall into functional categories, but they are not easily recognized by HMMs because (1) the RNAs themselves are often very short, and (2) functional RNA typically folds up in a deterministic fashion and therefore exhibits nonlocal dependencies along the RNA sequence.

Useful RNA modeling is therefore accomplished using covariance models, which are a subclass of stochastic context-free grammars. The foundational work in this area was due to Eddy and Durbin (1994), who addressed both the structure inference problem and the inference of transition and emission probabilities given the structure. They applied these algorithms to transfer RNAs (tRNAs), and the approach was the basis for widely used tools such as Rfam.

Much effort in RNA covariance models has been devoted to improving the time and space efficiency of the algorithms associated with covariance models. For example, Eddy (2002) introduced a memory-efficient variant of the core dynamic programming algorithm used to align a covariance model to an RNA sequence. This improvement was practically important, since it reduced the $O(N^3)$ space requirement for a length N RNA sequence. Other work has focused on accelerating database search using the modeled families.

Recent efforts have focused on algorithms for genome-wide screens to discover functional noncoding RNAs as well as small regulatory

RNAs like microRNAs. Various approaches to this problem have incorporated conservation as well as RNA structure prediction, both using covariance models and other methodologies. One such algorithm is RNAz (Washietl et al. 2005), which combines a measure for thermodynamic stability with a measure for structure conservation in an SVM approach to detect functional RNAs in multiple sequence alignments.

Phylogenetic Models

Phylogenetic models attempt to infer the series of evolutionary events (mutations, insertions, deletions, etc.) that gave rise to an observed collection of DNA or protein sequences. In most cases, these models ignore the possibility of copying DNA between individuals or species, and therefore represent the history as a phylogenetic tree, in which leaf nodes represent the observed sequences and the internal nodes represent unobserved ancestral sequences. Of primary interest is inferring the topology and branch lengths of this tree.

Methods for phylogenetic tree inference can be divided into three classes: parsimony, distance, and likelihood methods, all described in detail in Felsenstein (2003).

Parsimony methods search for a tree that requires the smallest number of mutations, insertions, or deletions along its branches. Because the search space of possible tree topologies is so large, this approach is feasible only for relative small sets of sequences – tens rather than hundreds. Also, because parsimony models do not allow for so-called back mutations – where a letter mutates to a different letter and then back again – and other similar events, parsimony models are provably suboptimal for distantly related sequences.

Distance methods replace parsimony with a generalized notion of distance, which may include back mutation. A series of increasingly sophisticated distance metrics have been developed in this domain, starting with the one-parameter Jukes-Cantor model and the two-parameter Kimura model. Given an all-versus-all distance matrix, various tree inference algorithms can be used, including neighbor joining and agglomerative hierarchical clustering (called UPGMA in phylogenetics).

The third class of models use a fully probabilistic approach and attempt to infer the tree with maximum likelihood, given the observed sequences. This approach was first outlined in 1973 (Felsenstein 1973), but was not computationally feasible for large sets of sequences until recently. Current methods employ Markov chain Monte Carlo methods to carry out the search.

More recently, the so-called alignment-free methods (Kuksa and Pavlovic 2009) have been considered for the narrower problem of species identification in the context of DNA barcoding. DNA barcoding was introduced as a taxonomic tool for characterizing species using fragments of a DNA sequence from standard gene regions, such as the mitochondrial DNA (mtDNA) (Hebert et al. 2003). These alignment-free methods are similar in spirit to the discriminative kernel approaches used for protein classification. They avoid the costly process of explicit phylogenetic tree-building and instead focus on more scalable identification of few species families.

Programs and Data

Following are some of the more popular web sites for performing biological sequence analysis:

- BLAST and PSI-BLAST (http://www.ncbi.nlm.nih.gov/BLAST) search a protein or DNA sequence with a given, query sequence, and return a ranked list of homologs.
- MEME (http://meme.sdsc.edu) searches a given set of DNA or protein sequences for one or more recurrent motif patterns.
- HMMER (http://hmmer.janelia.org) is an HMM toolkit for training and searching with profile HMMs of proteins.
- Pfam (http://pfam.janelia.org) is a searchable library of profile HMMs corresponding to a curated collection of homologous protein domains.
- Rfam (http://rfam.janelia.org) is an analogous database of multiple sequence alignments and

covariance models covering many common noncoding RNA families.

- PHYLIP (http://evolution.genetics.washington.edu/phylip.html) is a free software toolkit that includes many common phylogenetic inference algorithms.

Learning to Rank

Hang Li
Huawei Technologies, Hong Kong, China

Abstract

Many tasks in information retrieval, natural language processing, and data mining are essentially ranking problems. These include document retrieval, expert search, question answering, collaborative filtering, and keyphrase extraction. Learning to rank is a subarea of machine learning, studying methodologies and theories for automatically constructing a model from data for a ranking problem (Liu T-Y, Found Trends Inf Retr 3(3):225–331, 2009; Li H, Synth Lect Hum Lang Technol 4(1):1–113, 2011a; Li H, IEICE Trans Inf Syst 94-D(10):1854–1862, 2011b).

Learning to rank is usually formalized as a supervised learning task, while unsupervised learning and semi-supervised learning formulations are also possible. In learning, training data consisting of sets of objects as well as the total or partial orders of the objects in each set is given, and a ranking model is learned using the data. In prediction, a new set of objects is given, and a ranking list of the objects is created using the ranking model.

Learning to rank has been intensively studied in the past decade and many methods of learning to rank have been proposed. Popular methods include Ranking SVM, IR SVM, AdaRank, LambdaRank, and LambdaMART. The methods can be categorized into the pointwise, pairwise, and listwise approaches according to the loss functions which they use. It is known that learning-to-rank methods, such as LambdaMART, are being employed in a number of commercial web search engines.

In this entry, we describe the formulation as well as several methods of learning to rank. Without loss of generality, we take document retrieval as example.

Solution

Problem Formulation

In the supervised learning setting, learning to rank includes training and testing phases (see Fig. 1). In training, the learning system learns a ranking model from given training data, and in testing, given a query the ranking system assigns scores to documents with respect to the query using the ranking model and sorts the documents on the basis of the scores.

The training data consists of queries and documents. Each query is associated with a number of documents. The relevance of the documents with respect to the query is also given. The relevance can be represented in several ways. Here, we take the most widely used approach and assume that the relevance of a document with respect to a query is represented by a label, while the labels denote several grades (levels). The higher grade a document has, the more relevant the document is.

Suppose that $\mathcal{Q}$ is the query set and $\mathcal{D}$ is the document set. Suppose that $\mathcal{Y} = \{1, 2, \cdots, l\}$ is the label set, where labels represent grades. There exists a total order between the grades $l \succ l-1 \succ \cdots \succ 1$, where $\succ$ denotes the order relation. Further suppose that $Q = \{q_1, q_2, \cdots, q_m\}$ is the set of queries for training and q_i is the i-th query. $D_i = \{d_{i,1}, d_{i,2}, \cdots, d_{i,n_i}\}$ is the set of documents associated with query q_i, and $\mathbf{y}_i = \{y_{i,1}, y_{i,2}, \cdots, y_{i,n_i}\}$ is the set of labels associated with query q_i, where n_i denotes the sizes of D_i and $\mathbf{y}_i$; $d_{i,j}$ denotes the j-th document in D_i; and $y_{i,j} \in Y$ denotes the j-th grade

Learning to Rank, Fig. 1 An overview of learning to rank for document retrieval

label in $\mathbf{y}_i$. The original training set is denoted as $S = \{(q_i, D_i), \mathbf{y}_i\}_{i=1}^{m}$.

A feature vector $x_{i,j} = \phi(q_i, d_{i,j})$ is created from each query-document pair $(q_i, d_{i,j})$, $i = 1, 2, \cdots, m; j = 1, 2, \cdots, n_i$, where ϕ denotes the feature functions. That is to say, features are defined as functions of a query-document pair. For example, BM25 and PageRank are typical features. Letting $\mathbf{x}_i = \{x_{i,1}, x_{i,2}, \cdots, x_{i,n_i}\}$, the training data set is also represented as $S' = \{(\mathbf{x}_i, \mathbf{y}_i)\}_{i=1}^{m}$. Here $x \in \mathcal{X}$ and $\mathcal{X} \subseteq \Re^d$, where d denotes the number of features.

We aim to train a (local) ranking model $f(q,d) = f(x)$ that can assign a score to a given query-document pair q and d or equivalently to a given feature vector x. More generally, we can also consider training a global ranking model $F(q, D) = F(\mathbf{x})$.

Let the documents in D_i be identified by the integers $\{1, 2, \cdots, n_i\}$. We define a permutation (ranking list) $\boldsymbol{\pi}_i$ on D_i as a bijection from $\{1, 2, \cdots, n_i\}$ to itself. We use Π_i to denote the set of all possible permutations on D_i and use $\pi_i(j)$ to denote the rank (or position) of the j-th document (i.e., $d_{i,j}$) in permutation π_i. Ranking is nothing but to select a permutation $\pi_i \in \Pi_i$ for the given query q_i and the associated documents D_i using the scores given by the ranking model $f(q_i, d_i)$.

The test data consists of a new query q_{m+1} and associated documents D_{m+1}. We create feature vector $\mathbf{x}_{m+1}$, use the trained ranking model to assign scores to the documents D_{m+1}, sort them based on the scores, and give the ranking list of documents as output π_{m+1}.

The training and testing data is similar to, but different from, the data in conventional supervised learning such as classification and regression. Query and its associated documents form a group. The groups are i.i.d. data, while the instances within a group are not i.i.d. data. A local ranking model is a function of a query and a document or, equivalently, a function of a feature vector derived from a query and a document.

Evaluation on the performance of a ranking model is carried out by comparison between the ranking lists output by the model and the ranking lists given as the ground truth. Several evaluation measures are usually used in information retrieval, such as NDCG (Normalized Discounted Cumulative Gain), DCG (Discounted Cumulative Gain), MAP (Mean Average Precision), and Kendall's Tau.

Evaluation Measures: DCG and NDCG

We give definitions of DCG and NDCG; both are most utilized in document retrieval. NDCG is normalized and thus it is easier to use NDCG in comparison.

Given query q_i and associated documents D_i, suppose that π_i is the ranking list (permutation) on D_i and $\mathbf{y}_i$ is the set of labels (grades) of D_i. DCG measures the goodness of the ranking list with the labels. Specifically, DCG at position k is defined as

$$DCG(k) = \sum_{j:\pi_i(j)\leq k} G(j)D(\pi_i(j)),$$

where $G_i(\cdot)$ is a gain function, $D_i(\cdot)$ is a position discount function, $\pi_i(j)$ is the position of $d_{i,j}$ in π_i, and the summation is taken over the top k positions in the ranking list π_i. The gain function is normally defined as an exponential function of grade

$$G(j) = 2^{y_{i,j}} - 1,$$

where $y_{i,j}$ is the label (grade) of document $d_{i,j}$ in ranking list π_i. The position discount function is normally defined as a logarithmic function of position

$$D(\pi_i(j)) = \frac{1}{\log_2(1+\pi_i(j))},$$

where $\pi_i(j)$ is the position of document $d_{i,j}$ in ranking list π_i. DCG represents the cumulative gain of accessing the information from position one to position k with discounts on the positions. Hence, DCG at position k becomes

$$\mathrm{DCG}(k) = \sum_{j:\pi_i(j)\leq k} \frac{2^{y_{i,j}} - 1}{\log_2(1+\pi_i(j))}.$$

NDCG is normalized DCG, and NDCG at position k is defined as

$$\mathrm{NDCG}(k) = G^{-1}_{\max,i}(k)DCG(k),$$

where $G_{\max,i}(k)$ is the normalizing factor and is chosen such that a perfect ranking π_i^*'s NDCG score at position k is 1. In a perfect ranking, the documents with higher grades are always ranked higher. Note that there can be multiple perfect rankings for a query and associated documents. Then, NDCG at position k becomes

$$\mathrm{NDCG}(k) = G^{-1}_{\max,i}(k) \sum_{j:\pi_i(j)\leq k} \frac{2^{y_{i,j}} -1}{\log_2(1+\pi_i(j))}.$$

In evaluation, DCG and NDCG values are further averaged over queries.

Objective Function of Learning

Learning to rank is generally formalized as a supervised learning task. Suppose that $\mathcal{X}$ is the input space (feature space) consisting of lists of feature vectors and $\mathcal{Y}$ is the output space consisting of lists of grades. Further suppose that $\mathbf{x}$ is an element of $\mathcal{X}$ representing a list of feature vectors and $\mathbf{y}$ is an element of $\mathcal{Y}$ representing a list of grades. Let $P(X,Y)$ be an unknown joint probability distribution where random variable X takes $\mathbf{x}$ as its value and random variable Y takes $\mathbf{y}$ as its value.

Assume that $F(\cdot)$ is a function mapping from a list of feature vectors $\mathbf{x}$ to a list of scores. The goal of the learning task is to automatically learn a function $\hat{F}(\mathbf{x})$ given training data $(\mathbf{x}_1,\mathbf{y}_1),(\mathbf{x}_2,\mathbf{y}_2),\ldots,(\mathbf{x}_m,\mathbf{y}_m)$. Each training instance is comprised of feature vectors $\mathbf{x}_i$ and the corresponding grades $\mathbf{y}_i$ $(i = 1,\cdots,m)$. Here m denotes the number of training instances.

$F(\mathbf{x})$ and $\mathbf{y}$ can be further written as $F(\mathbf{x}) = (f(x_1), f(x_2),\cdots,f(x_n))$ and $\mathbf{y} = (y_1,y_2,\cdots,y_n)$. The feature vectors represent objects to be ranked. Here $F(\mathbf{x})$ denotes the global ranking function, $f(x)$ denotes the local ranking function, and n denotes the number of feature vectors and grades.

A loss function $L(\cdot,\cdot)$ is utilized to evaluate the prediction result of $F(\cdot)$. First, feature vectors $\mathbf{x}$ are ranked according to $F(\mathbf{x})$, and then the top n results of the ranking are evaluated using their corresponding grades $\mathbf{y}$. If the feature vectors with higher grades are ranked higher, then the loss will be small. Otherwise, the loss will be large. The loss function is specifically represented as $L(F(\mathbf{x}), \mathbf{y})$. Note that the loss function for ranking is slightly different from the loss functions in other statistical learning tasks, in the sense that it makes use of sorting.

The loss function can be defined, for example, based on NDCG (Normalized Discounted Cumulative Gain) and MAP (Mean Average Precision). In the former case, we have

$$L(F(\mathbf{x}), \mathbf{y}) = 1 - \text{NDCG}.$$

The risk function, i.e., the objective function in learning, is further defined as the expected loss function with respect to the joint distribution $P(X, Y)$:

$$R(F) = \int_{\mathcal{X} \times \mathcal{Y}} L(F(\mathbf{x}), \mathbf{y}) dP(\mathbf{x}, \mathbf{y}).$$

Given training data, the empirical risk function is defined as follows:

$$\hat{R}(F) = \frac{1}{m} \sum_{i=1}^{m} L(F(\mathbf{x}_i), \mathbf{y}_i). \tag{1}$$

The learning task then becomes minimization of the empirical risk function, as in other learning tasks. The minimization could be difficult due to the nature of the loss function (it is not continuous and it uses sorting). We can consider using a surrogate loss function $L'(F(\mathbf{x}), \mathbf{y})$.

The corresponding empirical risk function is defined as follows:

$$\hat{R}'(F) = \frac{1}{m} \sum_{i=1}^{m} L'(F(\mathbf{x}_i), \mathbf{y}_i). \tag{2}$$

One can also introduce a regularizer to the minimization. In such case, the learning problem becomes minimization of the regularized empirical risk function based on the surrogate loss.

For the surrogate loss function, there are also different ways to define it, which lead to different approaches to learning to rank, referred to as pointwise loss, pairwise loss, and listwise loss functions.

Methods

Ranking SVM and IR SVM

A perfect ranking implies perfect classification on all pairs of objects, and an imperfect ranking implies existence of incorrect classification on pairs of objects. Therefore, learning of a ranking model can be transformed to learning of a pairwise classification or regression model. This is the idea behind the pairwise approach to learning to rank. Ranking SVM proposed by Herbrich et al. (1999) is a typical example.

Ranking SVM takes pairs of objects (feature vectors) at different grades as new objects and takes the orders of the pairs of objects as positive or negative classes. It learns an SVM classifier which can classify the order of pair of objects and then utilizes the SVM classifier to assign scores to newly given objects and rank the objects on the basis of the scores. One can easily verify that if the classifier is a linear function, then it can be directly utilized as a ranking model.

It can be proved that the "pairwise" loss function in Ranking SVM is an upper bound of (1-NDCG) Li (2011a), and therefore Ranking SVM is a method equivalent to minimizing empirical risk based on a surrogate loss function (cf., Eq. (2)).

IR SVM proposed by Cao et al. (2006) is an extension of Ranking SVM for information retrieval (IR). Ranking SVM transforms ranking into pairwise classification, and thus it actually makes use of the 0-1 loss in the classification. There exists a gap between the loss function and the IR evaluation measures such as NDCG. IR SVM attempts to bridge the gap by modifying the 0-1 loss, that is, conducting cost-sensitive learning of Ranking SVM.

One problem with Ranking SVM is that it equally treats document pairs across different grades (levels). Another issue with Ranking SVM is that it equally treats document pairs from different queries. IR SVM addresses the above two problems by modifying the hinge loss function.

Specifically, it sets different losses for document pairs across different grades and from different queries. To emphasize the importance of correct ranking on the top, the loss function heavily penalizes errors related to the top. To increase the influence of queries with less documents, the loss function heavily penalizes errors from the queries.

AdaRank

Since the evaluation measures in IR are defined on lists of objects, it is more natural and effective to directly optimize "listwise" loss functions defined on lists. This is the presumption in the listwise approach to learning to rank. AdaRank, proposed by Xu and Li (2007), is one of the listwise algorithms. One advantage of AdaRank is its simplicity, and it is perhaps one of the simplest learning-to-rank algorithms.

In learning, ideally we would create a ranking model that can maximize the ranking accuracy in terms of an evaluation measure (e.g., NDCG) on the training data or equivalently minimize the empirical risk function in Eq. (1) specified as

$$\sum_{i=1}^{m}(1 - E(\pi_i, \mathbf{y}_i)),$$

where $\mathbf{x}_i$ is a list of feature vectors, $\mathbf{y}_i$ is the corresponding list of grades, π_i is the permutation of feature vectors $\mathbf{x}_i$ by the ranking model $f(x)$, $E(\pi_i, \mathbf{y}_i)$ is the evaluation result of π_i based on $\mathbf{y}_i$ in terms of the evaluation measure, and m is the number of training instances.

The empirical risk function is not smooth and differentiable, and thus straightforward optimization of the evaluation result might not work. Instead, we can consider optimizing an upper bound of the function. For example, one upper bound is the following function:

$$\sum_{i=1}^{m}\exp(-E(\pi_i, \mathbf{y}_i)),$$

which is continuous, differentiable, and even convex with respect to E.

AdaRank minimizes the upper bound, by taking the boosting approach. Mimicking the famous AdaBoost algorithm, AdaRank conducts stepwise minimization of the upper bound. More specifically, AdaRank repeats the process of reweighting the training instances, creating a weak ranker, and assigning a weight to the weak ranker. Finally, AdaRank linearly combines the weak rankers as the ranking model.

One can prove that AdaRank can continuously reduce the empirical risk during the training process, under certain conditions. When the evaluation measure is dot product, AdaRank can reduce the risk to zero.

LambdaRank and LambdaMART

The objective function (empirical risk function) in learning to rank is not continuous and differentiable, and it depends on sorting. This makes it difficult to use gradient decent to optimize the function. LambdaRank and LambdaMART, proposed by Burges (2010), manage to solve the problem by directly defining and utilizing a gradient function of the risk function.

Suppose that the ranking model, query, and documents are given. Then each document receives a score from the ranking model, and a ranking list can be created by sorting the documents based on the scores. Since the documents are also assigned ground truth labels, a ranking evaluation result based on an IR measure can be obtained. Suppose that we use a surrogate loss function L to approximate the IR evaluation measure. Then, an evaluation result based on the surrogate loss function L can also be obtained. It is this evaluation result which LambdaRank attempts to continuously optimize.

LambdaRank does not explicitly give the definition of the loss function. Instead it defines the *gradient* function of the surrogate loss function. More specifically, the gradient function is defined as

$$\frac{\partial L}{\partial s_i} = -\lambda_i(s_1, y_1, \cdots, s_n, y_n),$$

where $s_1, s_2, \cdots, s_n$ denote the scores of documents and $y_1, y_2, \cdots, y_n$ denote the labels of documents. Note that the index i is on a single document. That is to say, the gradient of a document depends on the scores and labels of the other documents. The sign is chosen such that a positive value for a document means that the document must reduce the loss. The gradients of documents are calculated after the current model generates a ranking list of documents for the query. The negative gradient function is called lambda function, and that is why the method is called LambdaRank. LambdaRank utilizes a neural network as its ranking model.

LambdaMART follows the idea of LambdaRank, but it utilizes an ensemble of trees as its ranking model and employs the Gradient Tree Boosting algorithm to build the ranking model. Specifically, LambdaMART directly uses the lambda function as the gradient function in the learning process of Gradient Tree Boosting.

In the Yahoo Learning to Rank Challenge, LambdaMART achieved the best performance. It is viewed as one of the state-of-the-art methods for learning to rank and is being used in a number of commercial search systems.

Applications

Learning to rank has been successfully applied to a wide variety of applications, including document retrieval, expert search, definition search, personalized search, online advertisement, collaborative filtering, question answering, keyphrase extraction, document summarization, and machine translation. Particularly, in document retrieval there are many signals which can represent relevance. Incorporating such information into the ranking model and automatically constructing the ranking model by using data become a natural choice. In fact, learning to rank has become one of the fundamental technologies for document retrieval.

[2]Department of Informatics, SMiLe CLiNiC, University of Sussex, Brighton, UK

Abstract

When applying machine learning techniques to real-world problems, prior knowledge plays a crucial role in enriching the learning system. This prior knowledge is typically defined by domain experts and can be integrated into machine learning algorithms in a variety of ways: as a preference of certain prediction functions over others, as a Bayesian prior over parameters, or as additional information about the samples in the training set used for learning a prediction function. The latter setup is called *learning using privileged information (LUPI)* and was adopted by Vapnik and Vashist in (Neural Netw, 2009). Formally, LUPI refers to the setting when, in addition to the main data modality, the learning system has access to an extra source of information

about the training examples. The additional source of information is only available during training and therefore is called privileged. The main goal of LUPI is to utilize privileged information and to learn a better model in the main data modality than one would learn without the privileged source. As an illustration, for protein classification based on amino-acid sequences, the protein tertiary structure can be considered additional information. Another example is recognizing objects in images; the textual information in the form of image tags contains additional object descriptions and can be used as privileged.

Theory/Solution

We formalize the LUPI setup for the task of supervised binary classification with a single source of privileged information. Assume that we are given a set of N training examples, represented by feature vectors $X = \{\mathbf{x}_1, \ldots, \mathbf{x}_N\} \subset \mathcal{X} = \mathbb{R}^d$, their label annotation, $Y = \{y_1, \ldots, y_N\} \in \mathcal{Y} = \{+1, -1\}$, and additional information, also in the form of feature vectors, $X^* = \{\mathbf{x}_1^*, \ldots, \mathbf{x}_N^*\} \subset \mathcal{X}^* = \mathbb{R}^{d^*}$, where $\mathbf{x}_i^*$ encodes the additional information we have about sample $\mathbf{x}_i$. We will refer to $\mathcal{X}$ and $\mathcal{X}^*$ as the original and the privileged data spaces, respectively. For learning a binary classification function $f : \mathcal{X} \to \mathcal{Y}$ from a space of all possible functions $\mathcal{F}$, one of the well-established methods is Support Vector Machine (Editor, this is a link to another encyclopedia entry called **Support Vector Machine**.) In Vapnik and Vashist (2009), the SVM+ method was introduced as a generalization of the SVM-based framework to solve LUPI. This SVM+ formulation can be directly extended for multiple sources of privileged information and for the regression estimation problem (more details in Vapnik and Vashist 2009).

SVM+

The SVM+ optimization admits the following form:

$$\underset{\substack{\mathbf{w}\in\mathbb{R}^d, b\in\mathbb{R}\\ \mathbf{w}^*\in\mathbb{R}^{d^*}, b^*\in\mathbb{R}}}{\text{minimize}} \ \frac{1}{2}\left(\|\mathbf{w}\|^2 + \gamma\|\mathbf{w}^*\|^2\right) + C\sum_{i=1}^{N}\langle\mathbf{w}^*, \mathbf{x}_i^*\rangle + b^* \tag{1a}$$

subject to, for all $i = 1, \ldots, N$,

$$y_i[\langle\mathbf{w}, \mathbf{x}_i\rangle + b] \geq 1 - [\langle\mathbf{w}^*, \mathbf{x}_i^*\rangle + b^*] \tag{1b}$$

$$\text{and} \qquad \langle\mathbf{w}^*, \mathbf{x}_i^*\rangle + b^* \geq 0. \tag{1c}$$

The above problem is a generalization of nonlinearly separable (soft-margin) SVM in which the slack variables are parameterized with unknown $\mathbf{w}^*$ and b^*, so that the slack value for each sample is $\xi_i = \langle\mathbf{w}^*, \mathbf{x}_i^*\rangle + b^*$.

The SVM+ optimization problem can be solved in the dual representation using a standard quadratic programming (QP) solver. For a medium-sized problem (thousands to hundred thousands of samples), a general purpose QP solver might not suffice, and special purpose algorithms have to be developed to solve the QP. In Pechyony and Vapnik (2011), suitable sequential minimal optimization (SMO) algorithms were derived to tackle the problem.

Motivation of SVM+

When the number of training examples N increases, soft-margin SVM solutions are known Vapnik (1999) to converge with a rate of $\mathrm{O}\left(\frac{1}{\sqrt{N}}\right)$ to the optimal classifier in the function class $\mathcal{F}$. This is in sharp contrast to hard-margin (linearly separable) solutions that converge with a rate of $\mathrm{O}\left(\frac{1}{N}\right)$. The difference in the learning rate lies in the number of variables to be estimated from the data. In the hard-margin SVM, the weight vector $\mathbf{w}$ and bias parameter b have to be learned. For the soft-margin SVM, in addition to the weight and bias parameters, N slack variables ξ_i – one for each training sample – have to be estimated. The idea of the SVM+ classifier is based on a direct observation that the soft-margin SVM can be turned into the hard-margin SVM if one had access to a so-called *slack oracle* that knows the optimal slack value ξ_i. Since, in practice, we do not have access to the oracle, we can instead estimate the slack function using the additional privileged data.

Relation to Existing Learning Settings

Other than the LUPI framework, there are several machine learning frameworks that exploit multiple sources of information to learn the classification model, among others, domain adaptation, multi-view learning, and multimodal learning. In Table 1, we overview the commonalities and differences of those settings for two sources of information, $\mathcal{X}$ and $\mathcal{X}^*$, and binary classification task $\mathcal{Y} = \{-1, +1\}$.

Applications

The LUPI framework is of interest for practical applications because it captures the typical learning-from-data setting where domain experts are able to provide additional knowledge about the data. For instance, Vapnik and Vashist (2009) explored protein tertiary structures (geometrical shapes) as additional information when the learning task is about classifying proteins based on their secondary structures (amino-acid sequences). In the context of recognizing animal objects such as leopard, panda, or horse in images, Sharmanska et al. (2013) considered physical attributes or properties such as furry, stripes, or smelly associated with the animals to be the extra information. In the longer term, the LUPI framework might have potential applications in the medical settings. For example, in terms of machine learning-aided diagnosis technologies, results from advanced medical tests such as fMRI, CT scans, or X-ray can be used as additional knowledge to compliment routinely collected test results such as the heart rate or the pulse. In the three settings described above, *protein geometrical shapes*, *object physical attributes*, and *advanced medical tests* share the properties that they are very hard and time consuming to gather data and are expensive to provide at test time.

Current and Future Directions

LUPI is an active research area both within machine learning and in application areas such as finance (Ribeiro et al. 2010) and computer vision (Sharmanska et al. 2013; Li et al. 2014). In machine learning, there is interest in algorithms and theoretical aspects of LUPI (Pechyony and Vapnik 2011, 2010; Lapin et al. 2014) and also in adapting SVM-based LUPI to other learning settings. For the latter, LUPI was generalized to learning to rank (Sharmanska et al. 2013), clustering (Feyereisl and Aickelin 2012), metric learning (Fouad et al. 2013), and structured prediction (Feyereisl et al. 2014) and in the Bayesian nonparametric (Editor, this is a link

to another encyclopedia entry called **Bayesian nonparametric**.) setting using Gaussian Processes (Editor, this is a link to another encyclopedia entry called **Gaussian Processes**.) (Hernández-Lobato et al. 2014). To compare different types of privileged information, a recent research direction (Wang et al. 2014) explores a bias-variance decomposition (Editor, this is a link to another encyclopedia entry called **bias-variance decomposition**.) tool. The work concludes that a useful privileged information is the one that leads to a large reduction in variance with only a slight penalty in bias with respect to the model trained without privileged information.

Learning Vector Quantization

Synonyms

LVQ

Definition

Learning vector quantization (LVQ) algorithms produce prototype-based classifiers. Given a set of labeled prototype vectors, each input vector is mapped to the closest prototype, and classified according to its label. The basic LVQ learning algorithm works by iteratively moving the closest prototype toward the current input if their labels are the same, and away from the input if not. Some variants of the algorithm have been shown to approximate Bayes optimal decision borders. The algorithm was introduced by Kohonen, and being prototype-based it bears close resemblance to ▶ competitive learning and ▶ Self-Organizing Maps. The differences are that LVQ is supervised and the prototypes are not ordered (i.e., there is no neighborhood function).

Least-Squares Reinforcement Learning Methods

Michail G. Lagoudakis
Technical University of Crete, Chania, Greece

Abstract

Most algorithms for sequential decision making rely on computing or learning a value function that captures the expected long-term return of a decision at any given state. Value functions are in general complex, nonlinear functions that cannot be represented compactly as they are defined over the entire state or state-action space. Therefore, most practical algorithms rely on value function approximation methods, and the most common choice for approximation architecture is a linear architecture. Exploiting the properties of linear architectures, a number of efficient learning algorithms based on least-squares techniques have been developed. These algorithms focus on different aspects of the approximation problem and deliver diverse solutions; nevertheless they share the tendency to process data collectively (batch mode) and, in general, achieve better results compared to their counterpart algorithms based on stochastic approximation.

Definition

Least-Squares Reinforcement Learning Methods are methods that focus on the problem of reinforcement learning (learning by trial and error) using least-squares techniques (optimization techniques for deriving solutions that minimize some form of squared error measure).

Motivation and Background

Consider a Markov decision process (MDP) $(\mathcal{S}, \mathcal{A}, \mathcal{P}, \mathcal{R}, \gamma, \mathcal{D})$, where $\mathcal{S}$ is the state space, $\mathcal{A}$ is the action space, $\mathcal{P}(s'|s,a)$ is a Markovian transition model, $\mathcal{R}(s,a)$ is a reward function, $\gamma \in (0,1]$ is the discount factor, and $\mathcal{D}$ is the initial state distribution. A linear approximation architecture approximates the value function $V^\pi(s)$ or $Q^\pi(s,a)$ of a stationary (stochastic) policy $\pi(a|s)$ as a linear weighted combination of linearly independent basis functions or features ϕ:

$$\hat{V}^\pi(s;w) = \sum_{j=1}^{k} \phi_j(s) w_j = \phi(s)^\top w$$

$$\hat{Q}^\pi(s,a;w) = \sum_{j=1}^{m} \phi_j(s,a) w_j = \phi(s,a)^\top w.$$

The parameters or weights of the approximation are the coefficients w.

Let V^π and $\hat{V}^\pi$ be the exact and the approximate, respectively, state value function of a policy π, both given as column vectors of size $|\mathcal{S}|$. Define $\boldsymbol{\Phi}_V$ as the $(|\mathcal{S}| \times k)$ matrix with elements $\phi_j(s)$, where $s \in \mathcal{S}$ span the rows and $j = 1, 2, \ldots, k$ span the columns. Then, $\hat{V}^\pi$ can be expressed compactly as $\hat{V}^\pi = \boldsymbol{\Phi}_V w^\pi$. Similarly, let Q^π and $\hat{Q}^\pi$ be the exact and the approximate, respectively, state-action value function of a policy π, both given as column vectors of size $|\mathcal{S}||A|$. Define $\boldsymbol{\Phi}_Q$ as the $(|\mathcal{S}||\mathcal{A}| \times m)$ matrix with elements $\phi_j(s,a)$, where $(s,a) \in (\mathcal{S} \times \mathcal{A})$ span the rows and $j = 1, 2, \ldots, m$ span the columns. Then, $\hat{Q}^\pi$ can be expressed compactly as $\hat{Q}^\pi = \boldsymbol{\Phi}_Q w^\pi$. In addition, let $\mathcal{R}$ be a vector of size $|\mathcal{S}||\mathcal{A}|$ with entries $\mathcal{R}(s,a)$ that contains the reward function, $\mathbf{P}$ be a stochastic matrix of size $(|\mathcal{S}||\mathcal{A}| \times |\mathcal{S}|)$ that contains the transition model $(\mathbf{P}((s,a),s') = \mathcal{P}(s'|s,a))$, and $\boldsymbol{\Pi}_\pi$ be a stochastic matrix of size $(|\mathcal{S}| \times |\mathcal{S}||\mathcal{A}|)$ that describes policy π $(\boldsymbol{\Pi}_\pi(s,(s,a)) = \pi(a|s))$. The state value function V^π and the state-action value function Q^π are the solutions of the linear Bellman equations

$$\begin{aligned} V^\pi &= \mathbf{\Pi}_\pi(\mathcal{R} + \gamma \mathbf{P} V^\pi) \\ Q^\pi &= \mathcal{R} + \gamma \mathbf{P} \mathbf{\Pi}_\pi Q^\pi \end{aligned}$$

and also the fixed points of the corresponding linear Bellman operators

$$\begin{aligned} V^\pi &= T_V^\pi(V^\pi), \text{ where } T_V^\pi(x) = \mathbf{\Pi}_\pi(\mathcal{R} + \gamma \mathbf{P} x) \\ Q^\pi &= T_Q^\pi(Q^\pi), \text{ where } T_Q^\pi(x) = \mathcal{R} + \gamma \mathbf{P} \mathbf{\Pi}_\pi x. \end{aligned}$$

If V^π and Q^π were known, they could be projected orthogonally onto the space spanned by the basis functions to obtain the optimal least-squares approximation. (For simplicity of presentation, we consider only uniform least-squares criteria in this text, but generalization to weighted least-squares criteria is possible in all cases.) For the state value function, we have

$$\begin{aligned} \hat{V}^\pi &= \boldsymbol{\Phi}_V w^\pi \\ &= \boldsymbol{\Phi}_V \left(\boldsymbol{\Phi}_V^\top \boldsymbol{\Phi}_V\right)^{-1} \boldsymbol{\Phi}_V^\top V^\pi \implies w^\pi \\ &= \boldsymbol{\Phi}_V^{-1} \boldsymbol{\Phi}_V \left(\boldsymbol{\Phi}_V^\top \boldsymbol{\Phi}_V\right)^{-1} \boldsymbol{\Phi}_V^\top V^\pi, \end{aligned}$$

whereas for the state-action value function, we have

$$\begin{aligned} \hat{Q}^\pi &= \boldsymbol{\Phi}_Q w^\pi \\ &= \boldsymbol{\Phi}_Q \left(\boldsymbol{\Phi}_Q^\top \boldsymbol{\Phi}_Q\right)^{-1} \boldsymbol{\Phi}_Q^\top Q^\pi \implies w^\pi \\ &= \boldsymbol{\Phi}_Q^{-1} \boldsymbol{\Phi}_Q \left(\boldsymbol{\Phi}_Q^\top \boldsymbol{\Phi}_Q\right)^{-1} \boldsymbol{\Phi}_Q^\top Q^\pi. \end{aligned}$$

The learning algorithms described here strive to find a set of parameters w, such that the approximate value function is a good approximation to the true one. However, since the exact value functions are unknown, these algorithms have to rely on information contained in the Bellman equations and the Bellman operators to derive expressions that characterize a good choice for w. It has been shown that, in many cases, this kind of learning is equivalent to approximating the MDP using a linear (compressed) model and solving exactly the approximate model (Parr et al. 2008).

Bellman Residual Minimizing Approximation

An obvious approach to deriving a good approximation is to require that the approximate function satisfies the linear Bellman equation as closely as possible. Substituting the approximation $\hat{V}^\pi$ into the Bellman equation for V^π yields an overconstrained linear system over the k parameters w^π:

$$\begin{aligned} \hat{V}^\pi &\approx \mathbf{\Pi}_\pi \left(\mathcal{R} + \gamma \mathbf{P} \hat{V}^\pi\right) \\ \boldsymbol{\Phi}_V w^\pi &\approx \mathbf{\Pi}_\pi \left(\mathcal{R} + \gamma \mathbf{P} \boldsymbol{\Phi}_V w^\pi\right) \\ \left(\boldsymbol{\Phi}_V - \gamma \mathbf{\Pi}_\pi \mathbf{P} \boldsymbol{\Phi}_V\right) w^\pi &\approx \mathbf{\Pi}_\pi \mathcal{R}. \end{aligned}$$

Solving this overconstrained system in the least-squares sense is a $(k \times k)$ system

$$\begin{aligned} &\left(\boldsymbol{\Phi}_V - \gamma \mathbf{\Pi}_\pi \mathbf{P} \boldsymbol{\Phi}_V\right)^\top \left(\boldsymbol{\Phi}_V - \gamma \mathbf{\Pi}_\pi \mathbf{P} \boldsymbol{\Phi}_V\right) w^\pi \\ &\quad = \left(\boldsymbol{\Phi}_V - \gamma \mathbf{\Pi}_\pi \mathbf{P} \boldsymbol{\Phi}_V\right)^\top \mathbf{\Pi}_\pi \mathcal{R} \end{aligned} \tag{1}$$

whose solution is unique and minimizes $\|T_V^\pi\left(\hat{V}^\pi\right) - \hat{V}^\pi\|_2$. Similarly, substituting the approximation $\hat{Q}^\pi$ into the Bellman equation for Q^π yields an overconstrained linear system over the m parameters w^π:

$$\begin{aligned} \hat{Q}^\pi &\approx \mathcal{R} + \gamma \mathbf{P} \mathbf{\Pi}_\pi \hat{Q}^\pi \\ \boldsymbol{\Phi}_Q w^\pi &\approx \mathcal{R} + \gamma \mathbf{P} \mathbf{\Pi}_\pi \boldsymbol{\Phi}_Q w^\pi \\ \left(\boldsymbol{\Phi}_Q - \gamma \mathbf{P} \mathbf{\Pi}_\pi \boldsymbol{\Phi}_Q\right) w^\pi &\approx \mathcal{R}. \end{aligned}$$

Solving this overconstrained system in the least-squares sense is a $(m \times m)$ system

$$\begin{aligned} &\left(\boldsymbol{\Phi}_Q - \gamma \mathbf{P} \mathbf{\Pi}_\pi \boldsymbol{\Phi}_Q\right)^\top \left(\boldsymbol{\Phi}_Q - \gamma \mathbf{P} \mathbf{\Pi}_\pi \boldsymbol{\Phi}_Q\right) w^\pi \\ &\quad = \left(\boldsymbol{\Phi}_Q - \gamma \mathbf{P} \mathbf{\Pi}_\pi \boldsymbol{\Phi}_Q\right)^\top \mathcal{R} \end{aligned} \tag{2}$$

whose solution is unique and minimizes $\|T_Q^\pi\left(\hat{Q}^\pi\right) - \hat{Q}^\pi\|_2$. In both cases, the solution minimizes the L_2 norm of the Bellman residual (the difference between the left-hand side and the right-hand side of the linear Bellman equation).

Least-Squares Fixed-Point Approximation

Recall that a value function is also the fixed point of the corresponding linear Bellman operator. Another way to go about finding a good approximation is to force the approximate value function to be a fixed point under the linear Bellman operator. For that to be possible, the fixed point has to lie in the space of approximate value functions which is the space spanned by the basis functions. Even though the approximate function itself lies in that space by definition, the result of applying the linear Bellman operator to the approximation will in general be out of that space and must be projected back. Considering the orthogonal projection $\left(\boldsymbol{\Phi}(\boldsymbol{\Phi}^\top\boldsymbol{\Phi})^{-1}\boldsymbol{\Phi}^\top\right)$ (which minimizes the L_2 norm) onto the column space of $\boldsymbol{\Phi}$, we seek an approximate value function that is invariant under one application of the linear Bellman operator followed by orthogonal projection onto the space spanned by the basis functions. More specifically, for the state value function, we require that

$$\begin{aligned}\hat{V}^\pi &= \boldsymbol{\Phi}_V\left(\boldsymbol{\Phi}_V^\top\boldsymbol{\Phi}_V\right)^{-1}\boldsymbol{\Phi}_V^\top\left(T_V^\pi(\hat{V}^\pi)\right)\\ \boldsymbol{\Phi}_V w^\pi &= \boldsymbol{\Phi}_V\left(\boldsymbol{\Phi}_V^\top\boldsymbol{\Phi}_V\right)^{-1}\\ &\qquad\boldsymbol{\Phi}_V^\top\left(\boldsymbol{\Pi}_\pi(\mathcal{R}+\gamma\mathbf{P}\boldsymbol{\Phi}_V w^\pi)\right).\end{aligned}$$

Note that the orthogonal projection to the column space of $\boldsymbol{\Phi}_V$ is well defined, because the columns of $\boldsymbol{\Phi}_V$ (the basis functions) are linearly independent by definition. The expression above is equivalent to solving a $(k \times k)$ linear system

$$\boldsymbol{\Phi}_V^\top(\boldsymbol{\Phi}_V - \gamma\boldsymbol{\Pi}_\pi\mathbf{P}\boldsymbol{\Phi}_V)w^\pi = \boldsymbol{\Phi}_V^\top\boldsymbol{\Pi}_\pi\mathcal{R} \qquad (3)$$

whose solution is guaranteed to exist for all, but finitely many, values of γ (Koller and Parr 2000) and minimizes (in fact, zeros out) the projected Bellman residual. Since the orthogonal projection minimizes the L_2 norm, the solution w^π yields a value function $\hat{V}^\pi$ which is the least-squares fixed-point approximation to the true state value function. Similarly, for the state-action value function, we require that

$$\begin{aligned}\hat{Q}^\pi &= \boldsymbol{\Phi}_Q\left(\boldsymbol{\Phi}_Q^\top\boldsymbol{\Phi}_Q\right)^{-1}\boldsymbol{\Phi}_Q^\top\left(T_Q^\pi(\hat{Q}^\pi)\right)\\ \boldsymbol{\Phi}_Q w^\pi &= \boldsymbol{\Phi}_Q\left(\boldsymbol{\Phi}_Q^\top\boldsymbol{\Phi}_Q\right)^{-1}\\ &\qquad\boldsymbol{\Phi}_Q^\top\left(\mathcal{R}+\gamma\mathbf{P}\boldsymbol{\Pi}_\pi\boldsymbol{\Phi}_Q w^\pi\right).\end{aligned}$$

This is equivalent to solving a $(m \times m)$ linear system

$$\boldsymbol{\Phi}_Q^\top\left(\boldsymbol{\Phi}_Q - \gamma\mathbf{P}\boldsymbol{\Pi}_\pi\boldsymbol{\Phi}_Q\right)w^\pi = \boldsymbol{\Phi}_Q^\top\mathcal{R} \qquad (4)$$

whose solution is again guaranteed to exist for all, but finitely many, values of γ (Koller and Parr 2000) and minimizes (in fact, zeros out) the projected Bellman residual. Since the orthogonal projection minimizes the L_2 norm, the solution w^π yields a value function $\hat{Q}^\pi$ which is the least-squares fixed-point approximation to the true state-action value function.

Structure of Learning System

Least-Squares Temporal Difference Learning

The least-squares temporal difference (LSTD) learning algorithm (Bradtke and Barto 1996) learns the least-squares fixed-point approximation to the state value function V^π of a fixed policy π. In essence, LSTD attempts to form and solve the linear system of Eq. 3 using sampling. Each sample (s, r, s') indicates a minimal interaction with the unknown process, whereby in some state s, a decision was made using policy π, and reward r was observed, as well as a transition to state s'. LSTD processes a set of samples collectively to derive the weights of the approximate value function. LSTD is an on-policy method; it requires that all training samples are collected using the policy under evaluation. The LSTD algorithm is summarized in Algorithm 1.

LSTD improves upon the temporal difference (TD) learning algorithm for linear architectures by making efficient use of data and converging

Algorithm 1 Least-squares temporal difference (LSTD)

```
$w = \textbf{LSTD}(D, k, \phi, \gamma)$
  Input: samples $D$, integer $k$, basis functions $\phi$, discount factor $\gamma$
  Output: weights $w$ of the learned state value function

  $\mathbf{A} \leftarrow \mathbf{0}$          // $(k \times k)$ matrix
  $b \leftarrow \mathbf{0}$          // $(k \times 1)$ vector
  for each sample $(s, r, s') \in D$ do
    $\mathbf{A} \leftarrow \mathbf{A} + \phi(s)\Big(\phi(s) - \gamma\phi(s')\Big)^\top$
    $b \leftarrow b + \phi(s)r$
  end for
  $w \leftarrow \mathbf{A}^{-1}b$
  return $w$
```

Algorithm 2 Bellman residual minimization learning (BRML)

```
$w = \textbf{BRML}(D, k, \phi, \gamma)$
  Input: paired samples $D$, integer $k$, basis functions $\phi$, discount factor $\gamma$
  Output: weights $w$ of the learned state value function

  $\mathbf{A} \leftarrow \mathbf{0}$          // $(k \times k)$ matrix
  $b \leftarrow \mathbf{0}$          // $(k \times 1)$ vector
  for each pair of samples $[(s, r, s'), (s, r, s'')] \in D$ do
    $\mathbf{A} \leftarrow \mathbf{A} + \Big(\phi(s) - \gamma\phi(s')\Big)\Big(\phi(s) - \gamma\phi(s'')\Big)^\top$
    $b \leftarrow b + \Big(\phi(s) - \gamma\phi(s')\Big)r$
  end for
  $w \leftarrow \mathbf{A}^{-1}b$
  return $w$
```

faster. The main advantage of LSTD over TD is the elimination of the slow stochastic approximation and the learning rate that needs careful adjustment. TD uses samples to make small modifications and then discards them. In contrast, with LSTD, the information gathered from a single sample remains present in the matrices of the linear system and is used in full every time the parameters are computed. In addition, as a consequence of the elimination of stochastic approximation, LSTD does not diverge.

LSTD(λ) (Boyan 1999) is an extension to LSTD that spans the spectrum between LSTD ($\lambda = 0$) and linear regression over Monte Carlo returns ($\lambda = 1$) for $\lambda \in [0, 1]$. LSTD(λ) for $\lambda > 0$ requires that samples come from complete episodes. RLSTD(λ) is a variant of LSTD(λ) that uses recursive least-squares techniques for efficient implementation (Xu et al. 2002).

Bellman Residual Minimization Learning

The main idea behind LSTD can also be used to learn the Bellman residual minimizing approximation to the state value function V^π of a fixedpolicy π. In this case, the goal is to form and solve the linear system of Eq. 1 using sampling. However, the structure of the system, in this case, requires that samples are "paired," which means that two independent samples (s, r, s') and (s, r, s'') for the same state s must be drawn to perform one update. This is necessary to obtain unbiased estimates of the system matrices. Each sample (s, r, s') again indicates a minimal interaction with the unknown process, whereby in some state s, a decision was made using policy π, and reward r was observed, as well as a transition to state s'. Obtaining paired samples is trivial with a generative model (a simulator) of the process, but virtually impossible when samples are drawn directly from a physical process. This fact makes the Bellman residual minimizing approximation somewhat impractical for learning, but otherwise a reasonable approach for computing approximate state value functions from the model of the process (Schweitzer and Seidmann 1985). The learning algorithm for Bellman residual minimization is summarized in Algorithm 2.

Hybrid Least-Squares Learning

Value function learning algorithms, either in the Bellman residual minimization or in the fixed-point sense, have been used within approximate policy iteration schemes for policy learning, but in practice, they exhibit quite diverse performance. Fixed-point approximations tend to deliver better policies, whereas Bellman residual minimizing approximations fluctuate less between different rounds of policy iteration. Motivated by a desire to combine the advantages of both approximations, some researchers have focused on learning hybrid approximations that lie somewhere between these two extremes. Johns et al. (2009) have proposed two different approaches to combining these two approximations. The first relies on a derivation that begins with the goal of minimizing a convex combination of the two objectives (Bellman residual and projected Bellman residual); the resulting learning algorithm is quite expensive as it requires the maintenance of three matrices and two vectors (as opposed to one matrix and one vector when learning a non-hybrid approximation), as well as the inversion of one of the three matrices at each update. The second approach focuses directly on a convex combination of the linear systems produced by the two extreme approximations (Eqs. 1 and 3); the resulting learning algorithm has the same complexity as non-hybrid algorithms and in many cases exhibits better performance than the original approximations. On the other hand, both hybrid learning algorithms still have to deal with the paired samples problem and additionally require tuning of the convex combination parameter.

Least-Squares Policy Evaluation

The least-squares policy evaluation (LSPE) learning algorithm (Nedić and Bertsekas 2003), like LSTD, learns the least-squares fixed-point approximation to the state value function V^{π} of a fixed policy π. Both LSPE and LSTD strive to obtain the solution to the same linear system (Eq. 3) but using different methods; LSPE uses an iterative method, whereas LSTD uses direct matrix inversion. Unlike LSTD, LSPE begins with some arbitrary approximation to the value function (given by a parameter vector w') and focuses on the one-step application of the Bellman operator within the lower-dimensional space spanned by the basis functions aiming at producing an incremental improvement on the parameters. In that sense, LSPE can take advantage of a good initialization of the parameter vector. Given the current parameters w' and a set $\{(s_k, r_k, s'_k) : k = 0, \ldots, t\}$ of samples, LSPE first computes the solution $\bar{w}$ to the least-squares problem

$$\min_{w} \sum_{k=0}^{t} \Big(\phi(s_k)^{\top} w - \big(r_k + \gamma \phi(s'_k)^{\top} w'\big)\Big)^2$$

Algorithm 3 Least-squares policy evaluation (LSPE)

```
$w = \mathbf{LSPE}(D, k, \phi, \gamma, w', \alpha)$
  Input: samples $D$, integer $k$, features $\phi$, discount factor $\gamma$, weights $w'$, stepsize $\alpha$
  Output: weights $w$ of the learned state value function

  $\mathbf{A} \leftarrow \mathbf{0}$            // $(k \times k)$ matrix
  $b \leftarrow \mathbf{0}$             // $(k \times 1)$ vector
  for each sample $(s, r, s') \in D$ do
      $\mathbf{A} \leftarrow \mathbf{A} + \phi(s)\phi(s)^{\top}$
      $b \leftarrow b + \phi(s)\big(r + \gamma\phi(s')^{\top} w'\big)$
  end for
  $\bar{w} \leftarrow \mathbf{A}^{-1} b$
  $w \leftarrow \alpha w' + (1 - \alpha)\bar{w}$
  return $w$
```

and then updates w' toward $\bar{w}$ using a stepsize $\alpha \in (0, 1]$. The LSPE algorithm is summarized in Algorithm 3.

The LSPE incremental update at the extreme can be performed whenever a new sample arrives or whenever a batch of samples becomes available to remedy computational costs. An efficiency improvement to LSPE is to use recursive least-squares computations, so that the least-squares problem can be solved without matrix inversion. LSPE(λ) for $\lambda \in [0, 1]$ is an extension of LSPE to multistep updates in the same spirit as LSTD(λ). LSPE(λ) for $\lambda > 0$ requires that samples come from complete episodes.

Least-Squares Policy Iteration

Least-squares policy iteration (LSPI) (Lagoudakis and Parr 2003) is a model-free, reinforcement learning algorithm for policy learning based on the approximate policy iteration framework. LSPI learns in a batch manner by processing multiple times the same set of samples. LSPI is an off-policy method; samples can be collected arbitrarily from the process using any policy. Each sample (s, a, r, s') indicates that the learner observed the current state s, chose an action a, and observed the resulting next state s' and the reward received r. LSPI iteratively learns a (weighted) least-squares fixed-point approximation of the state-action value functions (Eq. 4) of a sequence of improving (deterministic) policies π. At each iteration, the

Algorithm 4 Least-squares policy iteration (LSPI)

```
$w$ = LSPI($D, m, \phi, \gamma, \epsilon$)
  Input: samples $D$, integer $m$, basis functions $\phi$, discount factor $\gamma$, tolerance $\epsilon$
  Output: weights $w$ of the learned value function of the best learned policy

  $w \leftarrow \mathbf{0}$
  repeat
    $\mathbf{A} \leftarrow \mathbf{0}$        // $(m \times m)$ matrix
    $b \leftarrow \mathbf{0}$         // $(m \times 1)$ vector
    $w' \leftarrow w$
    for each sample $(s, a, r, s')$ in $D$ do
      $a' = \arg\max_{a'' \in \mathcal{A}} \phi(s', a'')^\top w'$
      $\mathbf{A} \leftarrow \mathbf{A} + \phi(s, a)\Big(\phi(s, a) - \gamma\phi(s', a')\Big)^\top$
      $b \leftarrow b + \phi(s, a)r$
    end for
    $w \leftarrow \mathbf{A}^{-1}b$
  until $(\|w - w'\| < \epsilon)$
  return $w$
```

Algorithm 5 Least-squares fitted Q-iteration

```
$w$ = LS-FQI($D, m, \phi, \gamma, N$)
  Input: samples $D$, integer $m$, basis functions $\phi$, discount factor $\gamma$, iterations $N$
  Output: weights $w$ of the learned value function of the best learned policy

  $i \leftarrow 0$
  $w \leftarrow \mathbf{0}$
  while $(i < N)$ do
    $\mathbf{A} \leftarrow \mathbf{0}$        // $(m \times m)$ matrix
    $b \leftarrow \mathbf{0}$         // $(m \times 1)$ vector
    for each sample $(s, a, r, s')$ in $D$ do
      $\mathbf{A} \leftarrow \mathbf{A} + \phi(s, a)\phi(s, a)^\top$
      $b \leftarrow b + \phi(s, a)\Big(r + \gamma \max_{a' \in \mathcal{A}}$
        $\{\phi(s', a')^\top w\}\Big)$
    end for
    $w \leftarrow \mathbf{A}^{-1}b$
    $i \leftarrow i + 1$
  end while
  return $w$
```

value function of the policy is approximated by solving a $(m \times m)$ linear system, formed using the single sample set and the policy from the previous iteration. LSPI offers a non-divergence guarantee, and in most cases, it converges in just a few iterations. LSPI exhibits excellent sample efficiency and has been used widely in many domains. Algorithm 4 summarizes LSPI.

The default internal policy evaluation procedure in LSPI is the variation of LSTD for the state-action value function (LSTDQ). However, any other value function learning algorithm, such as BRML or LSPE, could be used instead; nevertheless, the λ extensions are not applicable in this case, because the samples in LSPI have been collected arbitrarily and not by the policy being evaluated each time. The variation of LSPI that internally learns the Bellman residual minimizing approximation (Eq. 2) using BRML has produced inferior policies, in general, and suffers from the paired samples problem.

Least-Squares Fitted Q-Iteration

Fitted Q-iteration (FQI) (Ernst et al. 2005) is a batch reinforcement learning algorithm for policy learning based on the popular Q-learning algorithm. FQI uses an iterative scheme to approximate the optimal value function, whereby an improved value function Q is learned at each iteration by fitting a function approximator to a set of training examples generated using a set of samples from the process and the Q-learning update rule. Any function approximation architecture and the corresponding supervised learning algorithm could be used in the iteration. The simplest choice is to use least-squares regression along with a linear architecture to learn the least-squares fixed-point approximation of the state-action value function (Eq. 4). This version of least-squares fitted Q-iteration is summarized in Algorithm 5. In a sense, this version of FQI combines ideas from LSPE and LSPI. Like LSPI, FQI is an off-policy method; samples can be collected arbitrarily from the process using any policy. In practice, FQI produces very good policies within a moderate number of iterations.

Lift

Lift is a measure of the relative utility of a ▶ classification rule. It is calculated by dividing the probability of the consequent of the rule, given its antecedent by the prior probability of the consequent:

$$\text{lift}(x \to y) = P(Y = y|X = x)/P(Y = y).$$

In practice, the probabilities are usually estimated from either ▸ training data or ▸ test data. In this case,

$$\text{lift}(x \to y) = F(Y = y|X = x)/F(Y = y).$$

where $F(Y = y|X = x)$ is the frequency with which the consequent occurs in the data in the context of the antecedent and F($Y = y$) is the frequency of the consequent in the data.

Linear Discriminant

Definition

A discriminant is a function that takes an input variable x and outputs a class label y for it. A linear discriminant is a discriminant that uses a linear function of the input variables and more generally a linear function of some vector function of the input variables $f(x)$.

This entry focuses on one such linear discriminant function called Fisher's linear discriminant. Fisher's discriminant works by finding a projection of input variables to a lower dimensional space while maintaining a class separability property.

Motivation and Background

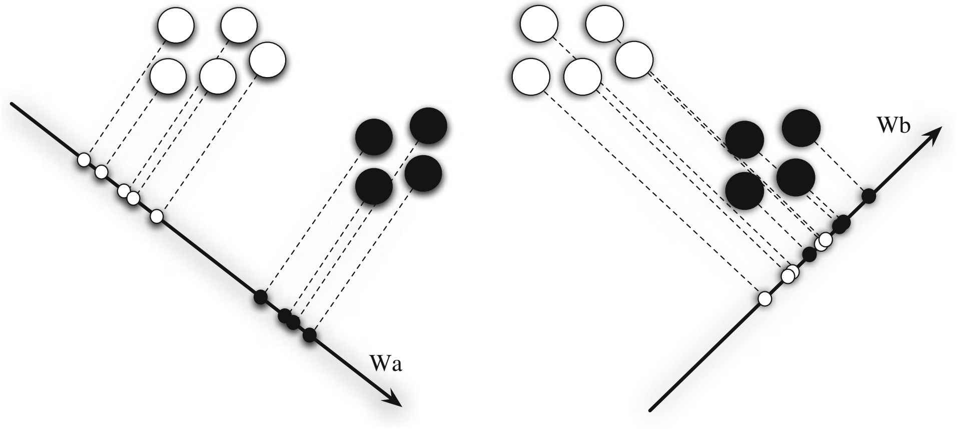
The curse of dimensionality (▸ Curse of Dimensionality) is an ongoing problem in applying statistical techniques to pattern recognition problems. Techniques that are computationally tractable in low-dimensional spaces can become completely impractical in high-dimensional spaces. Consequently, various methods have been proposed to reduce the dimensionality of the input or feature space in the hope of obtaining a more manageable problem. This relies on the fact that real data will often be confined to a region of the space having lower effective dimensionality, and in particular the directions over which important variations in the output variables occur may be so confined. For example, we can reduce a d-dimensional problem to one dimension if we project the d-dimensional data onto a line. However, arbitrary projections will usually produce cluttered projected samples from all of the classes. Thus, the aim is to find a good projection so that the projected samples are well separated. This is exactly the goal of Fisher's linear discriminant analysis.

Fisher's Discriminant for Two-Category Problem

Given N observed training data points $\{(x_i, y_i)\}_{i=1}^N$ where $y_i \in \{1, \ldots, \Omega\}$ is the label for an input variable $x_i \in \mathbb{R}^d$, our task is to find the underlying discriminant function, $f : \mathbb{R}^d \to \{1, \ldots, \Omega\}$. The linear discriminant seeks a projection of d-dimensional input onto a line in the direction of $w \in \mathbb{R}^d$, such that

$$f(x) = w^T x. \quad (1)$$

Subsequently, a class label y can be assigned by thresholding the projected values, for example, for $f(x) \geq C$ we assign $y = 1$ and otherwise we assign $y = 2$ for an appropriate choice of constant C. While the magnitude of w has no real significance (acts only as a scaling factor to y), the direction of w plays a crucial role.



Linear Discriminant, Fig. 1 Black and white encode class labels. Projection of samples onto two different lines. The *plot* on the left shows greater separation between the *white* and *black projected points*

Inappropriate choice of w can result in a non-informative heavily cluttered line. However, by adjusting the components of weight w, we can find a projection that maximizes the class separability (Fig. 1). It is crucial to note that whenever the underlying data distributions are multimodal and highly overlapping, it might not be possible to find such a projection.

Consider a two-category problem, a class label Ω_1 and a class label Ω_2 with N_1 and N_2 number of data points, respectively. The d-dimensional per-class sample mean is given by

$$\mu_1 = \frac{1}{N_1}\sum_{i\in\Omega_1} x_i \qquad \mu_2 = \frac{1}{N_2}\sum_{i\in\Omega_2} x_i. \tag{2}$$

The simplest class separability criterion is the separation of the projected class mean, that is, we can find the weight vector w that maximizes

$$\begin{aligned} m_2 - m_1 &= \frac{1}{N_2}\sum_{i\in\Omega_2} w^T x_i - \frac{1}{N_1}\sum_{i\in\Omega_1} w^T x_i \\ &= w^T(\mu_2 - \mu_1), \end{aligned} \tag{3}$$

where m_1 and m_2 are the projected class means. An additional unit length constraint on w, i.e., $\sum_i w_i^2 = 1$ should be imposed to have a well-defined maximization problem. The above separability criterion produces a line that is parallel to the line joining the two means. However, this projection is suboptimal whenever the data has distinct covariances depending on class (i.e., it is un-isotropic).

Fisher's criterion maximizes a large separation between the projected class means *while simultaneously* minimizing a variance within each class. This criterion can be expressed as

$$J(w) = \frac{w^T S_B w}{w^T S_W w}. \tag{4}$$

where the total within-class covariance matrix is

$$\begin{aligned} S_W &= \sum_{i\in\Omega_1} (x_i - \mu_1)(x_i - \mu_1)^T \\ &\quad + \sum_{i\in\Omega_2} (x_i - \mu_2)(x_i - \mu_2)^T , \end{aligned} \tag{5}$$

and a between-class covariance matrix is

$$S_B = (\mu_2 - \mu_1)(\mu_2 - \mu_1)^T . \tag{6}$$

The maximizer of (4) can be found by setting its first derivative with respect to the weights vector to zero, that is,

$$(w^T S_B w) S_W w = (w^T S_W w) S_B w. \tag{7}$$

It is clear from (6), that $S_B w$ admits the direction of $(\mu_2 - \mu_1)$ (Bishop 2006). As only the direction of w is important, we can drop the scaling factors in (7), those are $(w^T S_B w)$ and $(w^T S_W w)$. Multiplying both sides of (7) by S_W^{-1}, we can then obtain the solution of w that maximizes (4) as

$$w = S_W^{-1}(\mu_2 - \mu_1). \tag{8}$$

Fisher's Discriminant for Multi-category Problem

For the general Ω-class problem, we seek a projection from d-dimensional space to a $(\Omega-1)$-dimensional space which is accomplished by $\Omega - 1$ linear discriminant functions, that is,

$$f_c(x) = w_c^T x \qquad c = 1, \ldots, \Omega - 1. \tag{9}$$

In the matrix notation, $f(x) = W^T x$ for $W \in \mathbb{R}^{d\times(\Omega-1)}$ and $f(x) \in \mathbb{R}^{(\Omega-1)}$. The generalization of the within-class covariance matrix in (5) to the case of Ω classes is simply the total within-class covariance matrix over Ω classes, that is $S_W = \sum_{c=1}^{\Omega} S_c$ with $S_c = \sum_{i\in c}(x_i - \mu_c)(x_i - \mu_c)^T$. Following Duda and Hart (1973) and Bishop (2006), the between-class covariance matrix S_B is defined as substracting the within-class covariance matrix from the so-called total covariance matrix, $\sum_{i=1}^{N}(x_i - \mu)(x_i - \mu)^T$ with μ denoting the total sample mean of the dataset. One of the criteria to be optimized is (Fukunaga 1990)

$$J(w) = \mathrm{Trace}((W^T S_W W)^{-1}(W^T S_B W)). \tag{10}$$

The maximizer of (10) is eigenvectors of $S_W^{-1} S_B$ associated with $\Omega - 1$ largest eigenvalues. It is important to note that the between-class covariance matrix S_B is the sum of Ω matrices of rank one or less, and because only $\Omega - 1$ of these matrices are independent, S_B has rank at most equal to $\Omega - 1$ and so there are at most $\Omega - 1$ nonzero eigenvalues. Therefore, we are unable to find more than $\Omega - 1$ discriminant functions (see, e.g., Bishop 2006).

Definition

Linear regression is an instance of the ▶ Regression problem which is an approach to modeling a functional relationship between input variables x and an output/response variable y. In linear regression, a linear function of the input variables is used, and more generally a linear function of some vector function of the input variables $\boldsymbol{\phi}(x)$ can also be used. The linear function estimates the mean of y (or more generally the median or a quantile).

Motivation and Background

Assume we are given a set of data points sampled from an underlying but unknown distribution, each of which includes input x and output

y. The task of regression is to learn a hidden functional relationship between x and y from observed and possibly noisy data points, so y is to be approximated in some way by $f(x)$. This is the task covered in more detail in Regression. A general approach to the problem is to make the function $f()$ be linear. Depending on the optimization criteria used to fit between the linear function $f(x)$ and the output y, this can include many different regression techniques, but optimization is generally easier because of the linearity.

Theory/Solution

Formally, in a regression problem, we are interested in recovering a functional dependency $y_i = f(x_i) + \epsilon_i$ from N observed training data points $\{(x_i, y_i)\}_{i=1}^N$, where $y_i \in \mathbb{R}$ is the noisy observed output at input location $x_i \in \mathbb{R}^d$. For the linear parametric technique, we tackle this regression problem by parameterizing the latent regression function $f()$ by a parameter $w \in \mathbb{R}^H$, that is, $f(x_i) := \langle \phi(x_i), w \rangle$ for H fixed basis functions $\{\phi_h(x_i)\}_{h=1}^H$. Note that the function is a linear function of the weight vector w. The simplest form of the linear parametric model is when $\phi(x_i) = x_i \in \mathbb{R}^d$, that is, the model is also linear with respect to the input variables, $f(x_i) := w_0 + w_1 x_i^1 + \cdots + w_d x_i^d$. Here the weight w_0 allows for any constant offset in the data. With general basis functions such as polynomials, exponentials, sigmoids, or even more sophisticated Fourier or wavelets bases, we can obtain a regression function which is nonlinear with respect to the input variables although still linear with respect to the parameters.

In the subsequent section, the simplest and thus common linear parametric method for solving a regression problem is covered, the least squares method.

Least Squares Method

Let $X \in \mathbb{R}^{N \times d}$ be a matrix of input variables and $y \in \mathbb{R}^N$ be a vector of output variables. The least squares method minimizes the following sum of squared error:

$$E(w) = (Xw - y)^T (Xw - y) \tag{1}$$

to infer the weight vector w. Note that the above error function is quadratic in the w, thus the minimization has a unique solution and leads to a closed-form expression for the estimated value of the unknown weight vector w. The minimizer of the error function in (1) can be found by setting its first derivative with respect to the weight vector to zero, that is,

$$\partial_w E(w) = 2X^T (Xw - y) = 0 \tag{2}$$

$$w^* = (X^T X)^{-1} X^T y. \tag{3}$$

The term

$$(X^T X)^{-1} X^T := X^\dagger \tag{4}$$

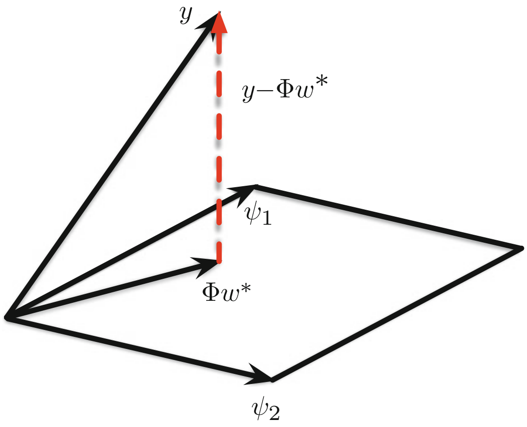
is known as the Moore-Penrose pseudo-inverse (Golub and Van Loan 1996) of the matrix X. This quantity can be regarded as a generalization of a matrix inverse to nonsquare matrices. Whenever X is square and invertible, $X^\dagger \equiv X^{-1}$. Having computed the optimal weight vector, we can then predict the output value at a novel input location x_{new} simply by taking an inner product: $y_{\text{new}} = \langle \phi(x_{\text{new}}), w^* \rangle$.

Under the assumption of an independent and normally distributed noise term, $\epsilon_i \sim \mathcal{N}(0, \sigma^2)$, the above least squares approach can be shown to be equivalent to the maximum likelihood solution. With the Gaussian noise term, the log-likelihood model on an output vector y and an input matrix X is

$$\ln p(y|X, w) = \ln \mathcal{N}(Xw, \sigma^2 I) \tag{5}$$

$$= -\frac{N}{2} \ln(2\pi\sigma^2) - \frac{1}{2\sigma^2} (y - Xw)^T (y - Xw). \tag{6}$$

Maximizing the above likelihood function with respect to w will give the optimal weight to be in the form of (3). We can also find the maximum likelihood estimate of the noise variance by setting the first derivative of (6) with respect to σ^2 to zero, that is,



Linear Regression, Fig. 1 Geometrical interpretation of least squares (Bishop 2006). The optimal solution w^* with respect to the least squares criterion corresponds to the orthogonal projection of y onto the linear subspace which is formed by the vectors of the basis functions

$$\sigma^2_{\text{ML}} = \frac{1}{N}(y - Xw)^T(y - Xw). \tag{7}$$

Geometrical Interpretation of Least Squares Method

Let y be a vector in an N-dimensional space whose axes are given by $\{y_i\}_{i=1}^N$. Each of the H basis functions evaluated at N input locations can also be represented as a vector in the same N-dimensional space. For notational convenience, we denote this vector as ψ_h. The H vectors ψ_h will span a linear subspace of dimensionality H whenever the number of basis functions H is smaller than the number of input locations N (see Fig. 1). Denote $\Phi \in \mathbb{R}^{N\times H}$ as a matrix whose rows are the vectors $\{\phi_h(x_i)\}_{h=1}^H$. Our linear prediction model, Φw (in the simplest form Xw) will be an arbitrary linear combination of the vectors ψ_h. Thus, it can lie anywhere in the H-dimensional space. The sum of squared error criterion in (1) then corresponds to the squared Euclidean distance between Φw and y. Therefore, the least squares solution of w corresponds to the orthogonal projection of y onto the linear subspace. This orthogonal projection is associated with the minimum of the squared Euclidean distance. As a side note, from Fig. 1, it is clear that the vector $y - \Phi w$ is normal (perpendicular) to the range of Φ; thus $\Phi^T\Phi w = \Phi^T y$ is called the normal equation associated with the least squares problem.

Practical Note

The computation of (3) requires an inversion of an H by H matrix $\Phi^T\Phi$ (or a d by d matrix X^TX). A direct inversion of this matrix might lead to numerical difficulties when two or more basis vectors ψ_h or input dimensions are (nearly) collinear. This problem can be addressed conveniently by using singular value decomposition (SVD) (Press et al. 1992). It is important to note that adding a regularization term (see also the later section on ridge regression) ensures the nonsingularity of $\Phi^T\Phi$ matrix, even in the presence of degeneracies.

Sequential Learning of Least Squares Method

Computation of the optimal weight vector in (3) involves the whole training set comprising N data points. This learning technique is known as a batch algorithm. Real datasets can however involve large numbers of data points which might make batch techniques computationally prohibitive. In contrast, sequential algorithms or online algorithms process one data point at a time and can be more suited to handle large datasets.

We can use a sequential algorithm called stochastic gradient descent for learning the optimal weight vector. The objective function of (1) can be decomposed into $\sum_{i=1}^N(\langle x_i, w\rangle - y_i)^2$. This transformation suggests a simple stochastic gradient descent procedure: we traverse the data point i and update the weight vector using

$$w^{t+1} \leftarrow w^t - 2\eta(\langle x_i, w^t\rangle - y_i)x_i, \tag{8}$$

This algorithm is known as least mean squares (LMS) algorithm. In the above equation, t denotes the iteration number, and η denotes the learning rate. The value of η needs to be chosen carefully to ensure the convergence of the algorithm.

Regularized/Penalized Least Squares Method

The issue of over-fitting as mentioned in Regression is usually addressed by introducing a regularization or penalty term to the objective function. The regularized objective function is now in the form of

$$E_{\text{reg}} = E(w) + \lambda R(w). \tag{9}$$

Here $E(w)$ measures the quality (such as least squares quality) of the solution on the observed data points, $R(w)$ penalizes complex solutions, and λ is called the regularization parameter which controls the relative importance between the two. This regularized formulation is sometimes called *coefficient shrinkage* as it shrinks coefficients/weights toward zero (cf. *coefficient subset selection* formulation where the best k out of H basis functions are greedily selected). Two simple penalty terms $R(w)$ are given next, but more generally measures of curvature can also be used to penalize non-smooth functions.

Ridge Regression

The regularization term is in the form of

$$R(w) = \sum_{d=1}^{D} w_d^2. \tag{10}$$

Considering $E(w)$ to be in the form of (1), the regularized least squares quality function is now

$$(Xw - y)^T(Xw - y) + \lambda w^T w. \tag{11}$$

Since the additional term is a quadratic of w, the regularized objective function is still quadratic in w, thus the optimal solution is unique and can be found in closed form. As before, setting the first derivative of (11) with respect to w to zero, the optimal weight vector is in the form of

$$\partial_w E_{\text{reg}}(w) = 2X^T(Xw - y) + 2\lambda w = 0 \tag{12}$$

$$w^* = (X^T X + \lambda I)^{-1} X^T y. \tag{13}$$

The effect of the regularization term is to put a small weight for those basis functions which are useful only in a minor way as the penalty for small weights is very small.

Lasso Regression

The regularization term is in the form of

$$R(w) = \sum_{d=1}^{D} |w_d|. \tag{14}$$

In contrast to ridge regression, lasso regression (Tibshirani 1996) has no closed-form solution. In fact, the non-differentiability of the regularization term has produced many approaches. Most of the methods involve quadratic programming and recently coordinate-wise descent algorithms for large lasso problems (Friedman et al. 2007). Lasso regression leads to sparsity in w, that is, only a subset of w is nonzero, so irrelevant basis functions will be ignored.

Link analysis; Network analysis

Definition

Many domains of interest today are best described as a linked collection of interrelated objects. Datasets describing these domains may describe homogeneous networks, in which there is a single-object type and link type, or richer, heterogeneous networks, in which there may be multiple object and link types (and possibly other semantic information). Examples of homogeneous networks include social networks, such as people connected by friendship links, or the WWW, a collection of linked web pages. Examples of heterogeneous networks include those in medical domains describing patients, diseases, treatments and contacts, or bibliographic domains describing publications, authors, and venues. *Link mining* refers to data mining techniques that explicitly consider these links when building predictive or descriptive models of the linked data. Commonly addressed link mining tasks include collective classification, object ranking, group detection, link prediction, and subgraph discovery. Additional important components include entity resolution, and other data cleaning and data mapping operations.

Motivation and Background

"Links," or more generically "relationships," among data instances are ubiquitous. These links often exhibit patterns that can indicate properties of the data instances such as the importance, rank, or category of the instances. In some cases, not all links will be observed; therefore, we may be interested in predicting the existence of links between instances. Or, we may be interested in identifying unusual or anomalous links. In other domains, where the links are evolving over time, our goal may be to predict whether a link will exist in the future, given the previously observed links. By taking links into account, more complex patterns may be discernable as well. This observation leads to other challenges focused on discovering substructures, such as communities, groups, or common subgraphs. In addition, links can also help in the process of ► entity resolution, or figuring out when two instance references refer to the same underlying entity.

Link mining is a newly emerging research area that is at the intersection of the work in link analysis (Feldman 2002; Jensen and Goldberg 1998) hypertext and web mining (Chakrabarti 2002), ► relational learning and ► inductive logic programming (Raedt 2008), and ► graph mining (Cook and Holder 2000). We use the term link mining to put a special emphasis on the links – moving them up to first-class citizens in the data analysis endeavor.

Theory/Solution

Traditional data mining algorithms such as ▶ association rule mining, market basket analysis, and cluster analysis commonly attempt to find patterns in a dataset characterized by a collection of independent instances of a single relation. This is consistent with the classical statistical inference problem of trying to identify a model given an independent, identically distributed (IID) sample. One can think of this process as learning a model for the node attributes of a homogeneous graph while ignoring the links between the nodes.

A key emerging challenge for data mining is tackling the problem of mining richly structured, heterogeneous datasets. These kinds of datasets are commonly described as networks or graphs. The domains often consist of a variety of object types; the objects can be linked in a variety of ways. Thus, the graph may have different node and edge (or hyperedge) types. Naively applying traditional statistical inference procedures, which assume that instances are independent, can lead to inappropriate conclusions about the data (Jensen 1999). Care must be taken that potential correlations due to links are handled appropriately. In fact, object linkage is knowledge that should be exploited. This information can be used to improve the predictive accuracy of the learned models: attributes of linked objects are often correlated, and links are more likely to exist between objects that have some commonality. In addition, the graph structure itself may be an important element to include in the model. Structural properties such as degree and connectivity can be important indicators.

Data Representation

While data representation and feature selection are significant issues for traditional machine learning algorithms, data representation for linked data is even more complex. Consider a simple example from Singh et al. (2005) of a social network describing actors and their participation in events. Such social networks are commonly called *affiliation networks* (Wasserman and Faust 1994), and are easily represented by three tables representing the actors, the events, and the participation relationships. Even this simple structure can be represented as several distinct graphs. The most natural representation is a bipartite graph, with a set of actor nodes, a set of event nodes, and edges that represent an actor's participation in an event. Other representations may enable different insights and analysis. For example, we may construct a network in which the actors are nodes and edges correspond to actors who have participated in an event together. This representation allows us to perform a more actor-centric analysis. Alternatively, we may represent these relations as a graph in which the events are nodes, and events are linked if they have an actor in common. This representation may allow us to more easily see connections between events.

This flexibility in the representation of a graph arises from a basic graph representation duality. This duality is illustrated by the following simple example: Consider a data set represented as a simple $G = (\mathbf{0}, \mathbf{L})$, where $\mathbf{0}$ is the set of objects (i.e., the nodes or vertices) and $\mathbf{L}$ is the set of links (i.e., the edges or hyperedges). The graph $G(\mathbf{0}, \mathbf{L})$ can be transformed into a new graph $G'(\mathbf{0}', \mathbf{L}')$, in which the links l_i, l_j in G are objects in G' and there exists an link between $o_i, o_j \in \mathbf{0}'$ if and only if l_i and l_j share an object in G. This basic graph duality illustrates one kind of simple data representation transformation. For graphs with multiple node and edge types, the number of possible transformations becomes immense. Typically, these reformulations are not considered as part of the link mining process. However, the representation chosen can have a significant impact on the quality of the statistical inferences that can be made. Therefore, the choice of an appropriate representation is actually an important issue in effective link mining, and is often more complex than in the case where we have IID data instances.

Link Mining and Link Discovery, Table 1 A simple categorization of different link mining tasks

b. Link prediction
c. Link ranking
3. Graph-related tasks
a. Subgraph discovery
b. Graph classification

Link Mining Tasks

Link mining puts a new twist on some classic data mining tasks, and also poses new problems. One way to understand the different types of learning and inference problems is to categorize them in terms of the components of the data that are being targeted. Table 1 gives a simple characterization. Note that for the object-related tasks, even though we are concerned with classifying, clustering, consolidating, or ranking the objects, we will be exploiting the links. Similarly for link-related tasks, we can use information about the objects that participate in the links, and their links to other objects and so on.

In addition, because of the underlying link structure, link mining affords the opportunity for inferences and predictions to be *collective* or dependent on one another. The simplest example of this is in collective classification, where the inferred label of one node can depend on the inferred label of its neighbors. There are a variety of ways of modeling and exploiting this dependence. Methods include performing joint inference in the appropriate probabilistic model, use of information diffusion models, constructing and optimizing the appropriate structured prediction using a max margin approach, and others.

Additional information on different link mining subtasks is provided in separate entries on *collective classification*, *entity resolution*, *group detection*, and *link prediction*. Related problems and techniques can be found in the entries on *relational learning*, *graph mining*, and *inductive logic programming*.

Edge prediction; Relationship extraction

Definition

Many datasets can naturally be represented as graph where nodes represent instances and links represent relationships between those instances. A fundamental problem with these types of data is that the link information in the graph may be of dubious quality; links may incorrectly exist between unrelated nodes and links may be missing between two related nodes. The goal of link prediction is to predict the existence of incorrect or missing links between the nodes of the graph.

Theory/Solution

Inferring the existences of edges between nodes in a graph has traditionally been referred to as *link prediction* (Liben-Nowell and Kleinberg 2003a; Taskar et al. 2003). Link prediction is a challenging problem that has been studied in various guises in different domains. For example, in social network analysis, there is work on predicting friendship links (Zheleva et al. 2008), event participation links (i.e., coauthorship O'Madadhain et al. 2005), communication links (i.e., email O'Madadhain et al. 2005), and links representing semantic relationships (i.e., advisor of Taskar et al. 2003, subordinate manager Diehl et al. 2007). In bioinformatics, there is interest in predicting the existence of edges representing physical protein–protein interactions (Szilagyi et al. 2005b; Yu et al. 2006), domain–domain interactions (Deng et al. 2002), and regulatory interactions (Albert et al. 2007). Similarly, in computer network systems, there is work in inferring unobserved connections between routers, as well as inferring relationships between autonomous systems and service providers (Spring et al. 2004). There is also work on using link prediction to improve recommender systems (Farrell et al. 2005), Web site navigation (Zhu 2003), surveillance (Huang and Lin 2008), and automatic document cross-referencing (Milne and Witten 2008).

We begin with some basic definitions and notation. We refer to the set of possible edges in a graph as *potential edges*. The set of potential edges depends on the graph type and how the edges for the graph are defined. For example, in a directed graph, the set of potential edges consists of all edges $e = (v_1, v_2)$ where v_1 and v_2 are any two nodes V in the graph (i.e., the number of potential edges is $|V| \times |V|$). In an undirected bipartite graph with two subsets of nodes $(V_1, V_2 \in V)$, while the edges still consist of a pair of nodes, $e = (v_1, v_2)$, there is an added condition such that one node must be from V_1 and the other node must be from V_2; this results in $|V_1| \times |V_2|$ potential edges. Next, we refer to set of "true" edges in a graph as *positive edges*, and we refer to the "true" non-edges in a graph (i.e., pairs of nodes without edges between them) as *negative edges*. For a given graph, typically we only have information about a subset of the edges; we refer to this set as the *observed* edges. The observed edges can include both positive and negative edges, though in many formulations there is an assumption of positive-only information. We can view link prediction as a probabilistic inference problem, where the evidence includes the observed edges, the attribute values of the nodes involved in the potential edge, and possibly other information about the network, and for any unobserved, potential edge, we want to compute the probability of it existing. This can be reframed as a binary classification problem by choosing some probability threshold and concluding that potential edges with existence probability above the threshold are true edges and those below the threshold are considered false edges (more complex schemes are possible as well). For noisy and incomplete networks, we use terminology from the machine learning literature and refer to an edge that is inferred to exist and is a true edge in the graph as a *true positive edge*, an edge that should exist but is not inferred as a *false negative edge*, an edge that should not exist and is not inferred as a *true negative edge*, and an edge that should not exist but is incorrectly inferred to exist as a *false positive edge*.

One of the early and simple formulations of the link prediction problem was proposed by Liben-Nowell and Kleinberg (2003b). They proposed a temporal prediction problem defined over a dynamic network where given a graph

$G_t(V_t, E_t)$ at time t, the problem is to infer the set of edges at the next time step $t + 1$. More formally, the objective is to infer a set of edges E_{new} where $E_{t+1} = E_t \bigcup E_{\text{new}}$. We use a more general definition of link prediction proposed by Taskar et al. (2003) where given a graph G and the set of potential edges in G, denoted $P(G)$, the problem of link prediction is to predict for all $p \in P(G)$ whether p exists or does not exist, remaining agnostic on whether G is a noisy graph with missing edges or a snapshot of a dynamic graph at a particular time point.

Approaches

In this section, we discuss the two general categories of the current link prediction models: topology-based approaches and node attribute-based approaches. Topology-based approaches are methods that rely solely on the topology of the network to infer edges. Node attribute-based approaches make predictions based on the attribute values of the nodes incident to the edges. In addition, there are models that make use of both structure and attribute values.

Topology-Based Approaches

A number of link prediction models have been proposed, which rely solely on the topology of the network. These models typically rely on some notion of structural proximity, where nodes that are close are likely to share an edge (e.g., sharing common neighbors, nodes with a small shortest path distance between). The earliest topological approach for link prediction was proposed by Liben-Nowell and Kleinberg (2003b). In this work, Liben-Nowell and Kleinberg proposed various structure-based similarity scores and applied them over the unobserved edges of an undirected graph. They then use a threshold k and only predict edges with the top k scores as existing. A variety of similarity scores were proposed, given two nodes v_1 and v_2, including graph distance (the length of the shortest path between v_1 and v_2), common neighbors (the size of the intersection of the sets of neighbors of v_1 and v_2), and more complex measures such as the Katz measure (the sum of the lengths of the paths between v_1 and v_2 exponentially damped by length to count short paths more heavily). Evaluating over a coauthorship network, the best performing proximity score measure was the Katz measure; however the simple measures, which rely only on the intersection of the set of nodes adjacent to both nodes, performed surprisingly well. A related approach was proposed by Yu et al. (2006), which applies the link prediction problem to predicting missing protein–protein interactions (PPI) from PPI networks generated by high-throughput methods. This work assumes that interacting proteins tend to form a clique. Thus, missing edges can be predicted by predicting the existence of edges that will create cliques in the network. More recent work by Clauset et al. (2008) has tried to go beyond predicting edges between neighboring nodes. In their problem domain of food webs, for example, pairs of predators often prey on a shared prey species but rarely prey on each other. Thus, in these networks, predicting "predator–prey" edges need to go beyond proximity. For this, they propose a "hierarchical random graph" approach, which fits a hierarchical model to all possible dendrograms of a given network. The model is then used to calculate the likelihood of an edge existing in the network.

Node Attribute-Based Approaches

Although topology is useful in link prediction, topology-based approaches ignore an important source of information in networks, the attributes of nodes. Often there are correlations in the attributes of nodes that share an edge with each other. One approach that exploits this correlation was proposed by Taskar et al. (2003). In their approach, Taskar et al. (2003) applied the relational Markov network (RMN) framework to link prediction to predicting the existence and class of edges between Web sites. They exploit the fact that certain links can only exist between nodes of the appropriate type. For example, an "advisor" edge can only exist between student and faculty.

Another approach that uses node attributes was proposed by Popescul and Ungar (2003). In that approach, they used a structured ▶ logistic regression model over learned relational features to predict citation edges in a citation network. Their relational features are built over attributes such as the words used in the paper nodes. O'Madadhain et al. (2005) also approached an attribute-based approach, constructing local conditional probability models based on the attributes such as node attribute similarity, topic distribution, and geographical location in predicting "co-participation" edges in an email communication network. More recently, there is work on exploiting other node attributes like the group membership of the nodes. Zheleva et al. (2008) showed that membership in family groups is very useful in predicting friendship links in social networks. Similarly, Sprinzak et al. (2006) showed that using protein complex information can be useful in predicting protein–protein interactions. Finally, we note that in link prediction, as in classification, the quality of predictions can be improved by making the predictions collectively. Aside from the relational Markov network approach by Taskar et al. (2003) mentioned earlier, Markov logic networks (Richardson and Domingos 2006) and probabilistic relational models (Getoor et al. 2003) have also been proposed for link prediction and are capable of performing joint inference.

Issues

There are a number of challenges that make link prediction very difficult. The most difficult challenge is the large class skew between the number of edges that exist and the number of edges that do not. To illustrate, consider directed graph denoted by $G(V, E)$. While the number of edges $|E|$ is often $O(|V|)$, the number of edges that do not exist is often $O(|V|^2)$. Consequently, the prior probability edge existence is very small. This causes many supervised models, which naively optimize for accuracy, to learn a trivial model, which always predicts that a link does not exist. A related problem in link prediction is the large number of edges whose existence must be considered. The number of potential edges is $O(|V|^2)$ and this limits the size of the datasets that can be considered.

In practice, there are general approaches to addressing these issues either prior to or during the link prediction. With both large class skew and number of edges to contend with, the general approach is to make assumptions that reduce the number of edges to consider. One common way to do this is to partition the set of nodes where we only consider potential edges between nodes of the same partition; edges between partitions are not explicitly modeled, but are assumed not to exist. This is useful in many domains where there is some sort of natural partition among the nodes available (e.g., geography in social networks, location of proteins in a cell), which make edges across partitions unlikely. Another way is to define some simple, computationally inexpensive distance measure such that only edges whose nodes are within some distance are considered.

Another practical issue in link prediction is that while real-world data often indicates which edges exist (positive examples), the edges which do not exist (negative examples) are rarely annotated for use by link prediction models. In bioinformatics, for example, the protein–protein interaction network of yeast, the most and annotated studied organism, is annotated with thousands of observed edges (physical interactions) between the nodes (proteins) gathered from numerous experiments. There are currently, however, no major datasets available that indicate which proteins definitely do not physically interact. This is an issue not only in creating and learning models for link prediction but is also an issue evaluating them. Often, it is unclear whether a predicted edge which is not in our ground truth data is an incorrectly predicted edge or an edge resulting from incomplete data.

Related Problems

In addition to the definition of link prediction discussed above, it is also important to mention three closely related problems: *link completion*, *leak detection*, and *anomalous link discovery*, whose objectives are different but very similar to link prediction. Link completion (Chaiwanarom and Lursinsap 2008; Goldenberg et al. 2003) and leak detection (Balasubramanyan et al. 2009; Carvalho and Cohen 2007) are a variation of link prediction over hypergraphs. A hypergraph is a graph where the edges (known as hyperedges) can connect any number of nodes. For example, in a hypergraph representing an email communication network, a hyperedge may connect nodes representing email addresses that are recipients of a particular email communication. In link completion, given the set of nodes that participate in a particular hyperedge, the objective is to infer nodes that are missing. For the email communication network example, link completion may involve inferring which email addresses need to be added to the recipient list of an email communication. Conversely, in leak detection, given the set of nodes participating in a particular hyperedge, the objective is to infer which nodes should not be part of that hyperedge. For example, in email communications, leak detection will attempt to infer which email address nodes are incorrectly part of the hyperedge representing the recipient list of the email communication.

The last problem, anomalous link discovery (Huang and Zeng 2006; Rattigan and Jensen 2005a), has been proposed as an alternate task to link prediction. As with link completion, the existence of the edges is assumed to be observed, and the objective is to infer which of the observed links are anomalous or unusual. Specifically, anomalous link discovery identifies which links are statistically improbable with the idea that these may be of interest for those analyzing the network. Rattigan and Jensen (2005b) show that some methods that perform poorly for link prediction can still perform well for anomalous link discovery.

Definition

In learning systems with kernels, the shape and size of a kernel plays a critical role for accuracy and generalization. Most kernels have a distance metric parameter, which determines the size and shape of the kernel in the sense of a Mahalanobis distance. Advanced kernel learning tune every kernel's distance metric individually, instead of turning one global distance metric for all kernels.

Locality Sensitive Hashing Based Clustering

Xin Jin[1] and Jiawei Han[2]
[1]PayPal Inc., San Jose, CA, USA
[2]University of Illinois at Urbana-Champaign, Urbana, IL, USA

The basic idea of the LSH (Gionis et al. 1999) technique is using multiple hash functions to hash the data points and guarantee that there is a high probability of collision for points which are close to each other and low collision probability for dissimilar points. LSH schemes exist for many distance measures, such as Hamming norm, L_p norms, cosine distance, earth movers distance (EMD), and Jaccard coefficient.

In LSH, define a family $H = \{h : S \to U\}$ as locality-sensitive, if for any a, the function $p(t) = Pr_H[h(a) = h(b) : ||a - b|| = x]$ is decreasing in x. Based on this definition, the probability of collision of points a and b is decreasing with their distance.

Although LSH was originally proposed for approximate nearest neighbor search in high dimensions, it can be used for clustering as well (Das et al. 2007; Haveliwala et al. 2000). The buckets could be used as the bases for clustering. Seeding the hash functions several times can help getting better quality clustering.

Definition

This entry addresses two topics: ▶ learning control and locally weighted regression.

▶ Learning control refers to the process of acquiring a control strategy for a particular control system and a particular task by trial and error. It is usually distinguished from adaptive control (Aström and Wittenmark 1989) in that the learning system is permitted to fail during the process of learning, resembling how humans and animals acquire new movement strategies. In contrast, adaptive control emphasizes single-trial convergence without failure, fulfilling stringent performance constraints, e.g., as needed in life-critical systems like airplanes and industrial robots.

Locally weighted regression refers to ▶ supervised learning of continuous functions (otherwise known as function approximation or ▶ regression) by means of spatially localized algorithms, which are often discussed in the context of ▶ kernel regression, ▶ nearest neighbor methods, or ▶ lazy learning (Atkeson et al. 1997). Most regression algorithms are global learning systems. For instance, many algorithms can be understood in terms of minimizing a global ▶ loss function such as the expected sum squared error:

$$J = E\left[\frac{1}{2}\sum_{i=1}^{N}(\mathbf{t}_i - \mathbf{y}_i)^2\right] = E\left[\frac{1}{2}\sum_{i=1}^{N}\left(\mathbf{t}_i - \phi(\mathbf{x}_i)^T\boldsymbol{\beta}\right)^2\right] \qquad (1)$$

where $E[\cdot]$ denotes the expectation operator, $\mathbf{t}_i$ the noise-corrupted target value for an input $\mathbf{x}_i$—which is expanded by basis functions into a basis function vector $\phi(\mathbf{x}_i)$-and $\boldsymbol{\beta}$ is the vector of (usually linear) regression coefficients. Classical feedforward ▶ neural networks, ▶ radial basis function networks, ▶ mixture models, or ▶ Gaussian process regression are all global function approximators in the spirit of Eq. (1).

In contrast, local learning systems conceptually split up the global learning problem into multiple simpler learning problems. Traditional locally weighted regression approaches achieve this by dividing up the cost function into multiple independent local cost functions,

$$\begin{aligned} J &= E\left[\frac{1}{2}\sum_{k=1}^{K}\sum_{i=1}^{N} w_{k,i}\left(\mathbf{t}_i - \mathbf{x}_i^T\boldsymbol{\beta}_k\right)^2\right] \\ &= \frac{1}{2}\sum_{k=1}^{K} E\left[\sum_{i=1}^{N} w_{k,i}\left(\mathbf{t}_i - \mathbf{x}_i^T\boldsymbol{\beta}_k\right)^2\right] \\ &= \frac{1}{2}\sum_{k=1}^{K} J_k. \end{aligned} \qquad (2)$$

resulting in K (independent) local model learning problems. A different strategy for local learning starts out with the global objective (Eq. 1) and reformulates it to capture the idea of local models that cooperate to generate a (global) function fit. This is achieved by assuming there are K feature functions ϕ_k, such that the kth feature function $\phi_k(\mathbf{x}_i) = w_{k,i}\mathbf{x}_i$, resulting in

$$\begin{aligned} J &= E\left[\frac{1}{2}\sum_{i=1}^{N}\left(\mathbf{t}_i - \phi(\mathbf{x}_i)^T\boldsymbol{\beta}\right)^2\right] \\ &= E\left[\frac{1}{2}\sum_{i=1}^{N}\left(\mathbf{t}_i - \sum_{k=1}^{K} w_{k,i}(\mathbf{x}_i^T\boldsymbol{\beta}_k)\right)^2\right]. \end{aligned} \qquad (3)$$

In this setting, local models are initially coupled and approximations are found to decouple the learning of the local models parameters.

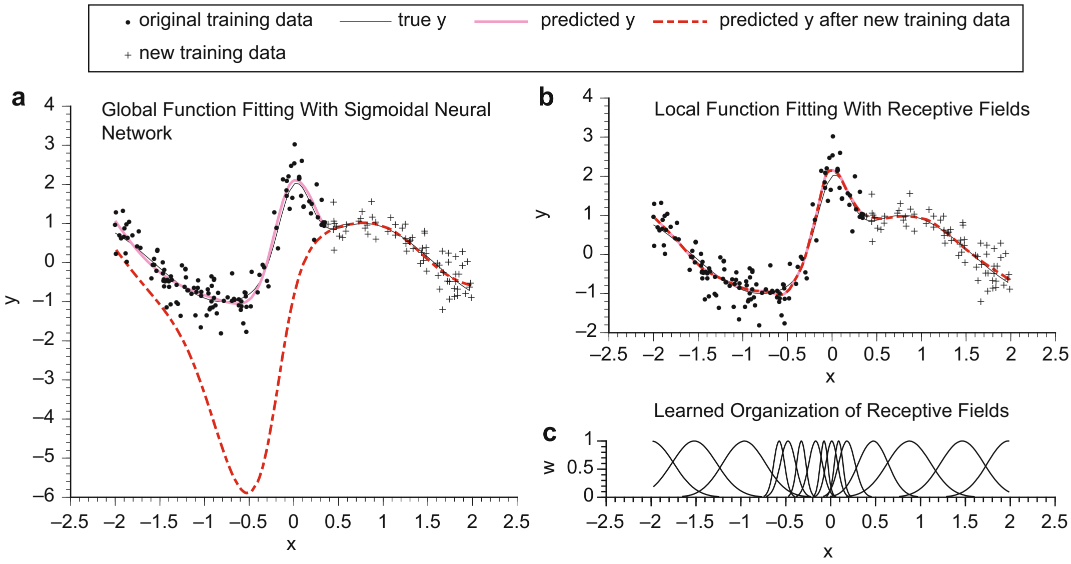
Motivation and Background

Figure 1 illustrates why locally weighted regression methods are often favored over global methods when it comes to learning from incrementally arriving data, especially when dealing with nonstationary input distributions. The figure shows the division of the training data into two sets: the "original training data" and the "new training data" (in dots and crosses, respectively).

Initially, a sigmoidal ▶ neural network and a locally weighted regression algorithm are trained on the "original training data," using 20 % of the data as a cross validation set to assess convergence of the learning. In a second phase, both learning systems are trained solely on the "new training data" (again with a similar cross-validation procedure), but without using any data from the "original training data." While both algorithms generalize well on the "new training data," the global learner incurred catastrophic interference, unlearning what was learned initially, as seen in Fig. 1a. Figure 1b shows that the locally weighted regression algorithm does not have this problem since learning (along with ▶ generalization) is restricted to a local area.

Appealing properties of locally weighted regression include the following:

- Function approximation can be performed incrementally with nonstationary input and output distributions and without significant danger of interference. Locally weighted regression can provide ▶ posterior probability



Locally Weighted Regression for Control, Fig. 1 Function approximation results for the function $y = \sin(2x) + 2\exp(-16x^2) + N(0, 0.16)$ with (**a**) a sigmoidal neural network, (**b**) a locally weighted regression algorithm (note that the data traces "true y," "predicted y," and "predicted y after new training data" largely coincide), and (**c**) the organization of the (Gaussian) kernels of (**b**) after training. See Schaal and Atkeson 1998 for more details

distributions, offer confidence assessments, and deal with heteroscedastic data.

- Locally weighted learning algorithms are computationally inexpensive to compute. It is well suited for online computations (e.g., for ▸ online and ▸ incremental learning) in the fast control loop of a robot—typically on the order of 100–1000 Hz.
- Locally weighted regression methods can implement continual learning and learning from large amounts of data without running into severe computational problems on modern computing hardware.
- Locally weighted regression is a nonparametric method (i.e., it does not require that the user determine a priori the number of local models in the learning system), and the learning systems grow with the complexity of the data it tries to model.
- Locally weighted regression can include ▸ feature selection, ▸ dimensionality reduction, and ▸ Bayesian inference—all which are required for robust ▸ statistical inference.
- Locally weighted regression works favorably with locally linear models (Hastie and Loader 1993), and local linearizations are of ubiquitous use in control applications.

Background

Returning to Eqs. (1) to (3), the main differences between global methods that directly solve Eq. (1) and local methods that solve either Eqs. (2) or (3) are listed below:

(i) A weight $w_{i,k}$ is introduced that focuses:
   - either the function approximation fit in Eq. (2)
   - or a local models contribution toward the global function fit in Eq. (3)

   on only a small neighborhood around a point of interest $\mathbf{c}_k$ in input space (see Eq. 4 below).

(ii) The learning problem is split into K independent optimization problems.

(iii) Due to the restricted scope of the function approximation problem, we do not need a nonlinear basis function expansion and can, instead, work with simple local functions or local polynomials (Hastie and Loader 1993).

The weights $w_{k,i}$ in Eq. (2) are typically computed from some ▶ kernel function (Atkeson et al. 1997) such as a squared exponential kernel:

$$w_{k,i} = \exp\left(-\frac{1}{2}\left(\mathbf{x}_i - \mathbf{c}_k\right)^T \mathbf{D}_k \left(\mathbf{x}_i - \mathbf{c}_k\right)\right) \quad (4)$$

with $\mathbf{D}_k$ denoting a positive semidefinite distance metric and $\mathbf{c}_k$ the center of the kernel. The number of kernels K is not finite. In many local learning algorithms, the kernels are never maintained in memory. Instead, for every query point $\mathbf{x}_q$, a new kernel is centered at $\mathbf{c}_k = \mathbf{x}_q$, and the localized function approximation is solved with weighted ▶ regression techniques (Atkeson et al. 1997).

Locally weighted regression should not be confused with mixture of experts models (Jordan and Jacobs 1994). ▶ Mixture models are *global* learning systems since the experts compete globally to cover training data. Mixture models address the ▶ bias-variance dilemma (Intuitively, the ▶ bias-variance dilemma addresses how many parameters to use for a function approximation problem to find an optimal balance between ▶ overfitting and oversmoothing of the training data.) by finding the right number of local experts. Locally weighted regression addresses the ▶ bias-variance dilemma in a local way by finding the optimal distance metric for computing the weights in the locally weighted regression (Schaal and Atkeson 1998).

Structure of Learning System

All local learning approaches have three critical components in common:

(i) Optimizing the regression parameters $\boldsymbol{\beta}_k$
(ii) Learning the distance metric $\mathbf{D}_k$ that defines a local model neighborhood
(iii) Choosing the location $\mathbf{c}_k$ of receptive field(s)

Local learning methods can be separated into "lazy" approaches that require all training data to be stored and "memoryless" approaches that compress data into a several local models and thus do not require storage of data points.

In the "lazy" approach, the computational burden of a prediction is deferred until the last moment, i.e., when a prediction is needed. Such a "compute-the-prediction-on-the-fly" approach is often called lazy learning and is a memory-based learning system where all training data is kept in memory for making predictions. A prediction is formed by optimizing the parameters $\boldsymbol{\beta}_q$ and distance metric $\mathbf{D}_q$ of one local model centered at the query point $\mathbf{c}_q = \mathbf{x}_q$.

Alternatively, in the "memoryless" approach, multiple kernels are created as needed to cover the input space, and the sufficient statistics of the weighted regression are updated incrementally with recursive ▶ least squares (Schaal and Atkeson 1998). This approach does not require storage of data points in memory. Predictions of neighboring local models can be blended, improving function fitting results in the spirit of committee machines.

We describe some algorithms of both flavors next.

Memory-Based Locally Weighted Regression (LWR)

The original locally weighted regression algorithm was introduced by Cleveland (1979) and popularized in the machine learning and learning control community by Atkeson (1989). The algorithm – categorized as a "lazy" approach – can be summarized as follows below (for algorithmic pseudo-code, see Schaal et al. 2002):

- All training data is collected in the rows of the matrix $\mathbf{X}$ and the vector (For simplicity, only functions with a scalar output are addressed. Vector-valued outputs can be learned either by fitting a separate learning system for each output or by modifying the algorithms to fit multiple outputs (similar to multi-output linear regression).) **t**.
- For every query point $\mathbf{x}_q$, the weighting kernel is centered at the query point.

- The weights are computed with Eq. (4), and all data points' weights are collected in the diagonal weight matrix $\mathbf{W}_q$
- The local regression coefficients are computed as

$$\boldsymbol{\beta}_q = \left(\mathbf{X}^T\mathbf{W}_q\mathbf{X}\right)^{-1}\mathbf{X}^T\mathbf{W}_q\mathbf{t} \qquad (5)$$

- A prediction is formed with $y_q = \left[\mathbf{x}_q^T\ 1\right]\boldsymbol{\beta}_q$.

As in all kernel methods, it is important to optimize the kernel parameters in order to get optimal function fitting quality. For LWR, the critical parameter determining the ▶ bias-variance tradeoff is the distance metric $\mathbf{D}_q$. If the kernel is too narrow, it starts fitting noise. If it is too broad, oversmoothing will occur. $\mathbf{D}_q$ can be optimized with leave-one-out cross validation to obtain a *globally* optimal value, i.e., the same $\mathbf{D}_q = \mathbf{D}$ is used throughout the entire input space of the data. Alternatively, $\mathbf{D}_q$ can be *locally* optimized as a function of the query point, i.e., obtain a $\mathbf{D}_q$ (as indicated by the subscript "q"). In the recent machine learning literature (in particular, work related to kernel methods), such input-dependent kernels are referred to as nonstationary kernels.

Locally Weighted Projection Regression (LWPR)

Schaal and Atkeson (1998) suggested a memoryless version of LWR, called RFWR, in order to avoid the expensive ▶ nearest neighbor computations—particularly for large training data sets—of LWR and to have fast real-time (In most robotic systems, "real time" means on the order of maximally 1–10 ms computation time, corresponding to a 1000 to 100 Hz control loop.) prediction performance. The main ideas of the RFWR algorithm (Schaal and Atkeson 1998) are listed below:

- Create new kernels only if no existing kernel in memory covers a training point with some minimal activation weight.
- Keep all created kernels in memory and update the weighted regression with weighted recursive ▶ least squares for new training points $\{\mathbf{x}, t\}$:

$$\boldsymbol{\beta}_k^{n+1} = \boldsymbol{\beta}_k^n + w\mathbf{P}^{n+1}\tilde{\mathbf{x}}\left(t - \tilde{\mathbf{x}}^T\boldsymbol{\beta}_k^n\right)$$

$$\text{where } \mathbf{P}_k^{n+1} = \frac{1}{\lambda}\left(\mathbf{P}_k^n - \frac{\mathbf{P}_k^n\tilde{\mathbf{x}}\tilde{\mathbf{x}}^T\mathbf{P}_k^n}{\frac{\lambda}{w} + \tilde{\mathbf{x}}^T\mathbf{P}_k^n\tilde{\mathbf{x}}}\right) \text{ and } \tilde{\mathbf{x}} = \left[\mathbf{x}^T\ 1\right]^T. \qquad (6)$$

- Adjust the distance metric $\mathbf{D}_q$ for each kernel with a gradient descent technique using leave-one-out cross validation.
- Make a prediction for a query point taking a weighted average of predictions from all local models:

$$\mathbf{y}_q = \frac{\sum_{k=1}^{K} w_{q,k}\hat{\mathbf{y}}_{q,k}}{\sum_{k=1}^{K} w_{q,k}} \qquad (7)$$

Adjusting the distance metric $\mathbf{D}_q$ with leave-one-out cross validation *without* keeping all training data in memory is possible due to the PRESS residual. The PRESS residual allows the leave-one-out cross validation error to be computed in closed form without needing to actually exclude a data point from the training data.

Another deficiency of LWR is its inability to scale well to high-dimensional input spaces since the ▶ covariance matrix inversion in Eq. (5) becomes severely ill-conditioned. Additionally, LWR becomes expensive to evaluate as the number of local models to be maintained increases. Vijayakumar et al. (2005) suggested local ▶ dimensionality reduction techniques to handle this problem. Partial least squares (PLS) regression is a useful ▶ dimensionality reduction method that is used in the LWPR algorithm (Vijayakumar et al. 2005). In contrast to PCA methods, PLS performs ▶ dimensionality reduction for ▶ regression, i.e., it eliminates subspaces of the input space that minimally correlates with the outputs, not just parts of the input space that have low variance.

While LWPR is typically used in conjunction with linear local models, the use of local nonparametric models, such as Gaussian processes, has also been explored (Nguyen-Tuong et al. 2008). Finally, LWPR is currently one of the best developed locally weighted regression algorithms for control (Klanke et al. 2008) and has been applied to learning control problems with over 100 input dimensions.

A Full Bayesian Treatment of Locally Weighted Regression

Ting et al. (2008) proposed a fully probabilistic treatment of LWR in an attempt to avoid cross-validation procedures and minimize any manual parameter tuning (e.g., gradient descent rates, kernel initialization, forgetting rates, etc.). The resulting Bayesian algorithm learns the distance metric of local linear model (For simplicity, a local linear model is assumed, although local polynomials can be used as well.) probabilistically, can cope with high input dimensions, and rejects data outliers automatically. The main ideas of Bayesian LWR are listed below (please see Ting 2009 for details):

- Introduce hidden variables $\mathbf{z}$ to the local linear model to decompose the statistical estimation problem into d individual estimation problems (where d is the number of input dimensions). The result is an iterative expectation-maximization (EM) algorithm that is of linear ▸ computational complexity in d and the number of training data samples N, i.e., $O(Nd)$.
- Associate a scalar weight w_i with each training data sample $\{\mathbf{x}_i, t_i\}$, placing a Bernoulli ▸ prior probability distribution over a weight w_{im} *for each input dimension* m so that the weights are positive and between 0 and 1:

$$w_i = \prod_{m=1}^{d} w_{im} \text{ where}$$

$$w_{im} \sim \text{Bernoulli}\left(q_{im}\right) \text{ for } i = 1, .., N; \quad m = 1, .., d \tag{8}$$

The weight w_i indicates a training sample's contribution to the local model. The formulation of the parameter q_{im} determines the shape of the weighting function applied to the local model. The weighting function q_{im} used in Bayesian LWR is listed below:

$$q_{im} = \frac{1}{1 + \left(x_{im} - x_{qm}\right)^2 h_m} \text{ for } i = 1, .., N; \quad m = 1, .., d \tag{9}$$

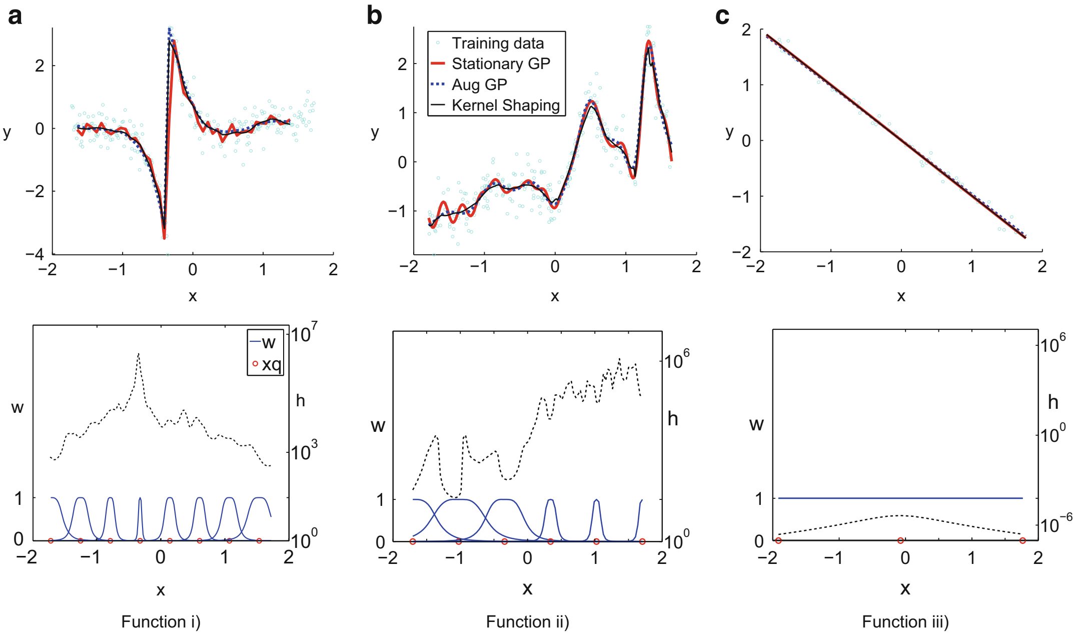
where $\mathbf{x}_q \in \Re^{d \times 1}$ is the query input point and h_m is the bandwidth parameter/distance metric of the local model in the m-th input dimension.
- Place a gamma ▸ prior probability distribution over the distance metric h_m:

$$h_m \sim \text{Gamma}\left(a_{hm0}, b_{hm0}\right) \tag{10}$$

where $\{a_{hm0}, b_{hm0}\}$ are the prior parameter values of the gamma distribution.
- Treat the model as an EM-like ▸ regression problem, using ▸ variational approximations to achieve analytically tractable inference of the ▸ posterior probability distributions.

This Bayesian method can also be applied as general kernel shaping algorithm for global ▸ kernel learning methods that are linear in the parameters (e.g., to realize nonstationary ▸ Gaussian processes (Ting et al. 2008), resulting in an augmented nonstationary ▸ Gaussian process).

Figure 2 illustrates Bayesian kernel shaping's bandwidth adaptation abilities on several synthetic data sets, comparing it to a stationary ▸ Gaussian process and the augmented nonstationary ▸ Gaussian process. For the ease of visualization, the following one-dimensional functions are considered: (i) a function with a discontinuity, (ii) a spatially inhomogeneous function, and (iii) a straight line function. Figure 2 shows the predicted outputs of all three models trained on noisy data drawn from data sets (i)–(iii). The local kernel shaping algorithm smoothens over regions where a stationary ▸ Gaussian process overfits, and yet, it still manages to capture regions of highly varying curvature, as seen in



Locally Weighted Regression for Control, Fig. 2 Predicted outputs using a stationary Gaussian process (GP), the augmented nonstationary GP, and local kernel shaping on three different data sets. Figures on the *bottom row* show the bandwidths learned by local kernel shaping and the corresponding weighting kernels (in *dotted black lines*) for various input query points (shown in *red circles*)

Fig. 2a, b. It correctly adjusts the bandwidths h with the curvature of the function. When the data looks linear, the algorithm opens up the weighting kernel so that all data samples are considered, as Fig. 2c shows.

From the viewpoint of ▶ learning control, ▶ overfitting—as seen in the ▶ Gaussian process in Fig. 2—can be detrimental since learning control often relies on extracting local linearizations to derive controllers. Obtaining the wrong sign on a slope in a local linearization may destabilize a controller.

In contrast to LWPR, the Bayesian LWR method is a "lazy" learner, although memoryless versions could be derived. Future work will also have to address how to incorporate ▶ dimensionality reduction methods for robustness in high dimensions. Nevertheless, it is a first step toward a probabilistic locally weighted regression method with minimal parameter tuning required by the user.

From Global to Local: Local Regression with Coupling Between Local Models

Meier et al. (2014) offer an alternative approach to local learning. They start out with the global objective (Eq. 3) and reformulate it to capture the idea of local models that cooperate to generate a function fit, resulting in

$$J = E\left[\frac{1}{2}\sum_{i=1}^{N}\left(\mathbf{t}_i - \sum_{k=1}^{K} w_{k,i}\left(\mathbf{x}_i^T \boldsymbol{\beta}_k\right)\right)^2\right]. \tag{11}$$

With this change, a local models' contribution $\hat{y}_k = \mathbf{x}_i^T \boldsymbol{\beta}_k$ toward the fit of target $\mathbf{t}_i$ is localized through weight $w_{k,i}$. However, this form of localization couples all local models. For efficient learning, local Gaussian regression (LGR) thus employs approximations to decouple learning of parameters. The main ideas of LGR are:

- Introduce Gaussian hidden variables $\mathbf{f}_k$ that form virtual targets for the weighted contribution of the kth local model:

$$f_{k,i} = \mathcal{N}\left(w_{k,i}(\mathbf{x}_i^T\boldsymbol{\beta}_k),\ \beta_m^{-1}\right) \tag{12}$$

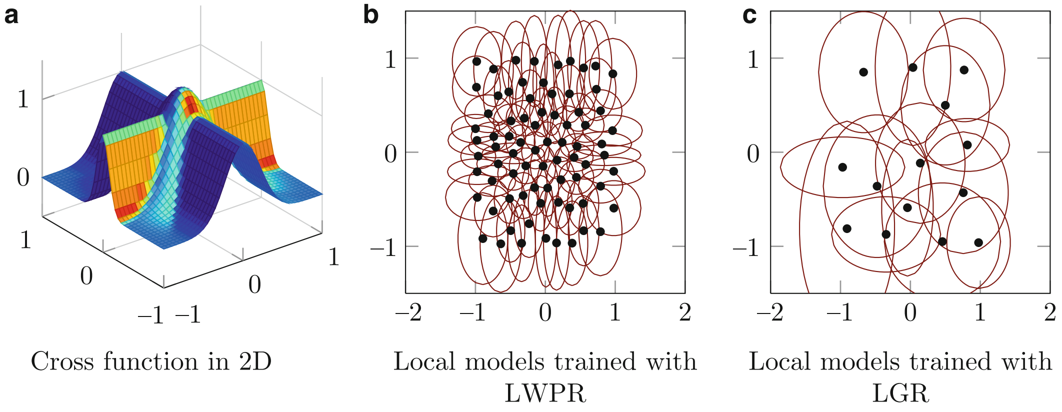
  Assume that the target t is observed with Gaussian noise and that the hidden variables f_k need to sum up to noisy target t_i

$$t_i = \mathcal{N}\left(\sum_k f_{k,i},\ \beta_y^{-1}\right) \tag{13}$$

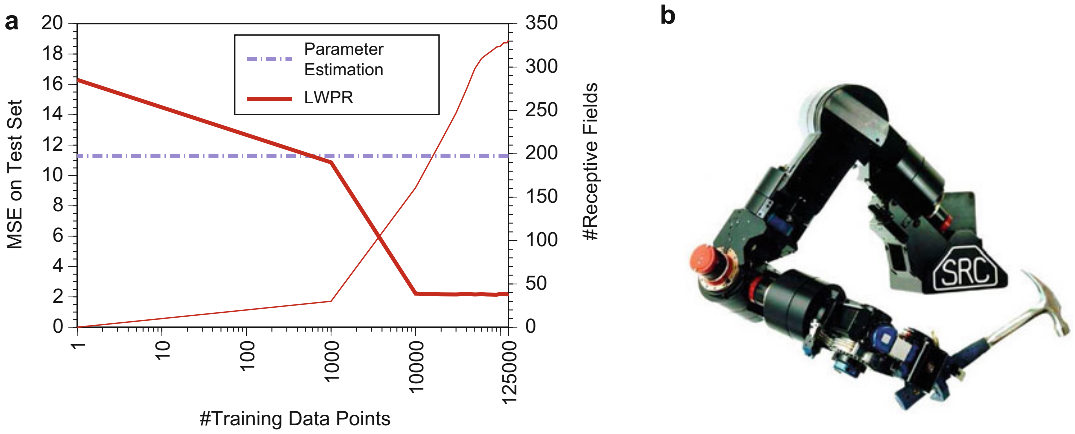
  In its exact form, this model learning procedure will couple all local models parameters.
- Employ a variational approximation to decouple local models. This results in an iterative (EM style) learning procedure, between updating posteriors over hidden variables $\mathbf{f}_k$ followed by posterior updates for regression parameters $\boldsymbol{\beta}_k$, for all local models $k = 1, \ldots, K$.
- The updates over the hidden variables $\mathbf{f}_k$ turn out to be a form of message passing between local model predictions. This step allows the redistribution of virtual target values for each local model. This *communication* between local models is what distinguishes LGR from typical LWR approaches. This update is linear in the number of local models and in the number of data points.
- The parameter updates ($\boldsymbol{\beta}_k$ and $\mathbf{D}_k$) per local model become completely independent through the variational approximation, resulting in a localized learning algorithm, similar in spirit to LWR.
- Place Gaussian priors over regression parameters $\boldsymbol{\beta}_k \sim \mathcal{N}(\boldsymbol{\beta}_k; 0, \text{diag}\,(\boldsymbol{\alpha}_k))$ that allow for automatic relevance determination of the input dimensions.
- For incrementally incoming data, apply recursive Bayesian updates that utilize the posterior over parameters at time step $t-1$ to be the prior over parameters at time step t. Furthermore, new local models are added if no existing local model is activated with some minimal activation weight, similar to LWPR.
- Prediction for a query input $\mathbf{x}_q$ becomes a weighted average of local models predictions

$$y_q = \sum_{k=1}^{K} w_{k,q}(\mathbf{x}_q^T\boldsymbol{\beta}_k)$$

More details and a pseudo-algorithm for incremental LGR can be found in Meier et al. (2014). Figure 3 illustrates the different shapes of local models being learned by LWPR and LGR. Local models learned by LGR *collaborate* to generate a good fit, as visualized in Fig. 3c. Compared to



Locally Weighted Regression for Control, Fig. 3 Local models trained on data from the 2D cross function for LWPR and LGR. Local models trained via LWPR (visualized in (**b**)) do not know of each other, while local models trained by LGR (visualized in (**c**)) *collaborate* to generate a function fit



Locally Weighted Regression for Control, Fig. 4 Learning an inverse dynamics model in real time with a high-performance anthropomorphic robot arm. (**a**) Learning curve LWPR online learning. (**b**) Seven degree-of-freedom Sarcos robot arm

LWPR, this often allows LGR to achieve similar predictive performance while using fewer local models.

Finally, an interesting structural feature of local ▶ Gaussian regression is that it easily extends to a model with finitely many local nonparametric ▶ Gaussian process models.

Applications

Learning Internal Models with LWPR

Learning an internal model is one of most typical applications of local regression methods for control. The model could be a forward model (e.g., the nonlinear differential equations of robot dynamics), an inverse model (e.g., the equations that predict the amount of torque to achieve a change of state in a robot), or any other function that models associations between input and output data about the environment. The models are used, subsequently, to compute a controller, e.g., an inverse dynamics controller similar to Eq. (16). Models for complex robots such as like humanoids exceed easily a hundred input dimensions. In such high-dimensional spaces, it is hopeless to assume that a representative data set can be collected for offline training that can generalize sufficiently to related tasks. Thus, the local regression philosophy involves having a learning algorithm that can learn rapidly when entering a new part of the state space such that it can achieve acceptable ▶ generalization performance almost instantaneously. Both LWPR (Vijayakumar et al. 2005) and incremental LGR (Meier et al. 2014) have been applied to inverse dynamics learning tasks.

Figure 4 demonstrates ▶ online learning of an inverse dynamics model for the elbow joint (cf. Eq. 16) for a Sarcos Dexterous Robot Arm. The robot starts with no knowledge about this model, and it tracks some randomly varying desired trajectories with a proportional-derivative (PD) controller. During its movements, training data consisting of tuples $(\mathbf{q}, \dot{\mathbf{q}}, \ddot{\mathbf{q}}, \tau)$—which model a mapping from joint position, joint velocities, and joint accelerations $(\mathbf{q}, \dot{\mathbf{q}}, \ddot{\mathbf{q}})$ to motor torques τ—are collected (at about every 2 ms). Here, every data point is used to train a LWPR function approximator, which generates a feedforward command for the controller. The learning curve is shown in Fig. 4a.

Using a test set created beforehand, the model predictions of LWPR are compared every 1000 training points with that of a parameter estimation method. The parameter estimation approach fits the minimal number of parameters to an analytical model of the robot dynamics under an idealized rigid body dynamics (RBD) assumptions, using all training data (i.e., not incrementally). Given that the Sarcos robot is a hydraulic robot, the RBD assumption is not very suitable, and, as Fig. 4a shows, LWPR (in thick red line) outperforms the analytical model (in dotted blue line) after a rather short amount of training. After about 5 min of training (about 125,000 data points), very good performance is achieved, using about 350 local models. This example demonstrates (i) the quality of function approximation that can be achieved with LWPR and (ii) the online allocation of more local models as needed.

Learning Paired Inverse-Forward Models

Learning inverse models (such as inverse kinematics and inverse dynamics models) can be challenging since the inverse model problem is often a relation, not a function, with a one-to-many mapping. Applying any arbitrary nonlinear function approximation method to the inverse model problem can lead to unpredictably bad performance, as the training data can form non-convex solution spaces, in which averaging is inappropriate. Architectures such as ▶ mixture models (in particular, mixture density networks) have been proposed to address problems with non-convex solution spaces. A particularly interesting approach in control involves learning linearizations of a forward model (which is proper function) and learning an inverse mapping within the local region of the forward model.

Ting et al. (2008) demonstrated such a forward-inverse model learning approach with Bayesian LWR to learn an inverse kinematics model for a haptic robot arm (shown in Fig. 5) in order to control the end effector along a desired trajectory in task space. Training data was collected while the arm performed random sinusoidal movements within a constrained box volume of Cartesian space. Each sample consists of the arm's joint angles $\mathbf{q}$, joint velocities $\dot{\mathbf{q}}$, end-effector position in Cartesian space $\mathbf{x}$, and end-effector velocities $\dot{\mathbf{x}}$. From this data, a forward kinematics model is learned:

$$\dot{\mathbf{x}} = \mathbf{J}(\mathbf{q})\dot{\mathbf{q}} \tag{14}$$

Locally Weighted Regression for Control, Fig. 5 SensAble Phantom haptic robotic arm

where $\mathbf{J}(\mathbf{q})$ is the Jacobian matrix. The transformation from $\dot{\mathbf{q}}$ to $\dot{\mathbf{x}}$ can be assumed to be locally linear at a particular configuration $\mathbf{q}$ of the robot arm. Bayesian LWR is used to learn the forward model, and, as in LWPR, local models are only added if a training point is not already sufficiently covered by an existing local model. Importantly, the kernel functions in LWR are localized only with respect to $\mathbf{q}$, while the regression of each model is trained only on a mapping from $\dot{\mathbf{q}}$ to $\dot{\mathbf{x}}$—these geometric insights are easily incorporated as ▶ priors in Bayesian LWR, as they are natural to locally linear models. Incorporating these ▶ priors in other function approximators, e.g., ▶ Gaussian process regression, is not straightforward.

The goal of the robot task is to track a desired trajectory $(\mathbf{x}, \dot{\mathbf{x}})$ specified only in terms of x and z positions and velocities, i.e., the movement is supposed to be in a vertical plane in front of the robot, but the exact position of the vertical plane is not given. Thus, the task has one degree of redundancy, and the learning system needs to generate a mapping from $\{\mathbf{x}, \dot{\mathbf{x}}\}$ to $\dot{\mathbf{q}}$. Analytically, the inverse kinematics equation is

$$\dot{\mathbf{q}} = \mathbf{J}^{\#}(\mathbf{q})\dot{\mathbf{x}} - \alpha(\mathbf{I} - \mathbf{J}^{\#}\mathbf{J})\frac{\partial g}{\partial \mathbf{q}} \tag{15}$$

where $J^{\#}(\mathbf{q})$ is the pseudo-inverse of the Jacobian. The second term is a gradient descent optimization term for redundancy resolution, specified here by a cost function g in terms of joint angles $\mathbf{q}$.

To learn an inverse kinematics model, the local regions of $\mathbf{q}$ from the forward model can be reused since any inverse of $\mathbf{J}$ is locally linear within these regions. Moreover, for locally linear models, all solution spaces for the inverse model are locally convex, such that an inverse can be learned without problems. The redundancy issue can be solved by applying an additional weight to each data point according to a reward function. Since the experimental task is specified in terms of $\{\dot{x}, \dot{z}\}$, a reward is defined, based on a desired y coordinate, y_{des}, and enforced as a soft constraint. The resulting reward function is $g = e^{-\frac{1}{2}h(k(y_{des}-y)-\dot{y})^2}$, where k is a gain and h specifies the steepness of the reward. This ensures that the learned inverse model chooses a solution that pushes $\dot{y}$ toward y_{des}. Each forward local model is inverted using a weighted ▶ linear regression, where each data point is weighted by the kernel weight from the forward model and additionally weighted by the reward. Thus, a piecewise locally linear solution to the inverse problem can be learned efficiently.

Figure 6 shows the performance of the learned inverse model (Learnt IK) in a figure-eight tracking task. The learned model performs as well as the analytical inverse kinematics solution (Analytical IK), with root-mean-squared tracking errors in positions and velocities very close to that of the analytical solution.

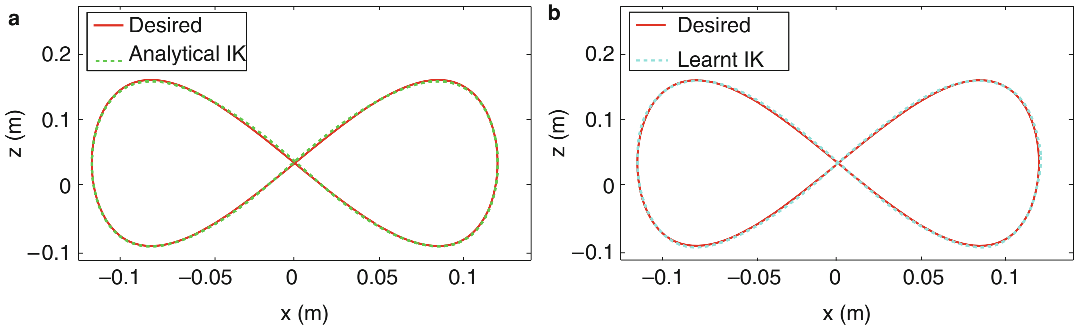
Learning Trajectory Optimizations

Mitrovic et al. (2008) have explored a theory for sensorimotor adaptation in humans, i.e., how humans replan their movement trajectories in the presence of perturbations. They rely on the iterative Linear Quadratic Gaussian (iLQG) algorithm (Todorov and Li 2004) to deal with the nonlinear and changing plant dynamics that may result from altered morphology, wear and tear, or external perturbations. They take advantage of the "on-the-fly" adaptation of locally weighted regression methods like LWPR to learn the forward dynamics of a simulated arm for the purpose of optimizing a movement trajectory between a start point and an end point.

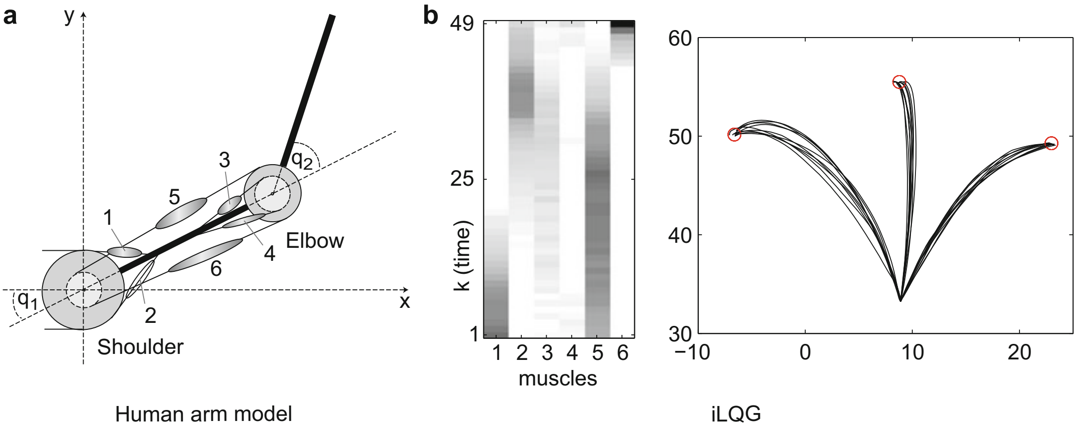
Figure 7a shows the diagram of a two degrees-of-freedom planar human arm model, which is actuated by four single-joint and two double-joint antagonistic muscles. Although kinematically simple, the system is over-actuated and, therefore, an interesting test bed because large redundancies in the dynamics have to be resolved. The dimensionality of the control signals makes adaptation processes (e.g., to external force fields) quite demanding.

The dynamics of the arm is, in part, based on standard RBD equations of motion:

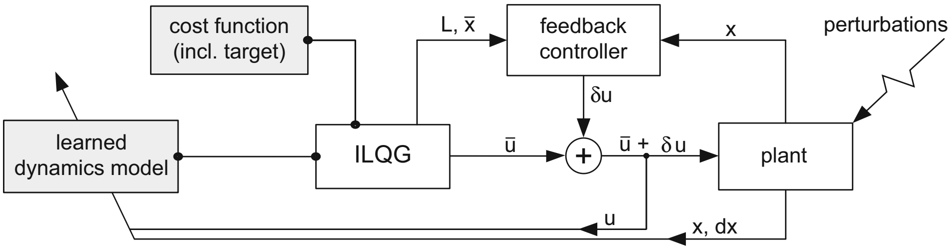
$$\tau = \mathbf{M}(\mathbf{q})\,\ddot{\mathbf{q}} + \mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})\,\dot{\mathbf{q}} \qquad (16)$$



Locally Weighted Regression for Control, Fig. 6 Desired versus actual trajectories for SensAble Phantom robot arm. (**a**) Analytical solution. (**b**) Learned solution



Locally Weighted Regression for Control, Fig. 7 (**a**) Human arm model with six muscles; (**b**) Optimized control sequence (*left*) and resulting trajectories (*right*) using the known analytic dynamics model. The control sequences (left target only) for each muscle (1–6) are drawn from bottom to top, with *darker gray* levels indicating stronger muscle activation

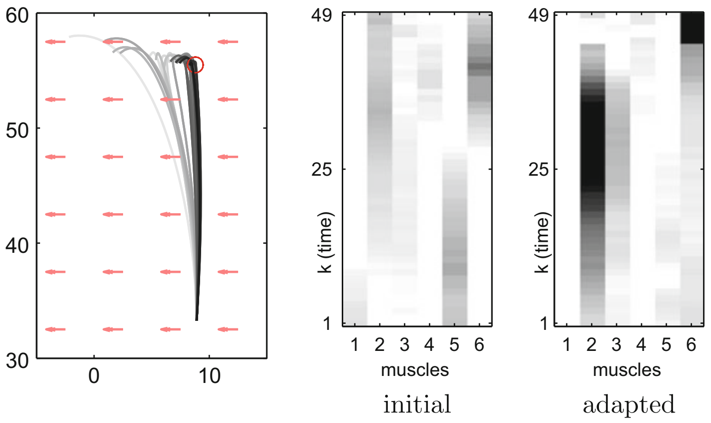


Locally Weighted Regression for Control, Fig. 8 Illustration of learning and control scheme of the iterative Linear Quadratic Gaussian (iLQG) algorithm with learned dynamics

where τ are the joint torques; $\mathbf{q}$ and $\dot{\mathbf{q}}$ are the joint angles and velocities, respectively; $\mathbf{M}(\mathbf{q})$ is the two-dimensional symmetric joint space inertia matrix; and $\mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})$ accounts for Coriolis and centripetal forces. Given the antagonistic muscle-based actuation, it is not possible to command joint torques directly. Instead, the effective torques from the muscle activations $\mathbf{u}$—which happens to be quadratic in $\mathbf{u}$—should be used. As a result, in contrast to standard torque-controlled robots, the dynamics equation in Eq. (16) is *non-linear in the control signals* $\mathbf{u}$.

The iLQG algorithm (Todorov and Li 2004) is used to calculate solutions to "localized" linear and quadratic approximations, which are iterated to improve the global control solution. However, it relies on an analytical forward dynamics model $\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}, \mathbf{u})$ and finite difference methods to compute gradients. To alleviate this requirement and to make iLQG adaptive, LWPR can be used to learn an approximation of the plant's forward dynamics model. Figure 8 shows the control diagram, where the "learned dynamics model" (the forward model learned by LWPR) is then updated in an ▸ online fashion with every iteration to cope with changes in dynamics. The resulting framework is called iLQG-LD (iLQG with learned dynamics).

Movements of the arm model in Fig. 7a are studied for fixed time horizon reaching movement. The manipulator starts at an initial position $\mathbf{q}_0$ and reaches toward a target $\mathbf{q}_{tar}$. The cost function to be optimized during the movement is a combination of target accuracy and amount of muscle activation (i.e., energy consumption). Figure 7b shows trajectories of generated movements for three reference targets (shown in red circles) using the feedback controller from iLQG with the analytical plant dynamics. The trajectories generated with iLQG-LD (where the forward



Locally Weighted Regression for Control, Fig. 9 Adaptation to a unidirectional constant force field (indicated by the *arrows*). *Darker lines* indicate better trained models. In particular, the left-most trajectory corresponds to the "initial" control sequence, which was calculated using the LWPR model *before* the adaptation process. The fully "adapted" control sequence results in a nearly straight line reaching movement

plant dynamics are learned with LWPR) are omitted as they are hardly distinguishable from the analytical solution.

A major advantage of iLQG-LD is that it does not rely on an accurate analytic dynamics model; this enables the framework to predict adaptation behavior under an ideal observer planning model. Reaching movements were studied where a constant unidirectional force field acting perpendicular to the reaching movement was generated as a perturbation (see Fig. 9 (left)). Using the iLQG-LD model, the manipulator gets strongly deflected when reaching for the target because the learned dynamics model cannot yet account for the "spurious" forces. However, when the deflected trajectory is used as training data and the dynamics model is updated ▸ online, the tracking improves with each new successive trial (Fig. 9 (left)). Please refer to Mitrovic et al. (2008) for more details. Aftereffects upon removing the force field, very similar to those observed in human experiments, are also observed.

Logic of Generality

Luc De Raedt
Department of Computer Science, Katholieke
Universiteit Leuven, Heverlee, Leuven, Belgium

Synonyms

Generality and logic; Induction as inverted deduction; Inductive inference rules; Is more general than; Is more specific than; Specialization

Definition

One hypothesis is *more general* than another one if it covers all instances that are also covered by the latter one. The former hypothesis is called a ▸ *generalization* of the latter one, and the latter a ▸ *specialization* of the former. When using logical formulae as hypotheses, the generality relation coincides with the notion of logical entailment, which implies that the generality relation can be analyzed from a logical perspective. The logical analysis of generality, which is pursued in this chapter, leads to the perspective of *induction as the inverse of deduction*. This forms the basis for an analysis of various logical frameworks for reasoning about generality and for traversing the space of possible hypotheses. Many of these frameworks (such as for instance, *θ-subsumption*) are employed in the field of ▸ inductive logic programming and are introduced below.

Motivation and Background

Symbolic machine learning methods typically learn by searching a hypothesis space. The hypothesis space can be (partially) ordered by the ▸ generality relation, which serves as the basis for defining operators to traverse the space as well as for pruning away unpromising parts of the search space. This is often realized through the use of refinement operators, that is, generalization and specialization operators. Because many learning methods employ a ▸ hypothesis language that is logical or that can be reformulated in logic, it is interesting to analyze the generality relation from a logical perspective. When using logical formulae as hypotheses, the generality relation closely corresponds to logical entailment. This allows us to directly transfer results from logic to a machine learning context. In particular, machine learning operators can be derived from logical inference rules. The logical theory of generality provides a framework for transferring these results. Within the standard setting of inductive logic programming, learning from entailment, specialization is realized through deduction, and generalization through induction, which is considered to be the inverse of deduction. Different deductive inference rules lead to different frameworks for generalization and specialization. The most popular one is that of θ-subsumption, which is employed by the vast majority of contemporary inductive logic programming systems.

Theory

A hypothesis g is *more general than* a hypothesis s if and only if g covers all instances that are also covered by s, more formally, if covers$(s) \subseteq$ covers(g), in which case, covers(h) denotes the set of all instances covered by the hypothesis h.

There are several possible ways to represent hypotheses and instances in logic (De Raedt 2008, 1997), each of which results in a different setting with a corresponding covers relation. Some of the best known settings are *learning from entailment*, learning from interpretations, and learning from proofs.

Learning from Entailment

In learning from entailment, both hypotheses and instances are logical formulae, typically *definite clauses*, which underlie the programming language Prolog (Flach 1994). Furthermore, when learning from entailment, a hypothesis h covers an instance e if and only if $h \models e$, that is, when h logically entails e, or equivalently, when e is a logical consequence of h. For instance, consider the hypothesis h:

```
  flies :- bird, normal.
  bird :- blackbird.
  bird :- ostrich.
```

The first clause or rule can be read as `flies` *if* `normal` *and* `bird`, that is, normal birds fly. The second and third states that blackbirds are birds. Consider now the examples e_1:

```
flies :- blackbird, normal, small.
```

and e_2:

```
flies :- ostrich, small.
```

Example e_1 is covered by h, because it is a logical consequence of h, that is, $h \models e_1$. On the other hand, example e_2 is not covered, which we denote as $h \not\models e_2$.

When learning from entailment, the following property holds:

Property 1 A hypothesis g is more general than a hypothesis s if and only if g logically entails s, that is, $g \models s$.

This is easy to see. Indeed, g is more general than s if and only if covers$(s) \subseteq$ covers(g) if and only if for all examples $e : (s \models e) \rightarrow (g \models e)$, if and only if $g \models s$. For instance, consider the hypothesis h_1:

```
flies :- blackbird, normal.
```

Because $h \models h_1$, it follows that h covers all examples covered by h_1, and hence, h generalizes h_1.

Property 1 states that the generality relation coincides with logical entailment when learning from entailment. In other learning settings, such as when *learning from interpretations*, this relationship also holds though the direction of the relationship might change.

Learning from Interpretations

In learning from interpretations, hypotheses are logical formulae, typically sets of definite clauses, and instances are interpretations. For propositional theories, interpretations are assignments of truth-values to propositional variables. For instance, continuing the `flies` illustration, two interpretations could be

{`blackbird, bird, normal, flies`} and {`ostrich, small`}

where we specify interpretations through the set of propositional variables that are true. An interpretation specifies a kind of possible world. A hypothesis h then covers an interpretation if and only if the interpretation is a model for the hypothesis. An interpretation is a model for a hypothesis if it satisfies all clauses in the hypothesis. In our illustration, the first interpretation is a model for the theory h, but the second is not. Because the condition part of the rule `bird :- ostrich.` is satisfied in the second interpretation (as it contains ostrich), the conclusion part, that is, bird, should also belong to the interpretation in order to have a model. Thus, the first example is covered by the theory h, but the second is not.

When learning from interpretations, a hypothesis g is more general than a hypothesis s if and only if for all examples e: (e is a model of s) → (e is a model of g), if and only if $s \models g$.

Because the learning from entailment setting is more popular than the learning from interpretations setting, we shall employ in this section the usual convention that states that one hypothesis g is more general than a hypothesis s if and only if $g \models s$.

An Operational Perspective

Property 1 lies at the heart of the theory of *inductive logic programming* and generalization because it directly relates the central notions of logic with those of machine learning (Muggleton and De Raedt 1994). It is also extremely useful because it allows us to directly transfer results from logic to machine learning.

This can be illustrated using traditional deductive inference rules, which start from a set of formulae and derive a formula that is entailed by the original set. For instance, consider the resolution inference rule for propositional definite clauses:

$$\frac{h \leftarrow g, a_1, \ldots, a_n, \text{ and } g \leftarrow b_1, \ldots, b_m}{h \leftarrow b_1, \ldots, b_m, a_1, \ldots, a_n,}. \quad (1)$$

This inference rule starts from the two rules above the line and derives the so-called *resolvent* below the line. This rule can be used to infer h_1 from h. An alternative deductive inference rule adds a condition to a rule:

$$\frac{h \leftarrow a_1, \ldots, a_n}{h \leftarrow a, a_1, \ldots, a_n,} \quad (2)$$

This rule can be used to infer that h_1 is more general than the clause used in example e_1. In general, a deductive inference rule can be written as

$$\frac{g}{s}. \quad (3)$$

If s can be inferred from g and the operator is *sound*, then $g \models s$. Thus, applying a deductive inference rule realizes specialization, and hence, deductive inference rules can be used as specialization operators. A *specialization operator* maps a hypothesis onto a set of its specializations. Because specialization is the inverse of generalization, *generalization operators* – which map a hypothesis onto a set of its generalizations – can be obtained by inverting deductive inference rules. The inverse of a deductive inference rule written in format (3) works from bottom to top, that is, from s to g. Such an inverted deductive inference rule is called an *inductive* inference rule. This leads to the view of induction as the inverse of deduction. This view is operational as it implies that each deductive inference rule can be inverted into an inductive one, and, also, that each inference rule provides an alternative framework for generalization.

An example of a generalization operator is obtained by inverting the adding condition rule (2). It corresponds to the well-known "dropping condition" rule (Michalski 1983). As will be seen soon, it is also possible to invert the resolution principle (1).

Before deploying inference rules, it is necessary to determine their properties. Two desirable properties are *soundness* and *completeness*. These properties are based on the repeated application of inference rules. Therefore, we write $g \vdash rs$ when there exists a sequence of hypotheses $h_1, \ldots, h_n$ such that

$$\frac{g}{h_1}, \frac{h_1}{h_2}, \ldots, \frac{h_n}{s} \text{ using } r. \quad (4)$$

A set of inference rules r is *sound* whenever $g \vdash rs$ implies $g \models s$; and *complete* whenever $g \models s$ implies $g \vdash rs$. In practice, soundness is always enforced though completeness is not always required in a machine learning setting. When working with incomplete rules, one should realize that the generality relation "$\vdash r$" is weaker than the logical one "$\models$."

The most important logical frameworks for reasoning about generality, such as θ-subsumption and resolution, are introduced below using the above introduced logical theory of generality.

Frameworks for Generality

Propositional Subsumption

Many propositional learning systems employ hypotheses that consist of rules, often definite clauses as in the `flies` illustration above. The propositional subsumption relation defines a generality relation among clauses and is defined through the adding condition rule (2). The properties follow from this inference rule by applying the logical theory of generalization presented above. More specifically, the generality relation $\vdash a$ induced by the adding condition rule states that a clause g is more general than a clause s, if s can be derived from g by adding a sequence of conditions to g. Observing that a clause $h \leftarrow a_1, \ldots, a_n$ is a disjunction of literals $h \vee \neg a_1 \vee \cdots \vee \neg a_n$ allows us to write it in set notation as $\{h, \neg a_1, \ldots, \neg a_n\}$. The soundness and completeness of propositional subsumption then follow from

$$g \vdash_a s \text{ if and only if } g \subseteq s \text{ if and only if } g \models s, \tag{5}$$

which also states that g subsumes s if and only if $g \subseteq s$.

The propositional subsumption relation induces a complete lattice on the space of possible clauses. A *complete lattice* is a partial order – a reflexive, antisymmetric, and transitive relation – where every two elements posses a unique least upper and greatest lower bound. An example lattice for rules defining the predicate `flies` in terms of `bird`, `normal`, and `small` is illustrated in the Hasse diagram depicted in Fig. 1.

The Hasse diagram also visualizes the different operators that can be used. The *generalization* operator ρ_g maps a clause to the set of its parents in the diagram, whereas the *specialization* operator ρ_s maps a clause to the set of its children. So far, we have defined such operators *implicitly* through their corresponding inference rules. In the literature, they are often defined *explicitly*:

$$\rho_g(h \leftarrow a_1, \ldots a_n)$$
$$= \{h \leftarrow a_1, \ldots a_{i-1}, a_{i+1}, \ldots, a_n | i = 1, \ldots, n\}. \tag{6}$$

In addition to using the inference rules directly, some systems such as Golem (Muggleton and Feng 1990) also exploit the properties of the underlying lattice by computing the least upper bound of two formulae. The least upper bound operator is known under the name of least general generalization (lgg) in the machine learning literature. It returns the least common ancestor in the Hasse diagram. Using a set notation for clauses, the definition of the lgg is:

$$\text{lgg}(c_1, c_2) = c_1 \cap c_2. \tag{7}$$

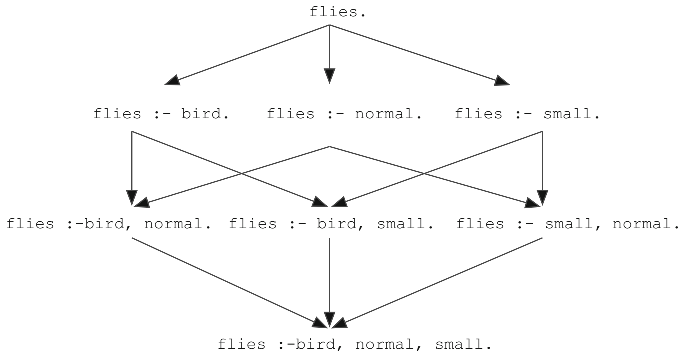
The least general generalization operator is used by machine learning systems that follow a cautious generalization strategy. They take two clauses corresponding to positive examples and minimally generalize them.

θ-Subsumption

The most popular framework for generality within inductive logic programming is θ-subsumption (Plotkin 1970). It provides a generalization relation for clausal logic and it extends propositional subsumption to first order logic.

A *definite clause* is an expression of the form $h \leftarrow a_1, \ldots, a_n$ where h and the a_i are logical atoms. An *atom* is an expression of the form $p(t_1, \ldots, t_m)$ where p is a *predicate name* (or, the name of a relation) and the t_i are terms. A *term* is either a constant (denoting an object in the domain of discourse), a variable, or a structured term of the form $f(u_1, \ldots, u_k)$ where f is a functor symbol (denoting a function in the domain of discourse) and the u_i are terms, see Flach (1994) for more details. Consider for instance the clauses

```
likes(X,Y) :- neighbours(X,Y).
likes(X,husbandof(Y)) :- likes(X,Y).
likes(X,tom) :- neighbours(X,tom),
             male(X).
```



Logic of Generality, Fig. 1 The Hasse diagram for the predicate `flies`

The first clause states that `X likes Y` if `X` is a `neighbour` of `Y`. The second one that `X likes` the `husband` of `Y` if `X likes Y`. The third one that all `male neighbours` of `tom` like `tom`.

θ-Subsumption is based not only on the adding condition rule (2) but also on the *substitution rule*:

$$\frac{g}{g\theta}. \tag{8}$$

The substitution rule applies a substitution θ to the definite clause g. A substitution $\{V_1/t_1, \ldots, V_n/t_n\}$ is an assignment of terms to variables. Applying a substitution to a clause c yields the instantiated clause, where all variables are simultaneously replaced by their corresponding terms.

θ-subsumption is then the generality relation induced by the substitution and the adding condition rules. Denoting this set of inference rules by t, we obtain our definition of θ-subsumption:

$$\begin{aligned} g\theta\text{-subsumption}s &\text{ if and only if } g \vdash_t s \\ &\text{if and only if } \exists\theta : g\theta \subseteq s. \end{aligned} \tag{9}$$

For instance, the first clause for `likes` subsumes the third one with the substitution `{Y/tom}`.

- θ-subsumption has some interesting properties:
- θ-subsumption is sound.
- θ-subsumption is complete for clauses that are not self-recursive. It is incomplete for self-recursive clauses such as

```
nat(s(X)) :- nat(X)
nat(s(s(Y))) :- nat(Y)
```

  for which one can use resolution to prove that the first clause logically entails the second one, even though it does not θ-subsume it.
- Deciding θ-subsumption is an NP-complete problem.

Because θ-subsumption is relatively simple and decidable whereas logical entailment between single clauses is undecidable, it is used as the generality relation by the majority of inductive logic programming systems. These systems typically employ a specialization or refinement operator to traverse the search space. To guarantee systematic enumeration of the search space, the specialization operator ρ_s can be employed. $\rho_s(c)$ is obtained by applying the adding condition or substitution rule with the following restrictions.

- The adding condition rule only adds atoms of the form $p(V_1, \ldots, V_n)$, where the V_i are variables not yet occurring in the clause c.
- The substitution rule only employs *elementary substitutions*, which are of the form
  - $\{X \,/\, Y\}$, where X and Y are two variables appearing in c
  - $\{V \,/\, ct\}$, where V is a variable in c and ct a constant

- $\{V / f(V_1, \ldots, V_n)\}$, where V is a variable in c, f a functor of arity n and the V_i are variables not yet occurring in c.

A generalization operator can be obtained by inverting ρ_s, which requires one to invert substitutions. Inverting substitutions is not easy. While applying a substitution $\theta = \{\texttt{V/a}\}$ to a clause c replaces all occurrences of `V` by `a` and yields a unique clause $c\theta$, applying the substitution rule in the inverse direction does not necessarily yield a unique clause. If we assume the elementary substitution applied to c with

$$\frac{c}{q(a,a)}. \tag{10}$$

was $\{\texttt{V/a}\}$, then there are at least three possibilities for c: `q(a,V)`, `q(V,a)`, and `q(V,V)`.

θ-subsumption is reflexive, transitive but unfortunately not anti-symmetric, which can be seen by considering the clauses

```
parent(X,Y) :- father(X,Y).
parent(X,Y) :- father(X,Y),
               father(U,V).
```

The first clause clearly subsumes the second one because it is a subset. The second one subsumes the first with the substitution {`X/U`, `V/Y`}. The two clauses are therefore equivalent under θ-subsumption, and hence also logically equivalent. The loss of the anti-symmetry complicates the search process. The naive application of the specialization operator ρs may yield syntactic specializations that are logically equivalent. This is illustrated above where the second clause for `parent` is a refinement of the first one using the adding condition rule. In this way, useless clauses are generated, and if the resulting clauses are further refined, there is a danger that the search will end up in an infinite loop.

Plotkin (1970) has studied the quotient set induced by θ-subsumption and proven various interesting properties. The quotient set consists of classes of clauses that are equivalent under θ-subsumption. The class of clauses equivalent to a given clause c is denoted by

$$[c] = \{c' | c' \text{ is equivalent with } c \text{ under } \theta\text{-subsumption}\}. \tag{11}$$

Plotkin proved that

- The quotient set is well-defined w.r.t. θ-subsumption.
- There is a representative, a canonical form, of each equivalence class, the so-called *reduced clause*. The reduced clause of an equivalence class is the shortest clause belonging to class. It is unique up to variable renaming. For instance, in the `parent` example above, the first clause is in reduced form.
- The quotient set forms a complete lattice, which implies that there is a least general generalization of two equivalence classes. In the inductive logic programming literature, one often talks about the least general generalization of two clauses.

Several variants of θ-subsumption have been developed. One of the most important ones is that of *OI*-subsumption (Esposito, Laterza, Malerba, and Semeraro, 1996). For functor-free clauses, it modifies the substitution rule by disallowing substitutions that unify two variables or that substitute a variable by a constant already appearing in the clause. The advantage is that the resulting relation is anti-symmetric, which avoids some of the above mentioned problems with refinement operators. On the other hand, the minimally general generalization of two clauses is not necessary unique, and hence, there exists no least general generalization operator.

Inverse Resolution

Applying resolution is a sound deductive inference rule and therefore realizes specialization. Reversing it yields inductive inference rules or generalization operators (Muggleton 1987; Muggleton and Buntine 1988). This is typically realized by combining the resolution principle with a copy operator. The resulting rules are called *absorption* (12) and *identification* (13). They start from the clauses below and induce the clause above the line. They are shown here only for the propositional case, as the first order case requires one to deal with substitutions as well as inverse substitutions.

$$\frac{h \leftarrow g, a_1, \ldots, a_n, \text{ and } g \leftarrow b_1, \ldots, b_m}{h \leftarrow b_1, \ldots, b_m, a_1, \ldots, a_n, \text{ and } g \leftarrow b_1, \ldots, b_m}. \tag{12}$$

$$\frac{h \leftarrow g, a_1, \ldots, a_n, \text{ and } g \leftarrow b_1, \ldots, b_m}{h \leftarrow b_1, \ldots, b_m, a_1, \ldots, a_n, \text{ and } h \leftarrow g, a_1, \ldots, a_n}. \tag{13}$$

Other interesting inverse resolution operators perform predicate invention, that is, they introduce new predicates that were not yet present in the original data. These operators invert two resolution steps. One such operator is the *intra-construction* operator (14). Applying this operator from bottom to top introduces the new predicate q that was not present before.

$$\frac{q \leftarrow l_1, \ldots, l_k, \text{ and } p \leftarrow k_1, \ldots, k_n, q \text{ and } q \leftarrow l'_1, \ldots, l'_m}{p \leftarrow k_1, \ldots, k_n, l_1, \ldots, l_k \text{ and } q \leftarrow k_1, \ldots, k_n, l'_1, \ldots, l'_m}. \tag{14}$$

The idea of inverting the resolution operator is very appealing because it aims at inverting the most popular deductive inference operator, but is also rather complicated due to the nondeterminism and the need to invert substitutions. Due to these complications, there are only few systems that employ inverse resolution operators.

Background Knowledge

Inductive logic programming systems employ background knowledge during the learning process. Background knowledge typically takes the form of a set of clauses B, which is then used by the covers relation. When learning from entailment in the presence of background knowledge B an example e is covered by a hypothesis h if and only if $B \cup h \models e$. This notion of coverage is employed in most of the work on inductive logic programming. In the intial `flies` example, the two clauses defining `bird` would typically be considered background knowledge.

The incorporation of background knowledge in the induction process has resulted in the frameworks for generality *relative* to a background theory. More formally, a hypothesis g is more general than a hypothesis s relative to the background theory B if and only if $B \cup g \models s$. The only inference rules that deal with multiple clauses are those based on (inverse) resolution. The other frameworks can be extended to cope with this generality relation following the logical theory of generalization. Various frameworks have been developed along these lines. Some of the most important ones are relative subsumption (Plotkin 1971) and generalized subsumption (Buntine 1998), which extend θ-subsumption and the notion of least general generalization toward the use of background knowledge. Computing the least general generalization of two clauses relative to the background theory is realized by first computing the most specific clauses covering the examples with regard to the background theory and then generalizing them using the least general generalization operator of θ-subsumption.

The first step is the most interesting one, and has been tackled under the name of *saturation* (Rouveirol 1994) and *bottom-clauses* (Muggleton 1995). We illustrate it within the framework of inverse entailment due to (Muggleton 1995). The bottom clause $\perp(c)$ of a clause c with regard to a background theory B is the most specific clause $\perp(c)$ such that

$$B \cup \perp(c) \models c. \tag{15}$$

If B consist of

```
polygon :- rectangle.
rectangle :- square.
oval :- circle.
```

and the example c is

```
positive :- red, square.
```

Then the bottom-clause $\bot\,(c)$ is

```
 positive :- red, rectangle,
                 square, polygon.
```

The bottom-clause is useful because it only lists those atoms that are relevant to the example, and only generalizations (under θ-subsumption) of $\bot\,(c)$ will cover the example. For instance, in the illustration, the bottom-clause mentions neither `oval` nor `circle` as clauses for `pos` containing these atoms will never cover the example clause c. Once the bottom-clause covering an example has been found the search process continues as if no background knowledge were present. Either specialization operators (typically under θ-subsumption) would search the space of clauses more general than $\bot\,(c)$, or the least general generalization of multiple bottom-clauses would be computed.

Equation (15) is equivalent to

$$B \cup \neg c \models \neg\bot(c). \tag{16}$$

which explains why the bottom-clause is computed by finding all factual consequences of $B \cup \neg c$ and then inverting the resulting clause again. On the example:

$\neg c = \{\neg$`positive, red, square`$\}$

and the set of all consequences is

$\neg\bot(\mathrm{c}) = \neg c \cup \{$`rectangle, polygon\verb`$\}$

which then yields $\bot(c)$ mentioned above. When dealing with first order logic, bottom-clauses can become infinite, and therefore, one typically imposes further restrictions on the atoms that appear in bottom-clauses. These restrictions are part of the *language bias*.

The textbook by Nienhuys-Cheng and de Wolf (1997) is the best reference for an in-depth formal description of various frameworks for generality in logic, in particular, for θ-subsumption and some of its variants. The book by De Raedt (2008) contains a more complete introduction to inductive logic programming and relational learning, and also introduces the key frameworks for generality in logic. An early survey of inductive logic programming and the logical theory of generality is contained in Muggleton and De Raedt (1994). Plotkin (1970, 1971) pioneered the use θ-subsumption and relative subsumption (under a background theory) for machine learning. Buntine (1998) extended these frameworks toward generalized subsumption, and Esposito et al. (1996) introduced *OI*-subsumption. Inverse resolution was first used in the system Marvin (Sammut and Banerji 1986), and then elaborated by Muggleton (1987) for propositional logic and by Muggleton and Buntine (1988) for definite clause logic. Various learning settings are studied by De Raedt (1997) and discussed extensively by De Raedt (2008). They are also relevant to probabilistic logic learning and ▸ statistical relational learning.

Logic Program

A logic program is a set of logical rules or ▶ clauses. Logic programs are employed to answer queries using the ▶ resolution inference rule. For example, consider the following logic program:

```
grandparent(X,Y) :- parent(X,Z),
                    parent(Z,Y).
parent(X,Y) :- father(X,Y).
parent(X,Y) :- mother(X,Y).
father(charles, william).
   mother(diana, william).
father(philip, charles).
   mother(elizabeth, charles).
father(john, diana).
   mother(frances, diana).
```

Using resolution we obtain the following answers to the query `:-grandparent(X,Y)`:

```
  X = philip,     Y = william ;
  X = john,       Y = william ;
  X = elizabeth,  Y = william ;
  X = frances,    Y = william.
```

Machine Learning and Game Playing

Johannes Fürnkranz
Knowledge Engineering Group, TU Darmstadt,
Darmstadt, Deutschland
Department of Information Technology,
University of Leoben, Leoben, Austria

Abstract

Game playing is a major application area for research in artificial intelligence in general (Schaeffer and van den Herik 2002) and for machine learning in particular (Fürnkranz and Kubat 2001). Traditionally, the field is concerned with learning in strategy games such as tic-tac-toe (Michie 1963), checkers (▶ Samuel's checkers player), backgammon (▶ TD-Gammon), chess (Baxter et al. 2000; Björnsson and Marsland 2003; Donninger and Lorenz 2006; Sadikov and Bratko 2006), Go (Silver et al. 2016), Othello (Buro 2002), poker (Billings et al. 2002), or bridge (Amit and Markovitch 2006). However, recently computer and video games have received increased attention (Laird and van Lent 2001; Spronck et al. 2006; Ponsen et al. 2006).

Motivation and Background

Since the early days of the field, game-playing applications have been popular test beds for machine learning. This has several reasons:

- *Games allow to focus on intelligent reasoning.* Other components of intelligent agents, such as perception or physical actions, can be ignored.
- *Games are easily accessible.* A typical game-playing environment can be implemented within a few days, often hours. Exceptions are real-time computer games, for which only a few open-source test beds exist.
- *Games are very popular.* It is not very hard to describe the agent's task to the general public, and they can easily appreciate the achieved level of intelligence.

There are various types of problems that keep reoccurring in game-playing applications, for which solutions with machine learning methods are desirable, including opening book learning, learning of evaluation functions, player modeling, and others, which will be dealt with in the following.

Structure of the Learning System

Game-playing applications offer various challenges for machine learning. A wide variety of learning techniques have been used for tackling these problems. We cannot provide details on the learning algorithms here, but will instead focus on the problems and give some of the most relevant and most recent pointers to the literature. A more detailed survey can be found in Fürnkranz (2001).

C. Sammut, G.I. Webb (eds.), *Encyclopedia of Machine Learning and Data Mining*,
DOI 10.1007/978-1-4899-7687-1

Learning of Evaluation Functions

The most extensively studied learning problem in game playing is the automatic adjustment of the weights of an evaluation function. Typically, the situation is as follows: the game programmer has provided the program with a library of routines that compute important features of the current board position (e.g., the number of pieces of each kind on the board, the size of the territory controlled, etc.). What is not known is how to combine these pieces of knowledge and how to quantify their relative importance. Most frequently, these parameters are combined linearly, so that the learning task is to adjust the weights of a weighted sum. The main problem is that there are typically no direct target values that could be used as training signals. Exceptions are games or endgames that have been solved completely, which are treated further below. However, in general, algorithms use ▸ preference learning (where pairs of moves or positions are labeled according to which one is preferred by an expert player) or ▸ reinforcement learning (where moves or positions are trained based on information about the eventual outcome of the game) for tuning the evaluation functions.

The key problem with reinforcement learning approaches is the ▸ credit assignment problem, i.e., even though a game has been won (lost), there might be bad (good) moves in the game. Reinforcement learning takes a radical stance at this problem, giving all positions the same reinforcement signal, hoping that erroneous signals will be evened out over time. An early classic in this area is MENACE, a tic-tac-toe player that simulates reinforcement learning with delayed rewards (Michie 1963) using a stack of matchboxes, one for each position, each containing a number of beads in different colors, which represent the different legal moves in the position. Moves are selected by randomly drawing a bead out of the box that represents the current position. After a game is won, all played moves are reinforced by adding beads of the corresponding colors to these boxes; in the case of a lost game, corresponding beads are removed, thereby decreasing the probability that the same move will be played again.

The premier example of a system that has tuned its evaluation function to expert strength by playing millions of games against itself is the backgammon program ▸ TD-Gammon. Its key innovation was the use of a ▸ neural network instead of a position table, so that the reinforcement signal can be generalized to new unseen positions. Many authors have tried to copy TD-Gammon's learning methodology to other games (Ghory 2004). None of these successors, however, achieved a performance that was as impressive as TD-Gammon's. The reason for this seems to be that backgammon has various characteristics that make it perfectly suited for learning from self-play. Foremost, among these are the facts that the dice rolls guarantee sufficient variability, which allows to use training by self-play without the need for an explicit exploration/exploitation trade-off, and that it only requires a very limited amount of search, which allows to ignore the dependencies of search algorithm and search heuristic. These points have, for example, been addressed with limited success in the game of chess, where the program KnightCap (Baxter et al. 2000) integrates ▸ temporal difference learning into a game-tree search by using the final positions of the principal variation for updates and by using play on a game server for exploration.

Many aspects of evaluation function learning are still discussed in the current literature, including whether there are alternatives to reinforcement learning (e.g., evolutionary algorithms), which training strategies should be used (e.g., self-play vs. play against a teacher), etc. One of the key problems that has already been mentioned in ▸ Samuel's Checkers Player, namely, the automated construction of useful features, remains still largely unsolved. Some progress has, e.g., been made in the game of Othello, where a simple algorithm, very much like ▸ APriori, has been shown to produce valuable conjunctions of basic features (Buro 2002).

Learning Search Control

A more challenging but considerably less investigated task is to automatically tune the various parameters that control the search in game-playing programs. These parameters influence, for example, how aggressive the search algorithm is in pruning unpromising parts of the search tree and which lines are explored in more depth. The key problem here is that these parameters are intertwined with the search algorithm and cannot be optimized independently, making the process very tedious and expensive.

There have been a few attempts to use ▸ explanation-based learning to automatically learn predicates that indicate which branches of the search tree are the most promising to follow. These approaches are quite related to various uses of ▸ explanation-based learning in planning, but these could not be successfully be carried over to game-tree search.

Björnsson and Marsland (2003) present a *gradient descent* approach that minimizes the total number of game positions that need to be searched in order to successfully solve a number of training problems. The idea is to adjust each parameter in proportion to its sensitivity to changes in the number of searched nodes, which is estimated with additional searches. The amount of positions that can be searched for each training position is bounded in order to avoid infinite solution times for individual problems, and simulated annealing is used to ensure convergence.

Monte Carlo Tree Search

Automated tuning of evaluation functions and search control parameters does not work well for all games. For many years, research in computer Go has not made much progress with conventional search-based and pattern learning algorithms. However, a breakthrough came when Monte Carlo techniques could be combined with tree search algorithms. The basic algorithm interleaves four phases (Browne et al. 2012):

1. *Selection:* select a node of the current search tree for expansion
2. *Expansion:* generate one (or more) of the successor nodes for the selected node
3. *Simulation:* starting from these nodes, simulate a game until a terminal state is reached
4. *Backpropagation:* propagate the observed result back to the root of the tree

The best known of such methods, UCT, may be viewed as the extension of the UCB method for solving ▸ k-armed bandit problems to search trees (Kocsis and Szepesvári 2006). In the selection phase, UCT computes the following term for choosing the next node at each interior node of the current tree:

$$\mathrm{UCT} = \bar{X}_j + C \cdot \sqrt{\frac{2 \ln n}{n_j}} \qquad (1)$$

where X_j is the average reward that has been observed at node j, n_j is the number of times the node has been visited, and n is the number of times its predecessor has been visited. Clearly, it can be seen that nodes with a high utility are generally preferred (exploitation), but the second term also increases the chances that nodes that have been rarely visited are selected (exploration). The parameter C can be adjusted to trade off exploration and exploitation. From the selected node, a single random rollout is conducted, and its outcome is used to adapt the X_j values in all visited nodes in the search tree.

MCTS is generally applicable but has been particularly successful in game playing, most notably in Computer Go. In particular, AlphaGo (Silver et al. 2016), which employs deep learning for training value networks to evaluate positions and policy networks to bias the simulation phase of MCTS towards promising moves, became the first computer player to beat a world-class Go player in a celebrated 5-game match in March 2016.

Opening Book Learning

Human game players not only rely on their ability to estimate the value of moves and positions but are often also able to play certain positions "by heart," i.e., without having to think about their next move. This is the result of home preparation, opening study, and *rote learning* of important lines and variations. As computers do not forget, the use of an opening book provides an easy way for increasing their playing strength. However, the construction of such opening books can be quite laborious, and the task of keeping it up-to-date is even more challenging.

Commercial game-playing programs, in particular chess programs, have thus resorted to tools that support the automatic construction of opening from large game databases. The key challenge here is that one cannot rely on statistical information alone: a move that has been successfully employed in hundreds of games may be refuted in a single game. Donninger and Lorenz (2006) describe an approach that evaluates the "goodness" of a move based on a heuristic formula that has been found by experimentation. This value is then added to the result of a regular alpha-beta search. The technique has been so successful that the chess program HYDRA, probably the strongest chess program today, has abandoned conventionally large man-made (and therefore error-prone) error books. Similar techniques have also been used in games like Othello (Buro 2002).

Pattern Discovery

In addition to databases of common openings and huge game collections, which are mostly used for the tuning of evaluation functions or the automatic generation of opening books (see above), many games or subgames have already been solved, i.e., databases are available in which the game-theoretic value of positions of these subgames can be looked up. For example, in chess all endgames with up to six pieces and in checkers all ten-piece endgames have been solved (Schaeffer et al. 2003). Other games, such as Connect-4, are solved completely, i.e., all possible positions have been evaluated, and the game-theoretic value of the starting position has been determined. Many of these databases are readily available; some of them (in the domains of chess, Connect-4, and tic-tac-toe) are part of the UCI repository for machine learning databases.

The simplest learning task is to train a classifier that is able to decide whether a given game position is a game-theoretical win or loss (or draw). In many cases, this is insufficient. For example, in the chess endgame king-rook-king, any position in which the white rook cannot be immediately captured and in which black is not a stalemate is, in principle, won by white. However, in order to actually win the game, it is not sufficient to simply make moves that avoid rook captures and stalemates. Thus, most databases contain the maximal number of moves that are needed for winning the position. Predicting this is a much harder, largely unsolved problem (some recent work can be found in Sadikov and Bratko 2006). In addition to the game-specific knowledge that could be gained by the extraction of patterns that are indicative of won positions, another major application could be a knowledge-based compression of these databases (the collection of all perfect-play chess endgame databases with up to six men is 1.2 TB in a very compressed database format; the win/loss checkers databases with up to ten men contain about 4×10^{13} positions compressed into 215 GB Schaeffer et al. 2003).

Player Modeling

Player modeling is an important research area in game playing, which can serve several purposes. The goal of *opponent modeling* is to improve the capabilities of the machine player by allowing it to adapt to its opponent and exploit his weaknesses. Even if a game-theoretical optimal solution to a game is known, a system that has the capability to model its opponent's behavior may obtain a higher reward. Consider, for example, the game of *rock-paper-scissors* aka *RoShamBo*, where either player can expect to win one third of the games (with one third of draws) if both players play their optimal strategies (i.e., randomly select one of their three moves). However, against a player that always plays *rock*, a player that is able to adapt his strategy to always playing *paper* can maximize his reward, while a player that sticks with the "optimal" random strategy will still win only one third of the games. One of the grand challenges in this line of work is a game like poker, where opponent modeling is crucial to improve over game-theoretical optimal play (Billings et al. 2002).

Player modeling is also of increasing importance in commercial computer games (see below). For one, ▸ behavioral cloning techniques could be used to increase the playing strength or credibility of artificial characters by copying the strategies of expert human players. Moreover, the playing strength of the characters can be adapted to the increasing skill level of the human player. Finally, agents that can be trained by nonprogrammers can also play an important role. For example, in massive multiplayer online role-playing games (MMORPGs), an avatar that is trained to simulate a user's game-playing behavior could take his creator's place at times when the human player cannot attend to his game character.

Commercial Computer Games

In recent years, the computer game industry has discovered artificial intelligence as a necessary ingredient to make games more entertaining and challenging, and, vice versa, AI has discovered computer games as an interesting and rewarding application area (Laird and van Lent 2001). In comparison to conventional strategy games, computer game applications are more demanding, as the agents in these games typically have to interact with a large number of partner or enemy agents in a highly dynamic, real-time environment, with incomplete knowledge about its states. Tasks include off-line or online player modeling (see above), virtual agents with learning capabilities, optimization of plans and processes, etc.

Computer players in games are often controlled with scripts. *Dynamic scripting* (Spronck et al. 2006) is an online ▸ reinforcement learning technique that is designed to be integrated into scripting languages of game-playing agents. Contrary to conventional reinforcement learning agents, it updates the weights of all actions for a given state simultaneously. This sacrifices guaranteed convergence, but this is desirable in a highly dynamic game environment. The approach was successfully applied to improving the strength of computer-controlled characters and increasing the entertainment value of the game by automated scaling of the difficult level of the game AI to the human player's skill level. Similar to the problem of constructing suitable features for the use in evaluation functions, the basic tactics of the computer player had to be handcoded. Ponsen et al. (2006) extend dynamic scripting with an ▸ evolutionary algorithm for automatically constructing the tactical behaviors.

Machine learning techniques are not only used for controlling players but also for tasks like skill estimation, for example, TrueSkill^{TM} (Herbrich et al. 2007), a Bayesian skill rating system which is used for ranking players in games on the Microsoft's Xbox 360. SAGA-ML (Southey et al. 2005) is a machine learning system for supporting game designers in improving the playability of a game.

Despite the large commercial potential, research in this area has just started, and the number of workshops and publications on this topic is rapidly increasing. For a list of commercial games using AI techniques, we refer to http://www.gameai.com.

Machine Learning for IT Security

Philip K. Chan
Florida Institute of Technology, Melbourne, FL, USA

Definition

The prevalence of information technology (IT) across all segments of society, greatly improves the accessibility of information, however, it also provides more opportunities for individuals to act with malicious intent. Intrusion detection is the task of identifying attacks against computer systems and networks. Based on data/behavior observed in the past, machine learning methods can automate the process of building detectors for identifying malicious activities.

Motivation and Background

Cyber security often focuses on preventing attacks using authentication, filtering, and encryption techniques, but another important facet is detecting attacks once the preventive measures are breached. Consider a bank vault: thick steel doors prevent intrusions, while motion and heat sensors detect intrusions. Prevention and detection complement each other to provide a more secure environment.

How do we know if an attack has occurred or has been attempted? This requires analyzing huge volumes of data gathered from the network, host, or file systems to find suspicious activities. Two general approaches exist for this problem: *misuse detection* (also known as *signature detection*), where we look for patterns signaling well-known attacks, and ▸ *anomaly detection*, where we look for deviations from normal behavior.

Misuse detection usually works reliably on known attacks (though false alarms and missed detections are not uncommon), but has the obvious disadvantage of not being capable of detecting new attacks. Though anomaly detection can detect novel attacks, it has the drawback of not being capable of discerning intent; it can only signal that some event is unusual, but not necessarily hostile, thus generating false alarms. A desirable system would employ both approaches. Misuse detection methods are more well understood and widely applied; however, anomaly detection is much less understood and more challenging.

Can we automate the process of building software for misuse and anomaly detection? Machine learning techniques hold promise in efficiently analyzing large amounts of recent activities, identifying patterns, and building detectors.

Besides computer attacks, spam email messages, though not intended to damage computer systems or data, are annoying and waste system resources. To construct spam detectors from large amounts of email messages, machine learning techniques have been used (see "References" and "Recommended Reading" for more).

Structure of Learning System

Machine learning can be used to construct models for misuse as well as anomaly detection.

Misuse Detection

For misuse detection, the machine learning goal is to identify characteristics of known attacks. One approach is to learn the difference between attacks and normal events, which can be casted as a classification problem. Given examples of labeled attacks and normal events, a learning algorithm constructs a model that differentiates attacks from normal events.

Lee et al. (1999) apply machine learning to detect attacks in computer networks. They first identify frequent episodes, associations of features that frequently appear within a time frame, in attack and normal data separately. Frequent episodes that only appear in attack data help construct features for the models. For example, if the SYN flag is set for a http connection is a frequent episode within 2 s and the episode only appears in the attack data, a feature is constructed for the number of http connections with the SYN flag set within a period of 2 s. Using RIPPER and based on different sets of features, they construct three models: traffic, host-based traffic, and content models. The three models are then combined using meta-learning.

Ghosh and Schwartzbard (1999) use neural networks to identify attacks in operating systems. Based on system calls in the execution traces of normal and attack programs, they first identify a number of "examplar" sequences of system calls. For each system call sequence, they calculate the distance from the examplar sequences. The number of input nodes for the neural network is equal to the number of examplars and values for the input nodes are distances from those examplar sequences. The value for the output node is whether the system call sequence is from an attack or normal program.

Anomaly Detection

For anomaly detection, the machine learning goal is to characterize normal behavior. The learned models of normal behavior are then used to identify events that are anomalies, events that deviate from the models. Since anomalies are not always attacks, to reduce false alarms, the learned models usually provide a scoring mechanism to indicate the degree of anomaly.

Warrender et al. (1999) identify anomalies in system calls in the operating systems. The model is a table of system call sequences from execution traces of normal programs. During detection, a sequence that is not in the table or occurs less than 0.001 % in the training data is considered a mismatch. The number of mismatches within a locality frame of 20 sequences is the anomaly score.

Mahoney and Chan (2003) introduce the LERAD algorithm for learning rules that identify anomalies in network traffic. LERAD first uses a randomized algorithm to generate candidate rules that represent associations. It then finds a set of high quality rules that can succinctly cover the training data. Each rule has an associated probability of violating the rule. During detection, based on the probability, LERAD provides a score for anomalous events that do not conform to the rules in the learned model.

Misuse Detection: Schultz et al. (2001) with program executables, Maxion and Townsend (2002) with user commands.

Anomaly Detection: Sekar et al. (2001) with program execution, Apap et al. (2002) with Windows Registry, Anderson et al. (1995) with system resources, Lane and Brodley (1999) with user commands.

Manhattan Distance

Susan Craw
Robert Gordon University, Aberdeen, UK

Synonyms

City block distance; L_1-distance; 1-norm distance; Taxicab norm distance

Definition

The Manhattan distance between two points $\mathbf{x} = (x_1, x_2, \ldots x_n)$ and $\mathbf{y} = (y_1, y_2, \ldots y_n)$ in n-dimensional space is the sum of the distances in each dimension:

$$d(\mathbf{x}, \mathbf{y}) = \sum_{i=1}^{n} \mid x_i - y_i \mid$$

It is called the Manhattan distance because it is the distance a car would drive in a city (e.g., Manhattan) where the buildings are laid out in square blocks and the straight streets intersect at right angles. This explains the other terms city block and taxicab distances. The terms L_1 and 1-norm distances are the mathematical descriptions of this distance.

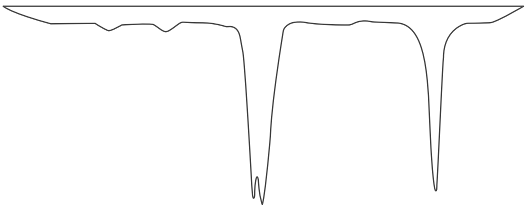
MCMC

Definition

A Markov Chain Monte Carlo (MCMC) algorithm is a method for sequential sampling in which each new sample is drawn from the neighborhood of its predecessor. This sequence forms a ► Markov chain, since the transition probabilities between sample values are only dependent on the last sample value. MCMC algorithms are well suited to sampling in high-dimensional spaces.

Motivation

Sampling from a probability density function is necessary in many kinds of approximation, including Bayesian inference and other applications in Machine Learning. However, sampling is not always easy, especially in high-dimensional spaces. Mackay (2003) gives a simple example to illustrate the problem. Suppose we want to find the average concentration of plankton in a lake, whose profile looks like this:



If we do not know the depth profile of the lake, how would we know where to sample from? If we take a boat out, would we have to sample almost exhaustively by fixing a grid on the surface of the lake and sinking our instrument progressively deeper, sampling at fixed intervals until we hit the bottom? This would be prohibitively expensive and if we had a similar problem, but with more dimensions, the problem becomes intractable. If we try to simplify the problem by drawing a random sample, how do we ensure that enough samples are taken from the canyons in the lake and not just the shallows, which account for most of the surface area?

The Algorithm

The general approach adopted in MCMC algorithms is as follows. We start sampling in some random initial state, represented by vector, $\boldsymbol{x}$. At each state, we can evaluate the probability density function, $P(\boldsymbol{x})$. We then choose a candidate next state, $\boldsymbol{x}'$, near the current state and evaluate $P(\boldsymbol{x}')$. Comparing the two, we decide whether to accept or reject the candidate. If we accept it, the candidate becomes the new current state and the process repeats for a fixed number of steps or until some convergence criterion is satisfied.

The Metropolis Algorithm

There are several variants of the general algorithm presented above. Each variant must specify how a candidate state is proposed and what criterion should be used to accept or reject the candidate. The Metropolis algorithm assumes that the next candidate is drawn from a symmetric distribution, $Q(x)$, centered on the current state, for example, a Gaussian distribution (Metropolis et al. 1953; Metropolis and Ulam 1949). This distribution is called the *proposal distribution.* The Metropolis algorithm is shown in Algorithm 1.

To decide if a candidate should be accepted or rejected, the algorithm calculates,

$$\alpha = \frac{P(x')}{P(x_i)}$$

where $\boldsymbol{x}_i$ is the current state and $\boldsymbol{x}'$ is the candidate state. If $\alpha > 1$, the candidate is immediately accepted. If $\alpha < 1$, then a stochastic choice is made with the candidate being accepted with probability α, otherwise, it is rejected.

Algorithm 1 The Metropolis Algorithm

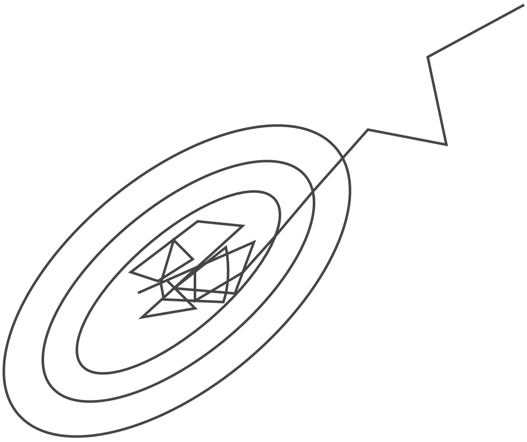
```
Given: target probability density function $P(\boldsymbol{x})$
    a proposal distribution, $Q$, e.g., a Gaussian
    the number of iterations, $N$
Output: a set of samples $\{x_i\}$ drawn from $P(\boldsymbol{x})$
Randomly select initial state vector, $x_0$
for $i = 0$ to $N - 1$
  create a new candidate $\boldsymbol{x}' = \boldsymbol{x}_i + \Delta\boldsymbol{x}$,
    where $\Delta\boldsymbol{x}$ is randomly chosen from $Q(\Delta\boldsymbol{x})$
  set $\alpha = \frac{P(x')}{P(x_i)}$
  if $\alpha \geq 1$ or with probability $\alpha$
    accept the new candidate and set $\boldsymbol{x}_{i+1} = \boldsymbol{x}'$
  else
    reject the candidate and set $\boldsymbol{x}_{i+1} = \boldsymbol{x}_i$
```

Hastings (1970) introduced a variant, the Metropolis–Hastings algorithm, which allows the proposal distribution to be asymmetric. In this case, the accept/reject calculation is:

$$\alpha = \frac{P(x')Q(x_i; x')}{P(x_i)Q(x'; x_i)}$$

Burn-In and Convergence

It can be difficult to decide how many iterations are needed before an MCMC algorithm achieves a stable distribution. Several factors affect the length of the Markov chain needed. Depending on the start state, many of the initial samples may have to be discarded, called *burn-in*, as illustrated below. The ellipses represent contours of the distribution.



The variance of the proposal distribution can also affect the chain length. If the variance is large, the jumps are large, meaning that there is varied sampling. However, this is also likely to mean that fewer samples are accepted. Narrowing the variance should increase acceptance but may require a long chain to ensure wide sampling, which is particularly necessary if the distribution has several peaks. See Andrieu et al. (2003) for a discussion of methods for improving convergence times.

Gibbs Sampling

An application of MCMC is inference in a ▶ Bayesian network, also known as ▶ Graphical Models. Here, we sample from evidence variables to find a probability for non-evidence variables. That is, we want to know what unknowns we can derive from the knowns and with what probability. Combining the evidence across a large network is intractable because we have to take into account all possible interactions of all variables, subject to the dependencies expressed in the network. Since there are too many combinations to compute in a large network, we approximate the solution by sampling. The Gibbs sampler is a special case of the Metropolis–Hastings algorithm that is well suited to sampling from distributions over two or more dimensions. It proceeds as in Algorithm 1, except that when a new candidate is generated, only one dimension is allowed to change while all the others are held constant. Suppose we have n dimensions and $\boldsymbol{x} = (x_1, \ldots, x_n)$. One complete pass consists of jumping in one dimension, conditioned on the values for all the other dimensions, then jumping in the next dimension, and so on. That is, we initialise x to some value, and then for each xi we resample $P(x_i|x_{j=6i})$ for j in $1 \ldots n$. The resulting candidate is immediately accepted. We then iterate, as in the usual Metropolis algorithm.

Policy search

Definition

A *Markov Decision Process* (MDP) is a discrete, stochastic, and generally finite model of a system to which some external control can be applied. Originally developed in the Operations Research and Statistics communities, MDPs, and their extension to ▸ Partially Observable Markov Decision Processes (POMDPs), are now commonly used in the study of ▸ reinforcement learning in the Artificial Intelligence and Robotics communities (Bellman 1957; Bertsekas and Tsitsiklis 1996; Howard 1960; Puterman 1994). When used for reinforcement learning, firstly the parameters of an MDP are learned from data, and then the MDP is processed to choose a behavior.

Formally, an MDP is defined as a tuple: $< \mathcal{S}, \mathcal{A}, T, R >$, where $\mathcal{S}$ is a discrete set of states, $\mathcal{A}$ is a discrete set of actions, $T : \mathcal{S} \times \mathcal{A} \rightarrow (\mathcal{S} \rightarrow R)$ is a stochastic transition function, and $R : \mathcal{S} \times \mathcal{A} \rightarrow R$ specifies the expected reward received for performing the given action in each state.

An MDP carries the *Markov* label because both the transition function, T, and the reward function, R, are Markovian; i.e., they are dependent only upon the current state and action, not previous states and actions. To be a valid transition function, the distribution over the resulting states, $\mathcal{S} \rightarrow R$, must be a valid probability distribution, i.e., non-negative and totalling 1. Furthermore, the expected rewards must be finite.

The usual reason for specifying an MDP is to find the optimal set of actions, or *policy*, to perform. We formalize the optimality criteria below. Let us first consider how to represent a policy. In its most general form the action, $a \in \mathcal{A}$, indicated by a policy, π, might depend upon the entire history of the agent; $\pi : (\mathcal{S} \times \mathcal{A})^* \times \mathcal{S} \rightarrow \mathcal{A}$. However, for each of the common optimality criteria considered below a Markov policy, $\mathcal{S} \rightarrow \mathcal{A}$, will be sufficient. i.e., for every MDP, for each of the optimality criteria below, there exists a Markov policy that performs as well as the best full policy. Similarly, there is no requirement for an MDP that a policy be stochastic or mixed.

Optimality Criteria

Informally, one wants to choose a policy so as to maximise the long term sum of immediate rewards. Unfortunately the naive sum, $\sum_{t=0}^{\infty} r_t$ where r_t is the expected immediate reward received at time t, usually diverges. There are different optimality criteria that can than be used as alternatives.

Finite Horizon

The easiest way to make sure that the sum of future expected rewards is bounded is to only consider a fixed, finite time into the future; i.e., find a policy that maximises $\sum_{t=0}^{n} r_t$ for each state.

Infinite Horizon Discounted

Rather than limiting the distance we look into the future, another approach is to *discount* rewards we will receive in the future by a multiplicative factor, γ, for each time-step. This can be justified as an inflation rate, as an otherwise unmodelled probability that the simulation ends each time-step, or simply as a mathematical trick to make the criteria converge. Formally we want a policy that maximises $\sum_{t=0}^{\infty} \gamma^t r_t$ for each state.

Average Reward

Unfortunately, the infinite horizon discounted optimality criterion adds another parameter to our model: the discount factor. Another approach is to optimize the average reward per time-step, or *gain*, by finding a policy that maximizes $\lim_{n\rightarrow\infty} \frac{1}{n} \sum_{t=0}^{n} r_t$ for each state. This is very similar to using *sensitive discount optimality*; finding a policy that maximizes the infinite horizon discounted reward as the discount factor approaches 1, $\lim_{\gamma\rightarrow 1} \sum_{t=0}^{\infty} \gamma^t r_t$, for each state.

When maximizing average reward, any finite deviation from the optimal policy will have negligible effect on the average over an infinite timeframe. This can make the agent "lazy." To counteract this, often a series of increasingly strict optimality criteria are used. The first is the "gain" optimality criterion given above – optimizing the long term average reward. The next is a "bias" optimality which selects from among all gain optimal policies the ones that also optimize transient initial rewards.

Value Determination

For the finite horizon, infinite horizon discounted, or bias optimality criteria, the optimality criteria can be calculated for each state, or for each state-action pair, giving a *value function*. Once found, the value function can then be used to find an optimal policy.

Bellman Equations

The standard approach to finding the value function for a policy over an MDP is a dynamic programming approach using a recursive formulation of the optimality criteria. That recursive formulation is known as the Bellman equation.

There are two, closely related, common forms for a value function; the state value function, $V : \mathcal{S} \to R$ and the state-action value function, $Q : \mathcal{S} \times \mathcal{A} \to R$. For a finite horizon undiscounted optimality criterion with time horizon n and policy π:

$$\begin{aligned}
\mathrm{Q}_n^\pi(s,a) &= \sum_{t=0}^{n} r_t \\
&= R(s,a) + \mathrm{E}_{s' \in T(s,a)} V_{n-1}^\pi(s') \\
&= R(s,a) + \sum_{s' \in \mathcal{S}} T(s,a)(s') V_{n-1}^\pi(s') \\
V_n^\pi(s) &= \mathrm{Q}_n^\pi(s, \pi(s))
\end{aligned}$$

For the infinite horizon discounted case:

$$\begin{aligned}
\mathrm{Q}^\pi(s,a) &= R(s,a) + \gamma \sum_{s' \in \mathcal{S}} T(s,a)(s') V^\pi(s') \\
V^\pi(s) &= \mathrm{Q}^\pi(s, \pi(s))
\end{aligned}$$

These equations can be turned into a method for finding the value function by replacing the equality with an assignment:

$$\begin{aligned}
\mathrm{Q}^\pi(s,a) &\leftarrow R(s,a) \\
&\quad + \gamma \sum_{s' \in \mathcal{S}} T(s,a)(s') \mathrm{Q}^\pi(s', \pi(s'))
\end{aligned}$$

As long as this update rule is followed infinitely often for each state/action pair, the Q-function will converge.

Prioritised sweeping: Rather than blindly updating each state/action, intelligent choice of where to update will significantly speed convergence. One technique for this is called Prioritized Sweeping (Moore 1993; Andre et al. 1997).

A priority queue of states is kept. Initially one complete pass of updates over all states is performed, but thereafter states are updated in the order they are pulled from the priority queue. Any time the value of a state, $V^\pi(s)$, changes, the priorities of all states, s', that can reach state s are updated; we update $\{s' | T(s', \pi(s'))(s) \neq 0\}$. The priorities are increased by the absolute change in $V^\pi(s)$.

The effect of the priority queue is to focus computation where values are changing rapidly.

Linear Programming Solutions

Rather than using the Bellman equation and dynamic programming, an alternative approach is to set up a collection of inequalities and use linear programming to find an optimal value function. In particular if we minimize,

$$\sum_{s \in \mathcal{S}} V^\pi(s)$$

subject to the constraints

$$\begin{aligned}
\forall_{s \in \mathcal{S}} 0 \leq V^\pi(s) - [R(s,a) \\
+ \gamma \sum_{s' \in \mathcal{S}} T(s,a)(s') V^\pi(s')],
\end{aligned}$$

then the resulting V^π accurately estimates the expected sum of discounted reward.

Bellman Error Minimization

A third approach to value determination is similar to the dynamic programming solution above. Rather than replacing the equality in the Bellman equation with an assignment, it turns the equation into an error function and adjusts the Q function to minimise the sum of squared Bellman residuals

(Baird 1995):

$$\begin{aligned}\text{Residual}(s) &= \text{Q}^{\pi}(s,\ a) - [R(s,\ a) \\ &\quad + \gamma \sum_{s' \in \mathcal{S}} T(s,\ a)(s')\text{Q}^{\pi}(s',\ \pi(s'))]\ \text{Err} \\ &= \sum_{s \in \mathcal{S}} \text{Residual}(s)^2\end{aligned}$$

Control Methods

The previous section gave us a way to obtain a value function for a particular policy, but what we usually need is a good policy, not a value function for the policy we already have. For an optimal policy, for each state:

$$\pi(s) = argmax_{a \in \mathcal{A}} Q^{\pi}(s, a)$$

If a policy, π, is not optimal then its value function can be used to find a better policy, π'. It is common to use the greedy policy for the value function:

$$\pi'(s) \leftarrow argmax_{a \in \mathcal{A}} Q^{\pi}(s, a)$$

This process can be used iteratively to find the optimal policy.

Policy iteration: Policy iteration alternates between value determination and greedy policy updating steps until convergence is achieved. The algorithm starts with a policy, π_1. The value function is calculated for that policy, $V^{\pi 1}$. A new policy is then found from that value function, π_2. This alternation between finding the optimal value function for a given policy and then improving the policy continues until convergence. At convergence the policy is optimal.

Value iteration: Rather than explicitly updating the policy, value iteration works directly with the value function. We define an update,

$$\begin{aligned}\text{Q}(s, a) &\leftarrow R(s, a) \\ &\quad + \gamma \sum_{s' \in \mathcal{S}} T(s, a)(s') \max_{a' \in A} \text{Q}(s', a'),\end{aligned}$$

with a maximization step included. As long as this update is performed often enough in each state, Q will converge. Once Q has converged, the greedy policy will be optimal.

Mixed policy iteration: The two previous methods, policy and value iteration, are two extremes of a spectrum. In practice updates to the policy and value function can occur asynchronously as long as the value and policy in each state are updated often enough.

Representations

In the above discussion we have discussed a number of functions, but not discussed how these functions are represented. The default representation is an array or tabular form which has no constraints on the function it can represent. However, the ▸ curse of dimensionality suggests that the number of states will, in general, be exponential in the problem size. This can make even a single complete iteration over the state space intractable. One solution is to represent the functions in a more compact form so that they can be updated efficiently. This approach is known as *function approximation*. Here we review some common techniques.

A class of representations is chosen to represent the functions we need to process: e.g., the transition, T, reward, R, Value, V or Q, and/or policy, π, functions. A particular function is selected from the chosen class by a parameter vector, $\boldsymbol{\theta}$.

There are two important questions that must be answered by any scheme using function approximation; does the resulting algorithm converge to a solution, and does the resulting solution bear any useful relationship with the optimal solution?

A simple approach when using a differentiable function to represent the value function is to use a form of ▸ temporal difference learning. For a given state, s, and action, a, the Bellman equation is used to calculate a new value, $Q^{new}(s, a)$, and then $\boldsymbol{\theta}$ is updated to move the value function toward this new value. This gradient based approach usually has a learning rate, $\alpha \in [0, 1]$, to adjust the speed of learning.

$$\text{Q}^{\text{new}}(s, a) \leftarrow R(s, a) + \gamma \sum_{s' \in \mathcal{S}} T(s, a)(s') V^{\text{old}}(s')$$

$$\Delta_{s,a}\theta = \alpha \frac{\partial \mathrm{Q}}{\partial \theta}(\mathrm{Q}^{\mathrm{new}}(s,a) - \mathrm{Q}^{01\mathrm{d}}(s,a))$$

This approach is known not to converge in general, although it does converge in some special cases. A similar approach with full Bellman Error minimization will not oscillate, but it may cause the $\boldsymbol{\theta}$ to diverge even as the Bellman residual converges.

Contraction mappings: The first class of function approximators that was shown to converge with the above update, apart from a complete tabular representation, was the class of contraction mappings (Gordon 1995). Simply put, these are function approximation classes where changing one value by a certain amount changes every other value in the approximator by no more than that amount. For example, linear interpolation and *tile coding* (Tile codings are also known as Cerebellar Motor Action Controllers (CMAC) in early work Albus 1981) are each contraction mappings whereas linear extrapolation is not.

Formally, let $\mathcal{S}$ be a vector space with max norm $||.||_\infty$. A function f is a contraction mapping if,

$$\forall a, b \in \mathcal{S}, \|f(a) - f(b)\|_\infty < \|a - b\|_\infty$$

The class of function approximations that form contraction mappings includes a number of common approximation techniques including *tile coding*. Tile coding represents a function as a linear combination of basis functions, $\boldsymbol{\phi}(s,a)$,

$$\hat{Q}(s,a) = \boldsymbol{\theta} \cdot \varphi(s,a),$$

where the individual elements of φ are binary features on the underlying state.

Linear approximations: The linear combination of basis functions can be extended beyond binary features. This will converge when temporal differencing updates are performed in trajectories through the state space following the policy being evaluated (Tsitsiklis and Van Roy 1997).

Variable resolution techniques: One technique for representing value functions over large state spaces is use a non-parametric representation. Munos gives a technique that introduces more basis functions for their approximation over time as needed (Munos and Moore 2001).

Dynamic Bayesian networks: Bayesian Networks are an efficient representation of a factored probability distribution. Dynamic Bayesian Networks use the Bayesian Network formalism to represent the transition function, $\mathcal{T}$, in an MDP (Guestrin et al. 2003). The reward and value functions are usually represented with linear approximations. The policy is usually represented implicitly by the value function.

Decision diagrams: Arithmetic Decision Diagrams (ADDs) are a compact way of representing functions from a factored discrete domain to a real range. ADDs can also be efficiently manipulated, with operators for the addition and multiplication of ADDs as well as taking the maximum of two ADDs. As the Bellman equation can be re-written using operators, it is possible to implement mixed policy iteration using this efficient representation St-Aubin et al. (2000).

Hierarchical representations: ▸ Hierarchical Reinforcement Learning factors out common substructure in the functions that represent an MDP in order to solve it efficiently. This has been done in many different ways. Dietterich's *MAXQ* hierarchy allowed a prespecified hierarchy to re-use common elements in a value function (Dietterich 2000). Sutton's *Options* framework focussed on temporal abstraction and re-use of policy elements (Sutton et al. 1998). Moore's *Airports* hierarchy allowed automatic decomposition of a problem where the specific goal could change over time, and so was made part of the state (Moore et al. 1999). Andre's *A-Lisp* system takes the hierarchical representation to an extreme by building in a Turing complete programming language (Andre and Russell 2002).

Greedy Algorithms Versus Search

In the previous sections the control problem was solved using a greedy policy for a value function. If the value function was approximate, then the resulting policy may be less than optimal. Another approach to improving the policy is to introduce search during execution. Given the current state, the agent conducts a forward search looking for the sequence of actions that produces the best intermediate reward and resulting state value combination.

These searches can be divided into two broad categories: deterministic and stochastic searches. Deterministic searches, such as LAO∗ (Hansen and Zilberstein 1998), expand through the state space using the supplied model of the MDP. In contrast stochastic, or Monte-Carlo, approaches sample trajectories from the model and use statistics gathered from those samples to choose a policy (Kocsis and Szepesvári 2006).

Markov Process

Synonyms

Markov chain; Markov model

A stochastic process in which the conditional probability distribution of future states of the process, given the present state and all past states, depends only upon the present state. A process with this property may be called Markovian. The best known Markovian processes are *Markov chains*, also known as *Markov Models*, which are discrete-time series of states with transition probabilities. Markov chains are named after Andrey Markov (1865–1922), who introduced several significant new notions to the concept of stochastic processes. Brownian motion is another well-known phenomenon that, to close approximation, is a Markov process.

Abstract

This chapter provides an overview of the maximum entropy framework and its application to a problem in natural language processing. The framework provides a way to combine many pieces of evidence from an annotated training set into a single probability model. The framework has been applied to many tasks in natural language processing, including part-of-speech tagging. This chapter covers the maximum entropy formulation, its relationship to maximum likelihood, a parameter estimation method, and the details of the part-of-speech tagging application.

Synonyms

Maxent models; Log-linear models; Statistical natural language processing

Definition

The term maximum entropy refers to an optimization framework in which the goal is to find the probability model that maximizes entropy over the set of models that are consistent with the observed evidence.

The information-theoretic notion of entropy is a way to quantify the uncertainty of a probability model; higher entropy corresponds to more uncertainty in the probability distribution. The rationale for choosing the maximum entropy model – from the set of models that meet the evidence – is that any other model assumes evidence that has not been observed (Jaynes 1957).

In most natural language processing problems, observed evidence takes the form of co-occurrence counts between some prediction of interest and some linguistic context of interest. These counts are derived from a large number of linguistically annotated examples, known as a corpus. For example, the frequency in a large corpus with which the word *that* co-occurs with the tag corresponding to determiner, or *DET*, is a piece of observed evidence. A probability model is consistent with the observed evidence if its calculated estimates of the co-occurrence counts agree with the observed counts in the corpus.

The goal of the maximum entropy framework is to find a model that is consistent with the co-occurrence counts, but is otherwise maximally uncertain. It provides a way to combine many pieces of evidence into a single probability model. An iterative parameter estimation procedure is usually necessary in order to find the maximum entropy probability model.

Motivation and Background

The early 1990s saw a resurgence in the use of statistical methods for natural language processing (Church and Mercer 1993). In particular, the IBM TJ Watson Research Center was a prominent advocate in this field for statistical methods such as the maximum entropy framework. Language modeling for speech recognition (Lau et al. 1993) and machine translation (Berger et al. 1996) were among the early applications of this framework.

Structure of Learning System

The goal of a typical natural language processing application is to automatically produce linguistically motivated categories or structures over freely occurring text. In statistically based approaches, it is convenient to produce the categories with a conditional probability model p such that $p(a|b)$ is the probability of seeing a prediction of interest a (e.g., a part-of-speech tag) given a linguistic context of interest b (e.g., a word).

The maximum entropy framework discussed here follows the machine learning approach to

NLP, which assumes the existence of a large corpus of linguistically annotated examples. This annotated corpus is used to create a training set, which in turn is used to estimate the probability model p.

Representing Evidence

Evidence for the maximum entropy model is derived from the training set. The training set is a list of (prediction, linguistic context) pairs that are generated from the annotated data. However, in practice, we do not record the entire linguistic context. Instead, linguistically motivated Boolean-valued questions reduce the entire linguistic context to a vector of question identifiers. Therefore, each training sample looks like:

Prediction	Question vector
a	$q_1 \dots q_n$

where a is the prediction and where $q_1 \dots q_n$ is a vector of questions that answered `true` for the linguistic context corresponding to this training sample. The questions must be designed by the experimenter in advance, and are specifically designed for the annotated data and the problem space.

In the framework discussed here, any piece of evidence is represented with a *feature*. A feature correlates a prediction a with an aspect of a linguistic context b, captured by some question:

$$f_j(a,b) = \begin{cases} 1 \text{ if } a = x \text{ and } q(b) = \text{true} \\ 0 \text{ otherwise} \end{cases}$$

Combining the Evidence

The maximum entropy framework provides a way to combine all the features into a probability model. In the conditional maximum entropy formulation (Berger et al. 1996), the desired model p^* is given by:

$$P = \{p | E_p f_j = E_{\tilde{p}} f_j, j = 1 \dots k\} \quad (1)$$

$$H(p) = -\sum_{a,b} \tilde{p}(b) p(a|b) \log p(a|b)$$

$$p^* = \text{argmax}_{p \in P} H(p)$$

where $H(p)$ is the conditional entropy of p, $\tilde{p}(b)$ is the observed probability of the linguistic context b in the training set, and P is the set of models that are consistent with the observed data. A model p is consistent if its own feature expectation $E_p f_j$ is equal to the observed feature expectation $E_{\tilde{p}} f_j$, for all $j = 1 \dots k$ features. $E_{\tilde{p}} f_j$ can be interpreted as the observed count of f_j in the training sample, normalized by the training sample size. Both are defined as follows:

$$E_p f_j = \sum_{a,b} \tilde{p}(b) p(a|b) f_j(a,b)$$

$$E_{\tilde{p}} f_j = \sum_{a,b} \tilde{p}(a,b) f_j(a,b)$$

According to the maximum entropy framework, the optimal model p^* is the most uncertain model among those that satisfy the feature constraints. It is possible to show that the form of the optimal model must be log-linear:

$$p^*(a|b) = \frac{1}{Z(b)} \prod_{j=1\dots k} \alpha_j^{f_j(a,b)} \quad (2)$$

$$Z(b) = \sum_{a'} \prod_{j=1\dots k} \alpha_j^{f_j(a',b)}$$

Here $Z(b)$ is a normalization factor, and $\alpha_j > 0$. Each model parameter α_j can be viewed as the "strength" of its corresponding feature f_j; the conditional probability is the normalized product of the feature weights of the active features.

Relationship to Maximum Likelihood

The maximum entropy framework described here has an alternate interpretation under the more commonly used technique of maximum likelihood estimation.

$$Q = \left\{ p | p(a|b) = \frac{1}{Z(b)} \prod_{j=1\dots k} \alpha_j^{f_j(a,b)} \right\}$$

$$L(p) = \sum_{a,b} \tilde{p}(a,b) \log p(a|b)$$

$$q^* = \underset{p \in Q}{\text{argmax}} L(p)$$

Here Q is the set of models of form (2), $\tilde{p}(a,b)$ is the observed probability of prediction a together with linguistic context b, $L(p)$ is the log-likelihood of the training set, and q^* is the maximum likelihood model. It can be shown that $p^* = q^*$; maximum likelihood estimation for models of the form (2) gives the same answer as maximum entropy estimation over the constraints on feature counts (1). The difference between approaches is that the maximum likelihood approach assumes the form of the model, whereas the maximum entropy approach assumes the constraints on feature expectations, and *derives* the model form.

Parameter Estimation

The Generalized Iterative Scaling (GIS) algorithm (Darroch and Ratcliff 1972) is the easiest way to estimate the parameters for this kind of model. The iterative updates are given below:

$$\alpha_j^{(0)} = 1$$

$$\alpha_j^{(n)} = \alpha_j^{(n-1)} \left[\frac{E_{\tilde{p}} f_j}{E_p f_j} \right]^{\frac{1}{C}}$$

GIS requires the use of a "correction" feature g and constant $C > 0$, which are defined so that $g(a,b) = C - \sum_{j=1\ldots k} f_j(a,b)$ for any (a,b) pair in the training set. Normally, the correction feature g must be trained in the model along with the k original features, although (Curran and Clark 2003) show that GIS converges even without the correction feature. The number of iterations needed to achieve convergence depends on certain aspects of the data, such as the training sample size and the feature set size, and is typically tuned for the problem at hand.

Other algorithms for parameter estimation include the Improved Iterative Scaling (Berger et al. 1996) algorithm and the Sequential Conditional GIS (Goodman 2002) algorithm. The list given here is not complete; many other numerical algorithms can be applied to maximum entropy parameter estimation, see Malouf (2002) for a comparison.

It is usually difficult to assess the reliability of features that occur infrequently in the training set, especially those that occur only once. When the parameters are trained from low frequency feature counts, maximum entropy models – as well as many other statistical learning techniques – have a tendency to "overfit" the training data. In this case, performance on training data appears very high, but performance on the intended test data usually suffers. *Smoothing* or *regularization* techniques are designed to alleviate this problem for statistical models; some smoothing techniques for maximum entropy models are reviewed in Chen and Rosenfeld (1999).

Applications

This framework has been used as a generic machine learning toolkit for many problems in natural language processing. Like other generic machine learning techniques, the core of the maximum entropy framework is invariant across different problem spaces. However, some information is specific to each problem space:

Predictions: The space of predictions for this model

Questions: The space of questions for this model

Feature Selection: Any possible (question, prediction) pair can be used as a feature. In complex models, only a small subset of all the possible features are used in a model. The feature selection strategy specifies how to choose the subset.

For a given application, it suffices to give the above three pieces of information to fully specify a maximum entropy probability model.

Part-of-Speech Tagging

Part-of-speech tagging is a well-known task in computational linguistics in which the goal is to disambiguate the part-of-speech of all the words in a given sentence. For example, it can be nontrivial for a computer to disambiguate the part-of-speech of the word *flies* in the following famous examples:

- Fruit *flies* like a banana.
- Time *flies* like an arrow.

The word *flies* behaves like a noun in the first case, and like a *verb* in the second case. In the machine learning approach to this problem, co-occurrence statistics of tags and words in the linguistic context are used to create a predictive model for part-of-speech tags.

The computational linguistics community has created annotated corpora to help build and test algorithms for tagging. One such corpus, known as the Penn treebank (Marcus et al. 1994), has been used extensively by machine learning and statistical NLP practitioners for problems like tagging. In this corpus, roughly 1 M words from the Wall St. Journal have manually been assigned part-of-speech tags. This corpus can be converted into a set of training samples, which in turn can be used to train a maximum entropy model.

Model Specification

For tagging, the goal is a maximum entropy model p that will produce a probability of seeing a tag at position i, given the linguistic context of the ith word, the surrounding words, and the previously predicted tags, written as $p(t_i|t_{i-1}\dots t_1, w_1\dots w_n)$. The intent is to use the model left-to-right, one word at a time. The maximum entropy model for tagging (Ratnaparkhi 1996) is specified as:

Predictions: The 45 part-of-speech tags of the Penn treebank

Questions: Listed below are the questions and question patterns. A question pattern has a placeholder variable (e.g., X, Y) that is instantiated by scanning the annotated corpus for examples in which the patterns match. Let i denote the position of the current word in the sentence, and let w_i and t_i denote the word and tag at position i, respectively.

- Does $w_i = X$?
- Does $w_{i-1} = X$?
- Does $w_{i-2} = X$?
- Does $w_{i+1} = X$?
- Does $w_{i+2} = X$?
- Does $t_{i-1} = X$?
- Does $t_{i-1}t_{i-2} = X, Y$?
- For word that occur less than 5 times in the training set:
  - Are the first K (for $K \leq 4$) characters $X_1 \dots X_K$?
  - Are the last K (for $K \leq 4$) characters $X_1 \dots X_K$?
  - Does the current word contain a number?
  - Does the current word contain a hyphen?
  - Does the current word contain an uppercase character?

Feature Selection: Any feature whose count in the training data is less than 10 is discarded.

While the features for each probability decision could in theory look at the entire linguistic context, they actually only look at a small window of words surrounding the current word, and a small window of tags to the left. Therefore each decision effectively makes the markov-like assumption given in Eq. (3).

$$p(t_i|t_{i-1}\dots t_1, w_1\dots w_n)$$

$$= p(t_i|t_{i-1}t_{i-2}w_{i-2}w_{i-1}w_iw_{i+1}w_{i+2}) \qquad (3)$$

$$= \frac{\prod_{j=1\dots k}\alpha_j^{f_j(t_i, t_{i-1}t_{i-2}w_{i-2}w_{i-1}w_iw_{i+1}w_{i+2})}}{Z(t_{i-1}t_{i-2}w_{i-2}w_{i-1}w_iw_{i+1}w_{i+2})} \qquad (4)$$

Equation (4) is the maximum entropy model for tagging. Each conditional probability of a prediction t_i given some context $t_{i-1}t_{i-2}w_{i-2}w_{i-1}w_i$ $w_{i+1}w_{i+2}$ is the product of the features that are active for that (prediction, context) pair.

Training Data

The training set is created by applying the questions to each word in the training set. For example, when scanning the word *flies* in the sentence "Time flies like an arrow" the training example would be:

Prediction	Question vector
$verb$	w_i = flies, w_{i-1} = Time, w_{i-2} = ∗bd∗, w_{i+1} = like, w_{i+2} = an, t_{i-1} = *noun*, $t_{i-1}t_{i-2}$ = *noun*, ∗bd∗

Here *bd* is a special symbol for boundary. The tags have been simplified for this example; the actual tags in the Penn treebank are more fine-grained than *noun* and *verb*.

Hundreds of thousands of training samples are used to create candidate features. Any possible (prediction, question) pair that occurs in training data is a candidate feature. The feature selection strategy is a way to eliminate unreliable or noisy features from the candidate set. For the part-of-speech model described here, a simple frequency threshold is used to implement feature selection.

Given a selected feature set, the GIS algorithm is then used to find the optimal value for the corresponding α_j parameters. For this application, roughly 50 iterations of GIS sufficed to achieve convergence.

Search for Best Sequence

The probability model described thus far will produce a distribution over tags, given a linguistic context including and surrounding the current word. In practice we need to tag entire sentences, which means that the model must produce a *sequence* of tags. Tagging is typically performed left-to-right, so that each decision has the left context of previously predicted tags. The probability of the best tag sequence for an n-word sentence is factored as:

$$\begin{aligned} &p(t_1 \dots t_n | w_1 \dots w_n) \\ &= \prod_{i=1\dots n} p(t_i | t_{i-1} \dots t_1, w_1 \dots w_n) \end{aligned}$$

The desired tag sequence is the one with the highest conditional sequence probability:

$$t_1^* \dots t_n^* = \operatorname*{argmax}_{t_1 \dots t_n} p(t_1 \dots t_n | w_1 \dots w_n)$$

A dynamic programming procedure known as the Viterbi algorithm is typically used to find the highest probability sequence.

Other NLP Applications

Other NLP applications have used maximum entropy models to predict a wide variety of linguistic structure. The statistical parser in Ratnaparkhi (1999) uses separate maximum entropy models for part-of-speech, chunk, and parse structure prediction. The system in Borthwick (1999) uses maximum entropy models for named entity detection, while the system in Ittycheriah et al. (2001) uses them as sub-components for both answer type prediction and named entity detection. Typically, such applications do not need to change the core framework, but instead need to modify the meaning of the predictions, questions, and feature selection to suit the intended task of the application.

Future Directions

Conditional random fields (Lafferty et al. 2001), or CRFs, are an alternative to maximum entropy models that address the *label bias* issue. Label bias affects sequence models that predict one element at a time, in which features at a given state (or word, in the case of POS tagging) compete with each other, but do not compete with features at any other state in the sequence. In contrast, a CRF model directly produces a probability distribution over the entire sequence, and therefore allows global competition of features across the entire sequence. The parameter estimation for CRFs is related to the Generalized Iterative Scaling algorithm used for maximum entropy models. See Sha and Pereira (2003) for a example of CRFs applied to noun phrase chunking.

Another recently published future direction is Collobert et al. (2011), which presents a multilayer neural network approach for several sequence labeling tasks, including POS tagging. This approach avoids task-specific feature engineering – like the questions in section "Model Specification" – and instead uses the neural network training algorithm to discover internal representations for the word and tag context. It also uses large amounts of unlabeled data to enhance the internal representations for words.

McDiarmid's Inequality

Synonyms

Bounded differences inequality

Definition

McDiarmid's inequality shows how the values of a bounded function of independent random variables concentrate about its mean. Specifically, suppose $f : \mathcal{X}^n \to R$ satisfies the bounded differences property. That is, for all $i = 1, \ldots, n$ there is a $c_i \geq 0$ such that for all $x_1, \ldots, x_n, x' \in \mathcal{X}$

$$\begin{aligned}&|f(x_1,\ldots,x_n)\\&\quad - f(x_1,\ldots,x_{i-1},x',x_{i+1},\ldots,x_n)| \leq c_i .\end{aligned}$$

If $\mathbf{X} = (X_1, \ldots, X_n) \in \mathcal{X}^n$ is a random variable drawn according to P^n and $\mu = E_{P^n}[f[\mathbf{X}]$ then for all $\epsilon > 0$

$$P^n(f(\mathbf{X}) - \mu \geq \epsilon) \leq \exp\left(\frac{2\epsilon^2}{\sum_{i=1}^n c_i^2}\right).$$

McDiarmid's is a generalization of Hoeffding's inequality, which can be obtained by assuming $\mathcal{X} = [a,b]$ and choosing $f(\mathbf{X}) = \sum_{i=1}^n X_i$. When applied to empirical risks this inequality forms the basis of many ▶ generalization bounds.

Abstract

Mean Shift is a clustering algorithm based on kernel density estimation. Various extensions have been proposed to improve speed and quality.

Synonyms

Density estimator

Definition

Mean shift (Comaniciu and Meer 2002) is a nonparametric algorithm for partitional clustering which does not require specifying the number of clusters and can form any shape of clusters. The mean shift procedure was originally proposed by Fukunaga and Hostetler (1975). Cheng (1995) adapted it for image analysis. Comaniciu, Meer, and Ramesh presented the mean shift approach to solve low-level vision problems: image segmentation (Comaniciu and Meer 2002), adaptive smoothing (Comaniciu and Meer 2002), and kernel-based object tracking (Comaniciu et al. 2003).

Given n data points $\mathbf{x}_i$, $i = 1, \ldots, n$ in the d-dimensional space R^d, the multivariate kernel density estimator obtained with kernel $K(\mathbf{x})$ and window radius h is given by

$$f(\mathbf{x}) = \frac{1}{nh^d} \sum_{i=1}^{n} K(\frac{\mathbf{x} - \mathbf{x}_i}{h}) \qquad (1)$$

Given the gradient of the density estimator, the mean shift is defined as the difference between the weighted (using the kernel as weights) mean and x, the center of the kernel,

$$\mathbf{m}_h(\mathbf{x}) = \frac{\sum_{i=1}^{n} \mathbf{x}_i g(||\frac{\mathbf{x}-\mathbf{x}_i}{h}||^2)}{\sum_{i=1}^{n} g(||\frac{\mathbf{x}-\mathbf{x}_i}{h}||^2)} - \mathbf{x} \qquad (2)$$

The mean shift vector is proportional to the normalized density gradient estimate, and thus points to the direction of the maximum increase in the density. By successively computing the mean shift vector and translating the kernel (window) by the vector, the mean shift procedure can guarantee converging at a nearby point where the gradient of density function is zero.

Extensions

There are many extensions to the mean shift algorithm. Methods have been proposed to improve the performance of mean shift on speed (Paris and Durand 2007) and on accuracy by adaptive bandwidths (Georgescu et al. 2003) and asymmetric kernels (Yilmaz 2007).

The mean shift algorithm is designed for static distributions; a modified algorithm called Continuously Adaptive Mean Shift (CAMSHIFT) (Bradski 1998) can deal with dynamically changing distributions, for example, the color probability distributions derived from video frame sequences.

Mean shift has been extended for manifold clustering. Subbarao and Meer (2006) and Tuzel et al. (2005) proposed extensions to Grassmann manifolds and Lie groups for motion segmentation and multibody factorization. The medoid shift (Sheikh et al. 2007) algorithm avoids the definition of a stopping criteria and performs data clustering on both linear and curved spaces. The quick shift (Vedaldi and Soatto 2008) algorithm was proposed to eliminate the over-fragmentation problem of medoid shift. Cetingul and Vidal (2009) proposed intrinsic mean shift for clustering on Stiefel and Grassmann manifolds. The approach presents an alternative mean shift formulation which performs the iterative optimization on the manifold of interest and intrinsically locates the modes via consecutive evaluations of a mapping.

Softwares

The following softwares have implementations of the mean shift clustering algorithm:

- Scikit-Learn. An open-source machine learning software written in Python. http://scikit-learn.org
- OpenCV. Open Source Computer Vision Library. Written in C/C++. http://opencv.org
- Apache Mahout. Open-source machine learning software in Java for use in Hadoop, with support on mean shift before version 0.8. http://mahout.apache.org
- ImageJ. A Java-based library for image analysis and processing. It has an image filtering plug-in using the mean shift filter. http://rsbweb.nih.gov/ij/plugins/mean-shift.html

Measurement Scales

Ying Yang
Australian Taxation Office, Box Hill, VIC,
Australia

Definition

Turning to the authority of introductory statistical textbooks (Bluman 1992; Samuels and Witmer 1999), there are two parallel ways to classify data into different types. Data can be classified into either categorical or ▸ numeric. Data can also be classified into different levels of ▸ measurement scales.

There are two parallel ways to classify data into different types. Data can be classified into either categorical or numeric. Data can also be classified into different *levels of* measurement scales.

Categorical versus Numeric

Variables can be classified as either categorical or numeric. **Categorical variables**, also often referred to as **qualitative variables**, are variables that can be placed into distinct categories according to some characteristics. Categorical variables sometimes can be arrayed in a meaningful rank order. But no arithmetic operations can be applied to them. Examples of categorical variables are

- Gender of a fish: male and female
- Student evaluation: fail, pass, good, and excellent

Numeric variables, also often referred to as *quantitative variables*, are numerical in nature. They can be ranked in order. They can also have meaningful arithmetic operations. Numeric variables can be further classified into two groups, discrete or continuous.

A *discrete variable* assumes values that can be counted. The variable cannot assume all values on the number line within its value range. An example of a discrete variable is *the number of children in a family*.

A *continuous variable* can assume all values on the number line within the value range. The values are obtained by measuring. An example of a continuous variable is *Fahrenheit temperature*.

Levels of Measurement Scales

In addition to being classified as either categorical or numeric, variables can also be classified by how they are categorized, counted, or measured. This type of classification uses measurement scales, and four common types of scales are used: nominal, ordinal, interval, and ratio.

The *nominal* level of measurement scales classifies data into mutually exclusive (nonoverlapping), exhaustive categories in which no order or ranking can be imposed on the data. An example of a nominal variable is *gender of a fish*: male and female.

The *ordinal* level of measurement scales classifies data into categories that can be ranked. However, the differences between the ranks cannot be calculated by arithmetic. An example of an ordinal variable is *student evaluation*, with values fail, pass, good, and excellent. It is meaningful to say that the student evaluation of pass ranks is higher than that of fail. It is not meaningful in the same way to say that the gender female ranks higher than the gender male.

The **interval** level of measurement scales ranks the data, and the differences between units of measure can be calculated by arithmetic. However, *zero* in the interval level of measurement means neither "nil" nor "nothing" as *zero* in arithmetic means. An example of an interval variable is *Fahrenheit temperature*. It is meaningful to say that the temperature A is two points higher than the temperature B. It is not meaningful in the same way to say that the student evaluation of pass is two points higher than that of fail. Besides, 0°F does not mean the absence of heat.

The **ratio** level of measurement scales possesses all the characteristics of interval measurement, and there exists a *zero* that, the same as arithmetic *zero*, means "nil" or "nothing." In consequence, true ratios exist between different units of measure. An example of a ratio variable is *number of children in a family*. It is meaningful to say that the number of children in the family A is twice that of the family B. It is not meaningful in the same way to say that the Fahrenheit temperature A is twice that of B.

The nominal level is the lowest level of measurement scales. It is the least powerful in terms of including data information. The ordinal level is higher. The interval level is even higher. The ratio level is the highest level. Any data conversion from a higher level of measurement scales to a lower level of measurement scales, such as ▸ discretization, will lose information. Table 1 gives a summary of the characteristics of different levels of measurement scales.

Measurement Scales, Table 1 Characteristics of different levels of measurement scales

Level	Ranking?	Arithmetic operation?	Arithmetic zero?
Nominal	No	No	No
Ordinal	Yes	No	No
Interval	Yes	Yes	No
Ratio	Yes	Yes	Yes

Summary

In summary, the following taxonomy applies to variable types:

- Categorical (qualitative) variables:
  Nominal
  Ordinal
- Numeric (quantitative) variables:
  Interval, either discrete or continuous
  Ratio, either discrete or continuous

Medicine: Applications of Machine Learning

Katharina Morik
Technische Universität Dortmund, Dortmund, Germany

Motivation

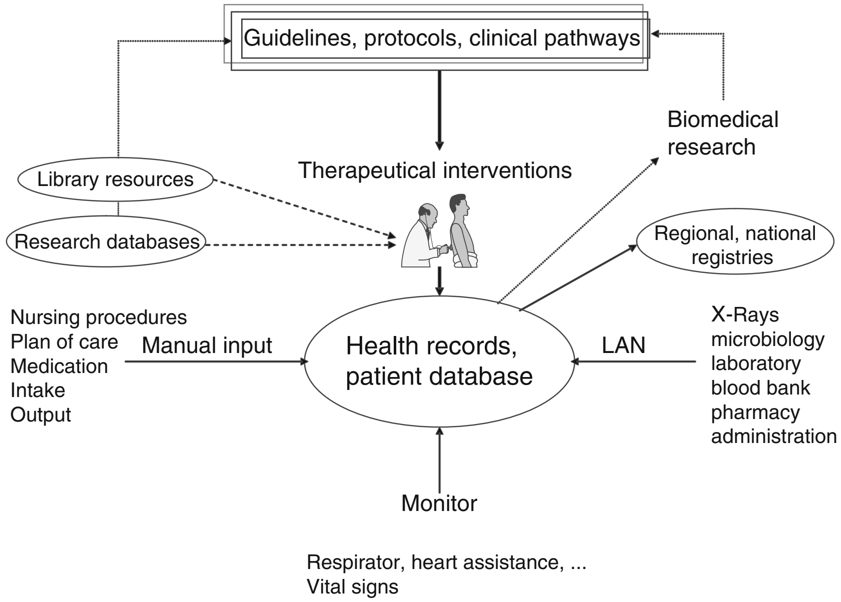
Health care has been an important issue in computer science since the 1960s. In addition to databases storing patient records, library resources (e.g., PubMed, a service of the U.S. National Library of Medicine that includes over 16 million citations from journals for biomedical articles back to the 1950s), administrative and financial systems, more sophisticated support of health care has been the aim of artificial intelligence (AI) from the very beginning on. Starting with expert systems which abstract laboratory findings and other vital parameters of a patient before they heuristically classify the patient into one of the modeled diagnoses (Shortliffe 1976), knowledge acquisition was discovered to be the bottleneck of systems for the automatic medical diagnosis. Machine learning came into play as a means of knowledge acquisition. Learning rules for (medical) expert systems focused on the heuristic classification step within expert systems. Given conveniently abstracted measurements of the patient's state, the classification was learned in terms of rules or ▶ decision trees. Since the early days, the use of machine learning for health care progressed in two ways:

- The abstraction of measurements of a patient's vital parameters is a learning task in its own right. Diverse kinds of data are to be handled: laboratory data, online measurements at the bedside, x-rays or other imaging data, genetic data,... Machine learning is confronted with a *diversity of representations* for the examples.
- Diagnosis is just one task in which physicians are to be supported. There are many more tasks which machine learning can ease. In intensive care, the addressee of the learning results can be a machine, e.g., the respirator. Financing health care and planning the medical resources (e.g., for a predicted epidemia) are yet another important issue. Machine learning is placed in a *diversity of medical tasks*.

The urgent need for sophisticated support of health care follows from reports which estimate up to 100,000 deaths in the USA each year due to medical error (Kohn et al. 2000).

Structure of the Problem

The overall picture of the medical procedures shows the kinds of data and how they are entered into the database of health records (a synonym is "patient database.") A monitoring system is given in intensive care units, which acquires ▶ time series from minute measurements. The observations at the bedside are entered manually into the system. The information from the hospital is entered via a local area network. The physician accesses information from libraries and research databases (dashed lines). Libraries, research databases, and biomedical research also influence the development of guidelines, protocols, and clinical pathways (dotted lines). Guidelines are rather abstract. Protocols of certain actions are integrated to become a clinical pathway which is a plan of both diagnostic and therapeutical actions for a typical patient with a specific diagnosis. The bold arrow shows the intended high-quality therapy. Guidelines and protocols promote evidence-based practices, reduce inter-clinician practice variations and support decision-making in patient care while constraining the costs of care. Computerized protocols can be generated based on guidelines. They have been proved useful in improving the quality and consistency of healthcare but the protocol development process is time-consuming (Ten Teije et al. 2006). This is where machine learning offers support. Usually, ontologies (e.g., in description logic) or other knowledge-based techniques (in medicine-specific formats like the Arden Syntax, GuideLine Interchange Format (GLIF), PROforma, Asbru, and EON) are used to support the development of protocols (de Clercq et al. 2004). By contrast, machine learning induces the current practices and their outcome from the health records (Smith et al. 2009). To reflect such use of Machine Learning, the bold arrows of the picture would need to be turned the other way around, protocols are learned from the data or evaluated based on the data. All (reversed) arrows mark possible applications of machine learning.



Diversity of Representations

The overall health record of a patient includes several types of data, not all of them are digital.

- Laboratory data consist of attributes almost always with numerical values, sometimes with discrete ordinal values, sometimes just binary values like “positive,” “negative.”
- Plain text states anamneses, diagnosis, and observations. From the text, key words can be transformed into attributes for machine learning.
- Online measurements at the bedside are time series. They are analyzed in order to find level changes or trends (Gather et al. 2006) and alarm the physician (Sieben and Gather 2007). In order to exploit the time series for further learning tasks, they often are abstracted (e.g., Bellazzi et al. 2002). Recently, online measurements from body sensors have raised attention in the context of monitoring patients at home (Amft and Tröster 2008).
- Sequences can also be considered time series, but the measurements are not equidistant and not restricted to numerical values. Examples are data gathered at doctors’ visits and long-term patient observations.
- X-rays or other imaging data (e.g., ultrasound imaging or more novel molecular imaging techniques like positron emission tomography, magnetic resonance imaging, or computer tomography) cannot be analyzed directly by machine learning algorithms. They require the extraction of features. It has been shown that the adequate extraction of features is more important than the selection of the best suited learning algorithm (Mavroforakis et al. 2006). The number of extracted features can become quite large. For instance, from 1,619 images of skin lesion, each 752 × 582 pixels, 107 features were extracted in order to detect melanoma using diverse learning algorithms (Dreiseitl et al. 2001). Hence, feature selection is also an important task in medical applications (Lucaces et al. 2009; Withayachumnankul et al. 2006). Often, different techniques are applied to gather data for the detection of the same disease. For instance, glaucoma detection uses standard automated perimetry or scanning laser or Heidelberg Retina Tomograph or stratus optical coherence tomography. It is not yet clear how important the choice among measurement types (devices) is with respect to feature extraction and machine learning.

- Tissue and blood: In vitro "data" also belong to health records. Immediately after biopsy or surgery, the tissue is transferred to the pathology department. After the pathologist has taken the sample needed for proper diagnosis, a representative tissue sample will be snap frozen and stored in liquid nitrogen or at −80 °C. Also blood cells are stored in a blood bank. From the specimen, the RNA is extracted and the so-called microarrays of gene expressions are developed and then scaled. The huge prognostic value of gene expression in patients with breast cancer has been shown by van't Veer et al. (2002). Genome research aims at revealing the impact of gene regulation and protein expression-regulation (taking into account the regulation of protein synthesis, protein ubiquitination, and post-translational modification) on, e.g., cancer diagnosis and response to therapies. Machine learning, particularly clustering, frequent itemset mining, and classification have been applied successfully (see learning from gene expression microarray data).

In addition to patient records, there are knowledge bases describing particular diseases or computerized protocols for particular therapies.

Medical Tasks

Diagnosis and Medication

Diagnosis is primarily a classification task. Given the description of the patient's state and a set of diseases, the learning algorithm outputs the classification into one of the classes. If physicians want to inspect the learned classifier, logic-based algorithms are preferred. Decision trees and the conceptual clustering algorithm AQ were used to diagnose breast cancer from nine abstracted descriptions like tumor size: 0–4, 5–9, ⋯ 50–54, 55–59 (Michalski et al. 1986; Cestnik et al. 1987).

▸ Bayesian methods were used to classify, e.g., diseases of the lymph node. Based on the examination of the extracted tissue, a pathologist enters the description. The Bayesian network (BN) outputs not only just one diagnosis, but the conditional probabilities for the diseases (Heckerman 1990). In particular, diagnosis for rather vague symptoms such as abdominal pain or lower back pain is well supported by BNs (McNaught et al. 2001). BNs are capable of incorporating given expert knowledge as priors. In order to combine textbook knowledge with empirical data, electronic literature was transformed into priors for BN structures. Then, from health records, the BN was learned as a model of ovarian tumors (Antal et al. 2004).

▸ Inductive logic programming (ILP) also allows to take into account background knowledge. This was used for an enhanced learning of medical diagnostic rules (Lavrac et al. 1993). The identification of glaucomatous eyes was effectively learned by ILP (Mizoguchi et al. 1997). One advantage of ILP is that the learned logic clauses can easily be integrated into a knowledge-based system and, hence, become operational for clinical practice.

Since some tests which deliver information about the patient's state can be costly – both, financially and in terms of a risk for the patient – ▸ cost-sensitive learning may be applied.

Since the error of classifying a patient as ill where he or she is not (false positives) is less harmful than classifying a patient as healthy where he or she is not (false negatives), the evaluation of the learning result most often is used in a biased way. The evaluation can be summarized in Table 1.

Precision is the proportion $\frac{A}{A+B}$, and *recall* is the proportion $\frac{A}{A+C}$. *Sensitivity* is synonymous to recall. In medical applications, sensitivity is balanced with respect to *specificity* being the proportion $\frac{B}{B+D}$ (synonym *false positives rate*). The analysis of the Receiver Operator Characteristic

Medicine: Applications of Machine Learning, Table 1
Evaluation measures

	True+	False−
Predicated+	A	B
Predicated−	C	D

(ROC) allows to evaluate learning according to sensitivity and specificity (see ▸ ROC analysis).

If not the understandability but only sensitivity and specificity are important, numerical learning algorithms are used to classify the patient's data. In particular, if the patient's state is described by numerical features, no discretization is necessary for numerical learners as is needed for the logic-based ones. Multilayer perceptrons (see ▸ Neural Networks), ▸ support vector machines (SVM), mixtures of Gaussians, and mixture of generalized Gaussian classifiers were trained on the numerical data of 189 normal eyes and 156 glaucomatous eyes (Goldbaum et al. 2002). The numerical description of the visual field is given by standard automated threshold perimetry. The medical standard procedure to interpret the visual field is to derive global indices. The authors compared performance of the classifiers with these global indices, using the area under the ROC curve. Two human experts were judged against the machine classifiers and the global indices by plotting their sensitivity–specificity pairs. The mixture of Gaussian had the greatest area under the ROC curve of the machine classifiers, and human experts were not better at classifying visual fields than the machine classifiers or the global indices.

Other approaches to glaucoma detection use different features describing the patient's state (Zangwill et al. 2004) or other numerical learners, e.g., ▸ logistic regression (Huang et al. 2006). For testing the learning from numerical attributes, the UCI Machine Learning Repository offers the arrhythmia database. The aim is to distinguish between the presence and absence of cardiac arrhythmia and to classify it in one of the 16 groups. About 279 attributes are given, 206 of them being numerical ones.

As has been shown in an application to intensive care, medication can be transformed into a set of classification tasks (Morik et al. 2000). Given measurements of eight vital signs, a decision is made for each of six drugs, whether to increase or to decrease it. This gives a set of classification tasks, which the ▸ SVM learned. Depending on the drug, the accuracy ranged from 81.3 % with 2.5 standard error to 86.9 % with 7 standard error. Additionally, on 41 cases, the SVM decision was compared with an expert's decisions when confronted with the same data. In 32 cases the expert chose the same direction of change as did the learned decision function. In 34 cases the learned decision was equal to the actual therapy. Another set of classification tasks were to decide every minute whether to increase, decrease, or leave the doses as it is. Again, each of these classifiers was learned by the SVM. From 1,319 examples decision functions were learned and tested on 473 examples. For training, an unbalanced cost function was used. The SVM cost factor for error was chosen according to $\frac{C_+}{C_-} = \frac{numberofnegativeexample}{numberofpositiveexample}$. The results again differed depending on the drug. For adrenaline, 79 % of the test cases were equally handled by the physician and the decision function. For adrenaline as well as for dobutamine, only in 1.5 % of the test cases the learned rule recommended the opposite direction of change. Again, a blind test with an expert showed that the learned recommendations' deviation from actual therapy was comparable to that of the human expert. Combining the two sets of classifications, for each minute and each patient, the support vector machine's decision function outputs a recommendation of treatment (Morik et al. 2000).

Prognosis and Quality of Care Assessment

Prognosis or outcome prediction is important for the evaluation of the quality of care provided. The standard statistical models use only a small set of covariates and a score variable, which indicates the severity of the illness. Machine learning may also rely on the aggregated score features, but is in addition capable of handling the features underlying the scores. Given health records of patients including the therapy, machine learning is to predict the outcome of care, e.g., classifies into mortal or surviving cases. The prediction of breast cancer survivability has been tested on a very large database comparing three learning methods (Delen et al. 2004). The results indicated that decision trees (here: C5) result in the best predictor with 93.6 % accuracy on the holdout sample (this prediction accuracy is better than any reported in the literature), artificial neural networks came out to be the second with 91.2 % accuracy, and the ▶ logistic regression models came out to be the worst of the three with 89.2 % accuracy.

Prediction of survival is a hard task for patients with serious stroke, because there is a long-term risk after the stay at the hospital. The scoring schemes (e.g., the Glasgow coma scale and the Ranking score) are not sufficient for predicting the outcome. In a data situation where 29 attributes (or features) were given for only 327 patient records, BNs were learned and compared with a handmade causal network. The results were encouraging – as soon as more electronic health records become available, the BNs will become closer to medical knowledge. Moreover, the discovery of relations on the basis of empirical data may enhance medical knowledge (Wu et al. 2001).

Carcinogenesis prediction was performed using ILP methods. As has become usual with cancer diagnosis and prognosis, there is a close link with microbiology (Srinivasan et al. 1994) (see Learning from gene expression microarray data).

Prognosis need not be restricted to mortality rates. In general, it is a means of quality assessment of clinical treatments. For instance, hemodialysis services have been assessed through temporal data mining by Bellazzi et al. (2002).

Finding subgroups of patients with devious reactions to a therapy might lead to a better understanding of a certain medical process (Atzmueller et al. 2005). While the before mentioned study aims at an enhanced expert – system interaction, a Dutch study aims at a more precise modeling of prognoses (Abu-Hanna and Lucas 2001). In an extensive study for eight different hospitals and 7,803 patients, two different models were combined: one for determining the subgroups and the other for building a model for each subgroup. For the prognoses of patients in an intensive care unit, subgroups have been detected using decision trees. The decision tree was trained to classify patients into the survival class and the mortality class on the basis of the nonaggregated features underlying the illness score. The leaves of the tree become subgroups. These are then used for training a logistic regression model of mortality based on the aggregated features.

Verification and Validation

Verification is the process of testing a model against a specification. In medicine, this often means to check clinical practice against expert protocols, or to check an actual diagnosis against one derived from textbook knowledge. Since many logic-based machine learning algorithms consist of a generalization and a specialization step, they can be used for verification. Generalization delivers rules from clinical data which can then be compared with given expert rules (protocols). Specialization is triggered by facts that contradict a learning hypothesis. Hence, using an expert rule as hypothesis, the learning algorithm counts the contradicting clinical cases and specializes the rule. For an early case study on verification and rule enhancement see, e.g., Morik et al. (1994). A more recent study compares a given clinical protocol for intensive care with actual therapies at another hospital (Scholz 2002). Decision trees and association rules have been learned in order to inspect and enhance the knowledge base of a web-based teledermatology system (Ou et al. 2007). While verification means to build the system right, validation means to build the right system. The borderline between verification and validation is fuzzy. On the one hand, medical practice is investigated with respect to the guidelines (verification), on the other hand, the guidelines are enhanced on the basis of medical practice (validation).

Moreover, learned models can be verified with respect to expert knowledge and validated with respect to clinical practice. A study on the hemodynamic monitoring of the critically ill integrated machine learning into a knowledge-based approach to evidence-based medicine. A knowledge base on drug effects was verified using patient records. Only 18 % of the observations showed vital signs of patients in the opposite direction than predicted by the knowledge base. Then, the knowledge base was used to validate therapeutical interventions proposed by a learned model. Accuracy measures of a model only reflect how well the learning result fits actual behavior of the physician and not how well it fits the "gold standard." Hence, a proposed intervention should be validated with respect to its effects on the patient. If the known effects push vital signs in the direction of the desired value range, the recommendation is considered sound, otherwise it is rejected. Using past data, the learned model was found to recommend an intervention with the desired effects in 81 % of the cases (Morik et al. 2002).

Intelligent Search in Medical Literature

Intelligent search in the overwhelming number of research publications supplies the information when it is needed. ILP has been successfully put to use for finding relevant medical documents (Dimec et al. 1999). Also the intelligent search in clinical free-text guidelines is an issue (Moskovitch et al. 2006). The techniques for text categorization can be applied to medical texts in the usual way. If the search engine not only labels the overall document but, in addition, phrases within it, the search could become more focused and also deliver paragraphs instead of complete texts. The biomedical challenge for *named entity recognition* requires the automatic extraction and classification of words referring to DNA, RNA, proteins, cell types, and cell lines from texts (Kim et al. 2004). Even more difficult is the discovery of medical knowledge from texts (Sanchez and Moreno 2005).

Epidemiology and Outbreak Detection

Understanding the transmission of infectious diseases and forecasting epidemics is an important task, since infections are distributed globally. Statistical approaches to spatio-temporal analysis of scan data are regularly used. There, a grid partitions the map into regions where occurrences of the disease are shown as points. "Hot spot" partitions are those of high density. By contrast, clustering detects hot spot regions depending on the data, hence, the shape of regions is flexible. Taking into account the a priori density of the population, a risk-adjusted nearest neighbor hierarchical clustering discovers "hot spot" regions. Also a risk-adjusted support vector machine with Gaussian kernel has successfully been applied to the problem of detecting regions with infectious disease outbreak. The discovery of hot spot regions can be exploited for predicting virus activity, if an indicator is known which can easily be observed. For instance, dead crows indicate activity of the West Nile virus. An overview of infectious disease informatics is given by Zeng et al. (2005).

Machine learning can also contribute to the understanding of the transmission of infectious diseases. A case study on tuberculosis epidemiology uses BNs to identify the distribution of tuberculosis patient attributes. The learning results captured the known statistical relationships. A relational model learned from the database directly using structured statistical models revealed several novel associations (Getoor et al. 2004).

A metaheuristic is a set of concepts that can be used to define heuristic methods that can be applied to a wide set of different problems. In other words, a metaheuristic can be seen as a general algorithmic framework that can be applied to different optimization problems with relatively few modifications. Examples of metaheuristics include simulated annealing, tabu search, iterated local search, evolutionary algorithms, and ant colony optimization.

Abstract

In the area machine learning / data mining many diverse algorithms are available nowadays and hence the selection of the most suitable algorithm may be a challenge. Tbhis is aggravated by the fact that many algorithms require that certain parameters be set. If a wrong algorithm and/or parameter configuration is selected, substandard results may be obtained. The topic of metalearning aims to facilitate this task. Metalearning typically proceeds in two phases. First, a given set of algorithms A (e.g. classification algorithms) and datasets D is identified and different pairs <ai,dj> from these two sets are chosen for testing. The dataset di is described by certain meta-features which together with the performance result of algorithm ai constitute a part of the metadata. In the second phase the metadata is used to construct a model, usually again with recourse to machine learning methods. The model represents a generalization of various base-level experiments. The model can then be applied to the new dataset to recommend the most suitable algorithm or a ranking ordered by relative performance. This article provides more details about this area. Besides, it discusses also how the method can be combined with hyperparameter optimization and extended to sequences of operations (workflows).

Synonyms

Adaptive learning; Dynamic selection of bias; Hyperparameter optimization; Learning to learn; Selection of algorithms, Ranking learning methods; Self-adaptive systems

Definition

Metalearning allows machine learning systems to benefit from their repetitive application. If a learning system fails to perform efficiently, one would expect the learning mechanism itself to adapt in case the same task is presented again. Metalearning differs from base learning in the scope of the level of adaptation; whereas learning at the base level is focused on accumulating experience on a specific task (e.g., credit rating, medical diagnosis, mine-rock discrimination, fraud detection, etc.), learning at the meta-level is concerned with accumulating experience on the performance of multiple applications of a learning system.

Briefly stated, the field of metalearning exploits the relation between tasks or domains and learning algorithms. Rather than starting afresh on each new task, metalearning facilitates evaluation and comparison of learning algorithms on many different previous tasks, establishes benefits and disadvantages, and then recommends the learning algorithm, or combination of algorithms, that maximizes some utility function on the new task. This problem can be seen as an instance of the algorithm selection task (Rice 1976).

The utility or usefulness of a given learning algorithm is often determined through a mapping between a characterization of the task and the algorithm's estimated performance (Brazdil and Henery 1994). In general, metalearning can recommend more than one algorithm. Typically, the number of recommended algorithms is significantly smaller than the number of all possible (available) algorithms (Brazdil et al. 2009).

Motivation and Background

The application of machine learning systems to classification and regression tasks has become a standard, not only in research but also in commerce and industry (e.g., finance, medicine, and engineering). However, most successful applications are custom designed, the result of skillful use of human expertise. This is due, in part, to the large, ever-increasing number of available machine learning systems, their relative complexity, and the lack of systematic methods for discriminating among them. The problem is further compounded by the fact that, in Knowledge Discovery from Databases, each operational phase (e.g., pre-processing, model generation) may involve a choice among various possible alternatives (e.g., progressive vs. random sampling, neural network vs. decision tree learning), as observed by Bernstein et al. (2005).

Current data mining systems are only as powerful as their users. These tools provide multiple algorithms within a single system, but the selection and combination of these algorithms must be performed before the system is invoked, generally by an expert user. For some researchers, the choice of learning and data transformation algorithms should be fully automated if machine learning systems are to be of any use to nonspecialists. Others claim that full automation of the data mining process is not within the reach of current technology. An intermediate solution is the design of assistant systems aimed at helping to select the right learning algorithm(s). Whatever the proposed solution, there seems to be an implicit agreement that metaknowledge should be integrated seamlessly into the data mining system. Metalearning focuses on the design and application of learning algorithms to acquire and use metaknowledge to assist machine learning users with the process of model selection. A general framework for this purpose, together with a survey of approaches, is in Smith-Miles (2008).

Metalearning is often seen as a way of redefining the space of inductive hypotheses searched by the learning algorithm(s). This issue is related to the idea of ▸ search bias, that is, search factors that affect the definition or selection of inductive hypotheses (Mitchell 1997). In this sense, metalearning studies how to choose the right bias dynamically and thus differs from base-level learning, where the bias is fixed or user parameterized. Metalearning can also be viewed as an important feature of self-adaptive systems, that is, learning systems that increase in efficiency through experience (Vilalta and Drissi 2002).

Structure of the Metalearning System

A metalearning system is essentially composed of two parts. One part is concerned with the acquisition of metaknowledge from machine learning systems. The other part is concerned with the application of metaknowledge to new problems with the objective of identifying an optimal learning algorithm or technique. The latter part – application of metaknowledge – can be used to help select or adapt suitable machine learning algorithms. So, for instance, if we are dealing with a ▸ classification task, metaknowledge can be used to select a suitable ▸ classifier for the new problem. Once this has been done, one can train the classifier and apply it to some unclassified sample for the purpose of class prediction.

In the following sections, we begin by describing scenarios corresponding to the case when metaknowledge has already been acquired. We then provide an explanation of how this knowledge is acquired.

Employing Metaknowledge to Select Machine Learning Algorithms

The aim of this section is to show that metaknowledge can be useful in many different settings. We will start by considering the problem of selecting suitable machine learning algorithms from a given set. The problem can be seen as a search problem. The search space includes the individual machine learning algorithms, and the aim is to identify the best algorithm. This process can be divided into two separate phases. In the first phase, the aim is to identify a suitable subset of machine learning algorithms based on an

(e)

Metalearning, Fig. 1 Selection of machine learning algorithms: determining the reduced space and selecting the best alternative

input dataset (Fig. 1a–1b). The selection method used in this process can exploit metaknowledge (Fig. 1c). This is in general advantageous, as it often leads to better choices. In some work the result of this phase is represented in the form of a ranked subset of machine learning algorithms (Fig. 1d). The subset of algorithms represents the reduced bias space. The ranking (i.e., ordering of different algorithms) represents the procedural search bias.

The second phase is used to search through the reduced space. Each option is evaluated using a given performance criterion (e.g., accuracy). Typically, cross-validation is used to identify the best learning algorithm (Fig. 1e). We note that metaknowledge does not completely eliminate the need for the search process but rather provides a more effective search. The search effectiveness depends on the quality of metaknowledge.

Input to and Output from the Metalearning System

A metalearning approach to solving the algorithm selection problem relies on dataset characteristics or meta-features that provide some information to differentiate performance among a given set of learning algorithms. These include various types of measures, or meta-features, discussed in detail below.

Much previous work in dataset characterization has concentrated on extracting statistical and information-theoretic parameters estimated from the training set. Measures include the number of classes, the number of features, the ratio of examples to features, the degree of correlation between features and target concept, the average class entropy, etc. (Engels and Theusinger 1998). The disadvantage of this approach is that there is a limit to how much information these meta-features can capture, given that all these measures are uni- or bilateral measures only (i.e., they capture relationships between two attributes only or one attribute and the class).

Another approach is based on what are called *landmarkers*; these are simple and fast learners (Pfahringer et al. 2000). The accuracy of these simplified algorithms is used to characterize a dataset and to identify areas where each type of learner can be regarded as an expert. An interesting variation on the theme of landmarking uses information obtained on simplified versions of the data (e.g., samples). Accuracy results on these samples serve to characterize individual datasets and are referred to as *subsampling landmarks*.

In principle, any machine learning algorithm can be used at the meta-level. However, one important aspect of the metalearning task is the scarcity of training data. As a result, many researchers in the past have used *lazy learning* methods, such as k-NN, since these delay the generalization of metadata to the application phase (Nakhaeizadeh and Schnabl 1997). However, other types of models, such as neural networks, ranking trees, and bagging ensembles, have been proposed and proved rather successful (Sun and Pfahringer 2012, 2013).

There are several possible outputs or types of model a metalearning system can produce. Some focus on selecting the best algorithm in the set of available base learners; some attempt to predict the actual performance of individual algorithms; yet others assess the relative performance of different pairs of algorithms; finally, some systems produce a complete ranking of the base learners that can then be followed by minimal testing to identify the truly best algorithm for the user's dataset. One significant advantage of ranking methods is that they offer a next best alternative if the first algorithm seems to be suboptimal. As the set of base learners may contain variants of the same algorithms, and it would be wasteful to test them all before moving on to other types of algorithms, a recent approach known as active testing has been proposed, which seeks to identify the most promising algorithm that has a chance of surpassing the best algorithm identified so far (Leite et al. 2012).

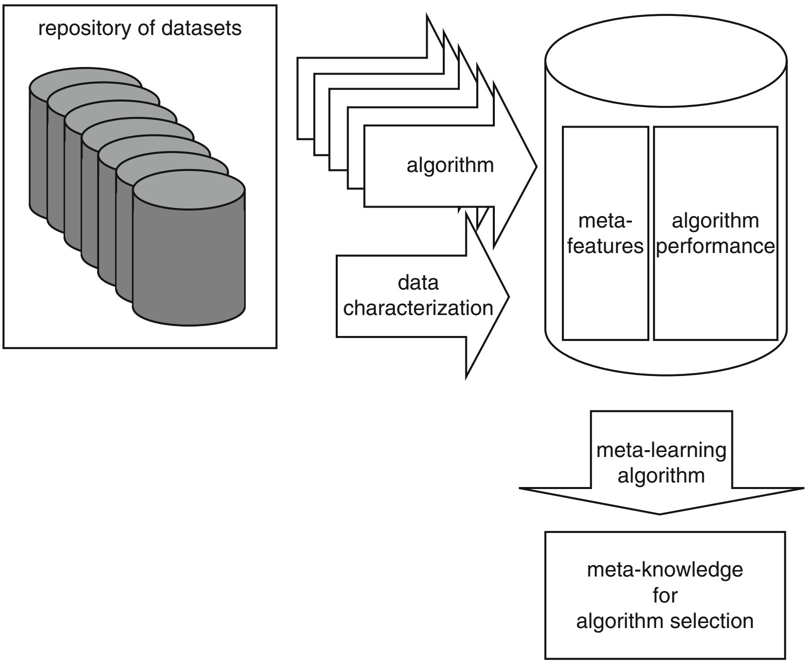
Acquisition of Metaknowledge

There are two natural ways in which metaknowledge can be acquired. One possibility is to rely on expert knowledge. Another possibility is to use an automatic procedure. We explore both alternatives briefly below.

One way of representing metaknowledge is in the form of rules that match domain (dataset) characteristics with machine learning algorithms. Such rules can be handcrafted, taking into account theoretical results, human expertise, and empirical evidence. For example, in decision tree learning, a heuristic rule can be used to switch from univariate tests to linear tests if there is a need to construct non-orthogonal partitions over the input space. This method has serious disadvantages however. First, the resulting rule set is likely to be incomplete. Second, timely and accurate maintenance of the rule set as new machine learning algorithms become available is problematic. As a result, most research has focused on automatic methods.

One other way of acquiring metaknowledge relies on automatic experimentation. For this we need a pool of problems (datasets) and a set of machine learning algorithms that we wish to consider. Then we need to define the experimental method that determines which alternatives we should experiment with and in which order (see Fig. 2 for details).

Suppose we have a dataset (characterized using certain meta-features), in combination with certain machine learning algorithms. The combination is assessed using an evaluation method (e.g., cross-validation) to produce performance results. The results, together with the characterization, represent a piece of metadata that is stored in the metaknowledge base. The process is then repeated for other combinations of datasets and algorithms.



Metalearning, Fig. 2 Acquisition of metadata for the metaknowledge base

Algorithm Selection and Hyperparameter Optimization

While this entry describes metalearning in the context of selecting algorithms for machine learning, there are a number of other areas, such as regression, time series forecasting, and optimization (Smith-Miles 2008), where algorithm selection is important and could benefit from a similar approach.

Similarly, there has been recent interest in the optimization community in the problem of hyperparameter optimization, wherein one seeks a set of hyperparameters for a learning algorithm, usually with the goal of obtaining good generalization and consequently low loss (Xu et al. 2008). Hyperparameter optimization is clearly relevant to algorithm selection, since most learning algorithms have parameters that can be adjusted and whose values may affect the performance of the learner. Historically, metalearning has largely ignored parameter selection, and hyperparameter optimization has largely ignored metalearning. Recent efforts in bringing the two fields together hold promise.

Applying Metalearning to Workflow Design for KDD

Much of the work in metalearning has focused on classification algorithm selection and thus addressed only a small fraction of the overall data mining process. In practice, users must not only select a classification learner but must often also consider various data pre-processing steps and other aspects of the process to build what are actually sequences of operations to apply to their data, also known as workflows. Several advances have been made in recent years in this area (Hilario et al. 2011; Kietz et al. 2012). Usually, it is possible to distinguish two phases. In the first phase, the system runs different experiments that involve different workflows for many diverse problems. The workflow may be generated automatically with the recourse to a given ontology of operators. The individual problems are characterized and the performance of different workflows recorded. This can be compared to running experiments with a set of classification algorithms and gathering the metaknowledge. In the second phase, the system carries out planning with the aim of designing a workflow that is likely to achieve good results. In this phase, a given ontology of operators can again be exploited. The expansion of the operators may be guided by the existing metaknowledge.

The aim is to give preference to the more promising expansions and generate a ranked list of viable workflows.

Minimum Description Length Principle

Teemu Roos
Department of Computer Science, Helsinki Institute for Information Technology, University of Helsinki, Helsinki, Finland

Abstract

The minimum description length (MDL) principle states that one should prefer the model that yields the shortest description of the data when the complexity of the model itself is also accounted for. MDL provides a versatile approach to statistical modeling. It is applicable to model selection and regularization. Modern versions of MDL lead to robust methods that are well suited for choosing an appropriate model complexity based on the data, thus extracting the maximum amount of information from the data without over-fitting. The modern

versions of MDL go well beyond the familiar $\frac{k}{2}\log n$ formula.

Philosophy

The MDL principle is a formal version of Occam's razor. While the Occam's razor only suggests that between hypotheses that are compatible with the evidence, one should choose the simplest one, the MDL principle also quantifies the compatibility of the hypotheses with the evidence. This leads to a trade-off between the complexity of the hypothesis and its compatibility with the evidence ("goodness of fit").

The philosophy of the MDL principle emphasizes that the evaluation of the merits of a model should not be based on its closeness to a "true" model, whose existence is often impossible to verify, but instead on the data. Inspired by Solomonoff's theory of universal induction, Rissanen postulated that a yardstick of the performance of a statistical model is the probability it assigns to the data. Since the probability is intimately related to code length (see below), the code length provides an equivalent way to measure performance. The key idea made possible by the coding interpretation is that the length of the description of the model itself can be quantified in the same units as the code length of the data, namely, bits. Earlier, Wallace and Boulton had made a similar proposal under the title minimum message length (MML) (Wallace and Boulton 1968). A fundamental difference between the two principles is that MML is a Bayesian approach while MDL is not.

The central tenet in MDL is that the better one is able to discover the regular features in the data, the shorter the code length. Showing that this is indeed the case often requires that we assume, for the sake of argument, that the data are generated by a true distribution and verify the statistical behavior of MDL-based methods under this assumption. Hence, the emphasis on the freedom from the assumption of a true model is more pertinent in the philosophy of MDL than in the technical analysis carried out in its theory.

Theory

The theory of MDL addresses two kinds of questions: (i) the first kind asks what is the shortest description achievable using a given model class, i.e., universal data compression; (ii) the second kind asks what can be said about the behavior of MDL methods when applied to model selection and other machine learning and data mining tasks. The latter kind of questions are closely related to the theory of statistical estimation and statistical learning theory. We review the theory related to these two kinds of questions separately.

Universal Data Compression

As is well known in information theory, the shortest expected code length achievable by a uniquely decodable code under a known data source, p^*, is given by the entropy of the source, $H(p^*)$. The lower bound is achieved by using a code word of length $\ell^*(x) = -\log p^*(x)$ bits for each source symbol x. (Here and in the following, log denotes base-2 logarithm.) Correspondingly, a code-length function ℓ is optimal under a source distribution defined by $q(x) = 2^{-\ell(x)}$. (For the sake of notational simplicity, we omit a normalizing factor $C = \sum_x 2^{-\ell(x)}$ which is necessary in case the code is not complete. Likewise, as is customary in MDL, we ignore the requirement that code lengths be integers.) These results can be extended to data sequences whereupon we write $x^n = x_1 \dots x_n$ to denote a sequence of length n.

While the case where the source distribution p^* is known can be considered solved in the sense that the average-case optimal code-length function ℓ^* is easily established as described above, the case where p^* is unknown is more intricate. Universal data compression studies similar lower bounds when the source distribution is not known or when the goal is not to minimize the expected code length. For example, when the source distribution is only known to be in a given *model class* (a set of distributions), $\mathcal{M}$, the goal may be to find a code that minimizes the *worst-case* expected code length under any source distribution $p^* \in \mathcal{M}$. A uniquely decodable code that achieves near-optimal code lengths with respect to a given model class is said to be *universal*.

Rissanen's groundbreaking 1978 paper (Rissanen 1978) gives a general construction for universal codes based on *two-part codes*. A two-part code first includes a code for encoding a distribution, q, over source sequences. The second part encodes the data using a code based on q. The length of the second part is thus $-\log q(x^n)$ bits. The length of the first part, $\ell(q)$, depends on the complexity of the distribution q, which leads to a trade-off between complexity measured by $\ell(q)$ and goodness of fit measured by $\log q(x)$:

$$\min_q(\ell(q) - \log q(x^n)). \tag{1}$$

For parametric models that are defined by a continuous parameter vector θ, a two-part coding approach requires that the parameters be quantized so that their code length is finite. Rissanen showed that given a k-dimensional parametric model class, $\mathcal{M} = \{p_\theta\,;\, \theta \in \Theta \subset \mathbb{R}^k\}$, the optimal quantization of the parameter space Θ is achieved by using accuracy of order $1/\sqrt{n}$ for each coordinate, where n is the sample size. The resulting total code length behaves as $-\log \hat{p}(x^n) + \frac{k}{2}\log n + \mathcal{O}(1)$, where $\hat{p}(x^n) = \max\{p_\theta(x^n) : \theta \in \Theta\}$ is the maximum probability under model class $\mathcal{M}$. Note that the leading terms of the formula are equivalent to the Bayesian information criterion (BIC) by Schwarz (Schwarz 1978). Later, Rissanen also showed that this is a *lower bound* on the code length of any universal code that holds for all but a measure-zero subset of sources in the given model class (Rissanen 1986).

The above results have subsequently been refined by studying the asymptotic and finite-sample values of the $\mathcal{O}(1)$ residual term for specific model classes. The resulting formulas lead to a more accurate characterization of model complexity, often involving the Fisher information (Rissanen 1996).

Subsequently, Rissanen and others have proposed other kinds of universal codes that are superior to two-part codes. These include Bayes-type mixture codes that involve a prior distribution for the unknown parameters (Rissanen 1986), predictive forms of MDL (Rissanen 1984; Wei 1992), and, most importantly, normalized maximum likelihood (NML) codes (Yuri 1987; Rissanen 1996). The latter have the important point-wise minimax property that they achieve the minimum worst-case point-wise redundancy:

$$\min_q \max_{x^n} -\log q(x^n) + \log \hat{p}(x^n),$$

where the maximum is over all possible data sequences of length n and the minimum is over all distributions.

Behavior of MDL-Based Learning Methods

The philosophy of MDL suggests that data compression is a measure of the success in discovering regularities in the data, and hence, better compression implies better modeling. Showing that this is indeed the case is the second kind of theory related to MDL.

Barron and Cover proposed the *index of resolvability* as a measure of the hardness of estimating a probabilistic source in a two-part coding setting (see above) (Barron and Cover 1991). It is defined as

$$R_n(p^*) = \min_q \left(\frac{\ell(q)}{n} + D(p^* \,||\, q) \right),$$

where p^* is the source distribution and $D(p^* \,||\, q)$ denotes the Kullback-Leibler divergence between p^* and q. Intuitively, a source is easily estimable if there exists a simple distribution that is close to the source. The result by Barron and Cover bounds the Hellinger distance between the true source distribution and the distribution $\hat{q}$ minimizing the two-part code length, Eq. (1), as

$$d_H^2(p^*, \hat{q}) \le \mathcal{O}(R_n(p^*)) \quad \text{in } p^*\text{-probability}.$$

For model selection problems, consistency is often defined in relation to a fixed set of alternative model classes and a criterion that selects one of them given the data. If the criterion leads to the simplest model class that contains the true source distribution, the criterion is said to be consistent. (Note that the additional requirement that the selected model class is the simplest one is needed in order to circumvent a trivial solution in nested model classes where simpler models are subsets of more complex model classes.) There are a large number of results showing that various MDL-based model selection criteria are consistent; for examples, see the next section.

Applications

MDL has been applied in a wide range of applications. It is well suited for model selection problems where one needs not only to estimate continuous parameters but also their number and, more generally, the *model structure*, based on statistical data. Other approaches applicable in many such scenarios include Bayesian methods (including minimum message length), cross validation, and structural risk minimization (see Cross-References below).

Some example applications include the following:

1. Autoregressive models, Markov chains, and their generalizations such as *tree machines* were among the first model classes studied in the MDL literature, see Rissanen (1978, 1984) and Weinberger et al. (1995).
2. Linear regression. Selecting a subset of relevant covariates is a classical example of a situation involving models of variable complexity, see Speed and Yu (1993), Wei (1992), and Rissanen (2000).
3. Discretization of continuous covariates enables the use of learning methods that use discrete data. The granularity of the discretization can be determined by applying MDL, see Fayyad and Irani (1993).
4. The structure of probabilistic graphical models encodes conditional independencies and determines the complexity of the model. Their structure can be learned by MDL, see, e.g., Lam and Bacchus (1994) and Silander et al. (2010)

Future Directions

The development of efficient and computationally tractable codes for practically relevant model classes is required in order to apply MDL more commonly in modern statistical applications. The following are among the most important future directions:

- While the original $\frac{k}{2}\log n$ formula is still regularly referred to as "the MDL principle," future work should focus on modern formulations involving more advanced codes such as the NML and its variations.
- There is strong empirical evidence suggesting that coding strategies with strong minimax properties lead to robust model selection methods, see, e.g., Silander et al. (2010). Tools akin to the index of resolvability are needed to gain better theoretical understanding of the properties of modern MDL methods.
- Scaling up to modern big data applications, where model complexity regularization is crucial, requires approximate versions of MDL with sublinear computational and storage requirements. Predictive MDL is a promising approach in handling high-throughput streaming data scenarios.

Minimum Message Length

Rohan A. Baxter
Australian Taxation Office, Sydney, NSW, Australia

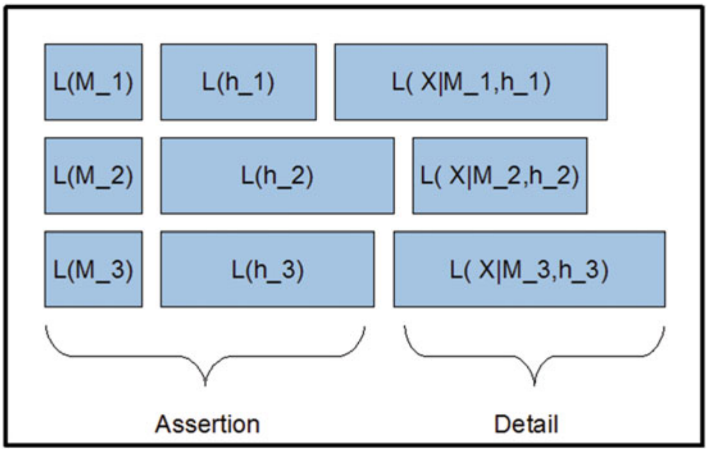
Abstract

The Minimum Message Length (MML) Principle is an information-theoretic approach to induction, hypothesis testing, model selection, and statistical inference. MML, which provides a formal specification for the implementation of Occam's Razor, asserts that the 'best' explanation of observed data is the shortest. MML was first published by Chris Wallace and David Boulton in 1968.

Definition

Minimum message length is a theory of ▸ inductive inference whereby the preferred model is the one minimizing the expected message length required to explain the data with the prior information.

Given the data represented in a finite binary string, E, an ▸ explanation of the data is a two-part ▸ message or binary string encoding the data to be sent between a sender and receiver. The first part of the message (the ▸ assertion) states a hypothesis, model, or theory about the source of the data. The second part (the ▸ detail) states those aspects of E which cannot be deduced from this assertion and prior knowledge. The sender and receiver are assumed to have agreed on the prior knowledge, the assertion code, and the detail code before the message is constructed and sent. The shared prior knowledge captures their belief about the data prior to seeing the data and is needed to provide probabilities or, equivalently, optimum codes, for the set of models. The assertion and detail codes can be equivalently considered to be the shared language for describing models (for the assertion code) and for describing data (for the detail code).



Minimum Message Length, Fig. 1 A view of model selection by MML. The data is coded assuming a model and parameters in the assertion. The model and parameters are coded in the assertion. As shown here, often different models have same probability, while the code lengths for model parameters and data detail differ between the different models

Out of all possible models which might be advanced about the data, MML considers the best inference as that model which leads to the shortest explanation. The length of the explanation can be calculated using ▶ Shannon's information, $L(E) = -\log(P(E))$, where $L(E)$ is the length of the shortest string encoding an event, E, and $P()$ is the probability of a message containing E.

To compare models, we calculate the explanation length for each and prefer the one with shortest explanation length. Figure 1 shows three models being evaluated and the different lengths of the assertion and details for each. Model 2 is preferred as it has the minimum message length.

Motivation and Background

The original motivation for minimum message length inductive inference is the idea that the best explanation of the facts is the shortest (Wallace and Boulton 1968). By inductive inference, we mean the selection of a best model of truth. This goal is distinct from a best model for prediction of future data or for choosing a model for making the most beneficial decisions. In the field of machine learning, greater focus has been on models for prediction and decision, but inference of the best models of truth has an important separate application.

For discrete models, MML looks like Bayesian model selection since choosing H to minimize the explanation length of data X

$$\begin{aligned} -\log P(H) - \log P(X|H) \\ = -\log(P(H)P(X|H)) \end{aligned}$$

is often, but not always, as discussed below, equivalent to choosing H to maximize the probability

$$P(H|X) \quad :$$

$$P(H|X) = \frac{P(H)P(X|H)}{P(X)}$$

where $P(X)$ is a constant for a given detail code.

For models with real-valued parameters, the equivalence between MML and Bayesian model selection always breaks down (Wallace 2005, p. 117). Stating the $P(H)$ in a message requires real-valued parameters in H to be stated to a limited precision. The MML coding approach replaces a continuum of possible hypotheses with a discrete subset of values and assigns a nonzero prior probability to each discrete theory. The discrete subsets are chosen to optimize the expected message length given the prior knowledge assumptions.

For models with only discrete-valued parameters, the equivalence between MML and Bayesian model selection may break down if the discrete values chosen involve the merging of values in the assumed prior distribution, $P(H)$ (Wallace 2005, p. 156). This may occur with a small dataset if the data is insufficient to justify a codebook distinguishing individual members of H.

Other than a discretized hypothesis space, MML shares many properties of Bayesian learning such as sufficiency, avoidance of overfitting, and consistency (Wallace 2005). One difference arising from the discretized hypothesis space is that MML allows inductive inference to be invariant under arbitrary monotonic transformations of parameter spaces. The Bayesian learning options for model choice such as the maximum a posteriori (MAP) estimate are not invariant under such transformations. Other theoretical benefits include consistency and guarantees against overfitting.

Message lengths of an explanation can be based on the theory of algorithmic complexity (Wallace and Dowe 1999), instead of Shannon's information. The algorithmic complexity (AC) of a string with respect to a universal Turing machine, T, can be related to Shannon's information by regarding T as defining a probability distribution over binary strings, $P(S)$, such that

$$P_{T(S)} = 2^{-AC(S)}, \forall S$$

The connection with algorithmic complexity has some appeal for applications involving data that are not random in a probabilistic sense, such as function approximation where data seems to be from a deterministic source. In these cases, after fitting a model, the data residuals can be encoded using AC randomness, since the probabilistic sense of randomness does not apply (Wallace 2005, p. 275).

Theory

Strict MML (SMML) estimators refer to the estimator functions which exactly minimize the expected message length (Wallace and Boulton 1975). Most practical MML estimators are not strict and are discussed in a separate section on Approximations.

A SMML estimator requires (Dowe et al. 2007):

- X, a data space, and a set of observations from the data space, $\{x_i : i \in N\}$.
- $p(x|h)$, a conditional probability function over data given a model, h.
- H is a model space. For example, H can be a simple continuum of known dimension k.
- $P(h)$: a prior probability density on the parameter space H: $\int_H P(h)dh = 1$.

X, H, and the functions P(h), $p(x|h)$ are assumed to be known *a priori* by both the sender and receiver of the explanation message. Both the sender and receiver agree on a code for X, using knowledge of X, H, $p(h)$, and $f(x|h)$ only.

The marginal prior probability of the data x follows from the assumed background knowledge:

$$r(x) = \int_H p(x|h)P(h)dh$$

The SMML estimator is a function $m : X \to H : m(x) = h$ which names the model to be selected.

The assertion, being a finite string, can name at most a countable subset of H. Call the subset $H^* = \{h_j : j = 1, 2, 3, \ldots\}$. The choice of H^* implies a coding distribution over $H^* : f(h_j) = q_j > 0 : j = 1, 2, 3, \ldots$ with $\sum_j q_j = 1$. So choice of $H^*$and q_j lead to a message length:

$$-\log q_j - \log p(x|h_j)$$

The sender, given x, will choose an h to make the explanation short. This choice is described by an estimator function: $m(x) : X \to H$ so that the length of the explanation is

$$I_1(x) = -\log q(m(x)) - \log p(x|m(x))$$

and the expected length is (Wallace 2005, p. 155):

$$I_1 = -\sum_{x \in X} r(x) [\log q(m(x)) \\ + \log p(x_i|m(x_i))]$$

Consider how to choose H^* and coding distribution q_j to minimize I_1. This will give the shortest explanation on average, prior to the sender seeing the actual data.

Define $t_j = \{x : m(x) = h_j\}$, so that t_j is the set of data which results in assertion h_j being used in the explanation. I_1 can now be written as two terms:

$$I_1 = -\sum_{h_j \in H_{start}} \left(\sum_{x_i \in t_j} r_i \right) \log q_j - \sum_{h_j \in H_{start}} \sum_{x_i \in t_j} r_i \log p(x_i|h_j)$$

The first term of $I_1$is minimized by choosing:

$$q_j = \sum_{x_i \in t_j} r_j$$

So the coding probability assigned to estimate $h_j$is the sum of the marginal probabilities of the data values resulting in h_j. It is the probability that estimate h_j will be used in the explanation based on the assumptions made.

The second term of I_1 is the average of the log likelihood over the data values used in h_j. Dowty (2013) gives a method for calculating the SMML estimator for a one-dimensional exponential family of statistical models with a continuous sufficient statistic. Techniques from differential geometry may lead to extensions of this work to linear and logistic regression models. This computational approach does not answer outstanding questions about the existence or uniqueness of SMML estimates.

Example with Binomial Distribution

This section describes the SMML estimator for the binomial distribution. For this problem with *100* independent trials giving success or failure, we have $p(x|p) = p^n(1-p)^{100} - s, h(p) = 1$, where s is the observed number of successes and p is the unknown probability of success.

We have a SMML estimator minimizing I_1 in Table 1. I_1 has *52.068* nits. Note that the partition p_j in Table 1 is not unique due to asymmetry in having *ten* partitions of *101* success counts. Note the difference between the SMML estimate, p_j, and the MAP estimate $\frac{s}{100}$ in this case. For example, for *50* observed successes, the MAP estimate is *0.5*, while SMML estimate is *0.58*. With *49* successes, the SMML estimate jumps to *0.41*, so it is very discrete. The SMML estimate spacings are consistent with the expected error and so the MAP estimates are arguably overly precise and smooth.

Minimum Message Length, Table 1 A SMML estimator for binomial distribution (Wallace 2005; Farr and Wallace 2002, p. 159)

j	s	*p_j*
1	0	0
2	1–6	0.035
3	7–17	0.12
4	18–32	0.25
5	33–49	0.41
6	50–66	0.58
7	67–81	0.74
8	82–93	0.875
9	94–99	0.965
10	100	1

This is less than *0.2* nits more than the optimal one-part code based on the marginal probability of the data $-\log r(x)$.

Approximations

SMML estimators are hard to find in practice and various approximations of SMML estimators have been suggested. We focus on the quadratic approximation here, often called the MML estimator or MML87 (Wallace and Freeman 1987). Other useful approximations have been developed and are described in Wallace (2005). The use of approximations in applications requires careful checking of the assumptions made by the approximation (such as various regularity conditions) to ensure the desirable theoretical properties of MML inductive inference still apply:

$$I_1(x) \approx -\log \frac{f(h')}{\sqrt{\frac{F(h')}{12}}} + \left[-\log p(x|h')\right] + \frac{0.5F(h',x)}{F(h')}$$

where $F(h)$ is the Fisher information:

$$F(h') = -E\frac{\partial^2}{(\partial h')^2}\log p(x|h')$$

$$= -\sum\nolimits_{x\in X} p(x|h')\frac{\partial^2}{(\partial h')^2}\log p(x|h')$$

The assumptions are (Wallace and Freeman 1987; Wallace 2005):

- *f*$(x|h)$ is approximately quadratic on theta near its maximum.
- H has a locally Euclidean metric.
- Fisher information is defined everywhere in H.
- $f(h)$ and $F(h)$ vary little over theta of order $\frac{1}{\sqrt{F(h)}}$.

A further approximation has the third term simplify to *0.5* only (Wallace 2005, p. 226) which assumes $F(h,x) \approx F(h)$.

The MML estimator is a discretized MAP estimator with the prior $P(h)$ being discretized as:

$$f(h') \approx \frac{P(h')}{\sqrt{F(h')}}$$

In practice, note that the Fisher information may be difficult to evaluate. Various approximations have been made for the Fisher information where appropriate for particular applications.

Applications

MML estimators have been developed for various probability distributions such as binomial, multinomial, and Poisson. MML estimators were developed for densities such as normal, von Mises, and Student's T (Wallace 2005). These estimators and associated coding schemes are then useful components for addressing more complex model selection problems in machine learning.

There have been many applications of MML estimators to model spaces from machine learning (Wallace 2005; O'Donnell et al. 2006; Allison 2009). We will now briefly note MML applications for mixture models, regular grammars, decision trees, and causal nets. MML estimators have also been developed for multiple linear regression (Wallace 2005), polynomial regression (Wallace 2005), neural networks (Allison 2009), ARMA time series, hidden Markov models (Edgoose and Allison 1999), sequence alignment (Allison 2009), phylogenetic trees (Allison 2009), factor analysis (Wallace 2005), cut-point estimation (Wallace 2005), and image segmentation.

Model-Based Clustering or Mixture Models

Clustering was the first MML application from Wallace and Boulton's 1968 paper (Wallace and Boulton 1968). Some changes to the coding scheme have occurred over the decades. A key development was the switch from definite assignment of classes to things to probabilistic assignment in the 1980s. The MML model selection and a particularly efficient search involving dynamic splitting and merging of clusters were implemented in a FORTRAN program called Snob (since it discriminated between things).

The assertion code consists of:

1. The number of classes
2. For each class
   2.1 The population proportion
   2.2 Parameters of the statistical distribution for each attribute (or an insignificant flag)

The detail code consists of, for each datum, the class to which it belongs, attribute values assuming the distribution parameters of the class. Bits-back coding is used to partially or probabilistically assign a class to each datum. This efficiency is needed to get consistent estimates.

Probabilistic Finite-State Machines

Probabilistic finite-state machines can represent probabilistic regular grammars (Wallace 2005). A simple assertion code for the discrete FSM structure, as developed by Wallace and Georgeff, is the following:

- State the number of states, S, using a prior $P(S)$.
- For each state, code the number of arcs leaving the state, $\log(K+1)$, where $K+1$ is maximum number of arcs possible.
- Code the symbols labeling the arcs, $\log\begin{pmatrix} K+1 \\ C \\ a_s \end{pmatrix}$.
- For each arc, code the destination state, $a_s \log S$.

The number of all states other than state 1 is arbitrary, so the code permits $(S-1)!$, equal length, and different descriptions of the same FSM. This inefficiency can be adjusted for by subtracting $\log(S-1)!$

A candidate detail code used to code the sentences is an incremental code where each transition from state to state is coded incrementally, using $\log n_{sk} + \frac{1}{v_s} + a_s$ where n_{sk} is the number of times this arc has already been followed and v_s is the number of times the state has already been left.

This application illustrates some general issues about assertion codes for discrete structures:

1. There can be choices about what to include in the assertion code or not. For example, the transition probabilities are not part of the assertion code above, but could be included, with adjustments, in an alternative design (Wallace 2005).
2. Simple approaches with interpretable priors may be desirable even if using non-optimal codes. The assumptions made should be validated. For example, arcs between states in FSMs are usually relatively sparse (a_s ≪ S) so a uniform distribution is not a sensible prior here.
3. Redundancy comes from being able to code equivalent models with different descriptions. For some model spaces, determining the equivalence is either not possible or very expensive computationally.
4. Redundancy can come from the code allowing description of models that cannot arise. For example, the example assertion code could describe a FSM with states with no arcs.
5. Exhaustive search of model space can only be done for small FSMs. For larger applications, the performance of the MML model selection is conflated with performance of the necessary search space heuristics. This issue also occurs with decision trees, causal nets, etc.

In a particular application, it may be appropriate to trade-off redundancy with interpretability in assertion code design.

Decision Trees

Assertion codes for decision trees and graphs have been developed (Wallace and Patrick 1993; Wallace 2005). An assertion describes the structure of the tree, while the detail code describes the target labels. The number of attributes, the arity of each attribute, an agreed attribute order, and probability that a node is a leaf or split node are assumed known by the sender and receiver. Like the PFSM transition probabilities, the leaf class distributions are not explicitly included in the decision tree model (a point of distinction from Bayesian tree approaches).

An assertion code can be constructed by performing a prefix traversal of the tree describing each node. Describing a node requires −log_2 P_L if it is a leaf and −log_2 P_s if it is a split node. If it is a split node, the attribute that it splits on must be specified, requiring log_2 (number of available attributes). If it is a leaf node, the data distribution model should be specified. For example, the parameters of a binomial distribution if the data consists of two classes.

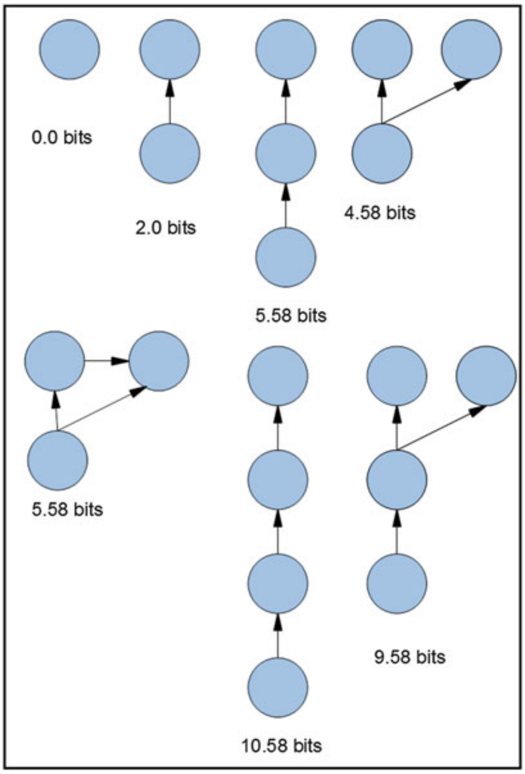
Causal Nets (Dai et al. 1997; Neil et al. 1999; O'Donnell et al. 2006)

The assertion code has two parts.
First part: DAG

1. Specify an ordering of variables, log $N!$.
2. Specify which of M_a possible arcs are present, $\log(N(N-1)/2)$ bits on assumption probability an arc is present is 0.5.

   Second part: Parameters
3. For each variable, state the form of conditional distribution and then the parameters of the distribution. Then encode all N values of v_j according to the distribution.

Note that the assertion code is intermixed with the detail code for each variable (Wallace 2005). Further adjustments are made to deal with grouping of causal nets with various equivalences or near equivalences. This requires a further approximation because no attempt is made to code the best representative causal net from the group of causal nets described (Fig. 2).



Minimum Message Length, Fig. 2 Assertion code lengths for different DAGS using the example coding scheme

Future Directions

There seems a potential for further development of feasible approximations that maintain the key SMML properties. The crossover of exciting new developments in coding theory may also help with the development of MML estimators. Examples include stochastic encoding such as bits-back coding, discovered by Wallace in 1990 (Wallace 1990) and since expanded to many new application areas showing connections between MML with variational learning and ensemble learning (Honkela and Valpola 2004). Another area is the relationship between optimum hypothesis discretization and indices of resolvability and rate-distortion optimization (Lanterman 2001).

MML estimators will continue to be developed for the new model spaces that arise in machine learning. MML relevance seems assured because with complex models, such as social networks, the best model is the useful outcome, rather than a prediction or posterior distribution of networks.

Open-source software using MML estimators for difference machine learning models is available (MML software).

Definition of Key Terms Used Above

Inductive inference: Choice of a model, theory, or hypothesis to express an apparent regularity or pattern in a body of data about many particular instances or events.

Explanation: A code with two parts, where the first part is an assertion code and the second part is a detail code.

Assertion: The code or language shared between the sender and receiver that is used to describe the model.

Detail: The code or language shared between the sender and receiver that is used to describe the data conditional on the asserted model.

Message: A binary sequence conveying information is called a message.

Shannon's information: If a message announces an event E_1 of probability $P(E_1)$, its information content is $-\log_2 P(E_1)$. This is also its length in bits.

Missing Attribute Values

Ivan Bruha
McMaster University, Hamilton, ON, Canada

Synonyms

Missing values; Unknown attribute values; Unknown values

Definition

When inducing ▶ decision trees or ▶ decision rules from real-world data, many different aspects must be taken into account. One important aspect, in particular, is the processing of *missing* (*unknown*) ▶ attribute values. In machine learning (ML), instances (objects, observations) are usually represented by a list of attribute values; such a list commonly has a fixed length (i.e., a fixed number of attributes).

The topic of missing attribute values has been analyzed in the field of ML in many papers (Brazdil and Bruha 1992; Bruha and Franek 1996; Karmaker and Kwer 2005; Long and Zhang 2004; Quinlan 1986, 1989). Grzymala-Busse (2003) and Li and Cercone (2006) discuss the treatment of missing attribute values using the rough set strategies.

There are a few directions in which missing (unknown) attribute values as well as the corresponding routines for their processing may be studied and designed. First, the *source of "unknownness"* should be investigated; there are several such sources (Kononenko 1992):

- A value is *missing* because it was forgotten or lost
- A certain attribute is *not applicable* for a given instance (e.g., it does not exist for a given observation)
- An attribute value is *irrelevant* in a given context
- For a given observation, the designer of a training database does not care about the value of a certain attribute (the so-called *dont-care* value)

The first source may represent a random case, while the remaining ones are of structural character.

Moreover, it is important to define formulas for *matching instances* (examples) containing missing attribute values with decision trees and decision rules as different matching routines vary in this respect.

Strategies for Missing Value Processing

The aim of this section is to survey the well-known strategies for the processing of missing attribute values. Quinlan (1989) surveys and investigates quite a few techniques for processing unknown attribute values processing for the TDIDT family. This chapter first introduces the seven strategies that are applied in many ML algorithms. It then discusses particular strategies for the four paradigms: Top Down Induction Decision Trees (TDIDT), (also known as the decision tree paradigm, or divide-and-conquer), covering paradigm (also known as the decision rules paradigm), Naive Bayes, and induction of ▶ association rules. The conclusion compares the above strategies and then portrays possible directions in combining these strategies into a more robust system.

To deal with real-world situations, it is necessary to process incomplete data – i.e., data with missing (unknown) attribute values. Here we introduce the seven strategies (routines) for processing missing-attribute-values. They differ in the style of the solution of their matching formulae. There are the following natural ways of dealing with unknown attribute values:

1. Ignore the example (object, observation) with missing values: strategy *Ignore* (*I*)
2. Consider the missing (unknown) value as an additional regular value for a given attribute: strategy *Unknown* (*U*) or
3. Substitute the missing (unknown) value for matching purposes by a suitable value which is either
   - The most common value: strategy *Common* (*C*)
   - A proportional fraction: strategy *Fraction* (*F*)
   - Any value: strategy *Anyvalue* (*A*)
   - Random value: strategy *Random* (*Ran*)
   - A value determined by a ML approach: strategy *Meta-Fill-In* (*M*) of the known values of the attribute that occur in the training set

Dealing with missing attribute values is in fact determined by matching a selector (see the corresponding definitions below) with an instance. A matching procedure of a selector with a fully specified instance returns the uniform solution: the instance either matches or not. Dilemmas arise when a partially defined instance is to be matched.

We now informally introduce a couple of definitions. An inductive algorithm generates a knowledge base (decision tree or a set of decision rules) from a*training set* of K training examples, each accompanied by its desired ▶ class $C_r, r = 1, \dots, R$. Examples are formally represented by N ▶ attributes, which are either discrete (symbolic) or numerical (continuous). A discrete attribute $A_n, n = 1 \dots, N$, comprises $J(n)$ distinct values $V_1, \dots, V_{J(n)}$. A numerical attribute may attain any value from a continuous interval. The symbolic/logical ML algorithms usually process the numerical attributes by ▶ discretization/fuzzification procedures, either on-line or off-line; see e.g., Bruha and Berka (2000).

An example (object, observation) can thus be expressed as an N-tuple $\mathbf{x} = [x_1, \dots, x_N]$, involving N attribute values. A *selector* S_n is defined as an attribute-value pair of the form $x_n = V_j$, where V_j is the jth value of the attribute A_n (or the jth interval of a numerical attribute A_n).

To process missing values, we should know in advance (for $r = 1, \dots, R, n = 1, \dots, N, j = 1, \dots, J(n)$):

- The overall*absolute* frequencies $F_{n,j}$ that express the number of examples exhibiting the value V_j for each attribute A_n
- The *class-sensitive absolute* frequencies $F_{r,n,j}$ that express the number of examples of the class C_r exhibiting the value V_j for each attribute A_n
- The *overall relative* frequencies $f_{n,j}$ of all known values V_j for each attribute A_n
- The *class-sensitive relative* frequencies $f_{r,n,j}$ of all known values V_j for each attribute A_n and for a given class C_r

The underlying idea for learning relies on the class distribution; i.e., the class-sensitive frequencies (overall and class-sensitive frequencies) are utilized. As soon as we substitute a missing value by a suitable one, we take the desired class of the example into consideration in order not to increase the noise in the data set. On the other hand, the overall frequencies are applied within classification.

We can now define the matching of an example $\mathbf{x}$ with a selector S_n by the so-called *matching ratio* = 0 if $x_n \neq V_j$

$$\mu(\mathbf{x}, S_n)\{= 1 \text{ if } x_n = V_j\} \qquad (1)$$
$$\in [0; 1] \text{ if } x_n \text{ is unknown (missing)}$$

A particular value of the matching ratio is determined by the selected routine (strategy) for missing value processing.

(I) Strategy Ignore: Ignore Missing Values: This strategy simply ignores examples (instances) with at least one missing attribute value before learning. Hence, no dilemma arises when determining matching ratios within learning. However, this approach does not contribute to any enhancement of processing of noisy or partly specified data.

As for classification, a missing value does not match any regular (known) value of a selector. Thus, a selector's matching ratio is equal to 0 for any missing value. Consequently, only a path of nodes in a decision tree or a decision rule that tests only the regular values during classification may succeed. If there is no such path of nodes in a decision tree or such a rule has not been found, then the default principle is applied; i.e., the instance with missing value(s) is classified as belonging to the majority class.

(U) Strategy Unknown: Unknown Value as a Regular One: An unknown (missing) value is considered as an additional attribute value. Hence, the number of values is increased by one for each attribute that depicts an unknown value in the training set. The matching ratio of a selector comprising the test of the selector S_n and an instance with the nth attribute missing is equal to 1 if this test (selector) is of the form

x_n =? where "?," represents the missing (unknown) value.

Note that selectors corresponding to the numerical (continuous) attributes are formed by tests $x_n \in V_j$ (where V_j is a numerical interval) or x_n =?.

(C) Strategy Common: The Most Common Value: This routine needs the class-sensitive absolute frequencies $F_{r,n,j}$ to be known before the actual learning process, and the overall frequencies $F_{n,j}$ before the classification. A missing value of a discrete attribute A_n of an example belonging to the class C_r is replaced by the *class-sensitive common* value, which maximizes the Laplacian formula $\frac{F_{r,n,j}+1}{F_{n,j}+R}$ over j for the given r and n. If the maximum is reached for more than one value of A_n, then the value V_j with the greatest frequency $F_{r,n,j}$ is selected as the common value.

A missing value within the classification is replaced by the *overall common* value, which maximizes $F_{n,j}$ over the subscript j. Consequently, the matching ratio yields 0 or 1, as every missing value is substituted by a concrete, known value.

The Laplacian formula utilized within the learning phase prefers those attribute values that are more predictive for a given class, contrary to the conventional "maximum frequency" scheme. For instance, let an attribute have two values: the value V_1 with the absolute frequencies [4, 2] for the classes C_1 and C_2, and the value V_2 with frequencies [3, 0] for these two classes. Then, when looking for the most common value of this attribute for the class C_1, the maximum frequency chooses the value V_1 as the most common value, whereas the Laplacian formula prefers the value V_2 as the more predictive for the class C_1.

(F) Strategy Fraction: Split into Proportional Fractions:

- Learning phase

The learning phase requires that the relative frequencies $f_{r,n,j}$ above the entire training set be known. Each example $\mathbf{x}$ of class C_r with a missing value of a discrete attribute A_n is substituted by a collection of examples before the actual learning phase, as follows: the missing value of A_n is replaced by all known values V_j of A_n and C_r. The weight of each split example (with the value V_j) is

$$w_j = w(\mathbf{x}) * f_{r,n,j},\ j = 1, \ldots, J(n)$$

where $w(\mathbf{x})$ is the weight of the original example $\mathbf{x}$. The weight is assigned by the designer of the training set and represents the designer's subjective judgment of the importance of that particular example within the entire training set. The matching ratio of the split examples is accomplished by (1) in a standard way.

If a training example involves more missing attribute values, then the above splitting is done for each missing value. Thus, the matching ratio may rapidly decrease. Therefore, this strategy, *Fraction,* should involve a methodology to avoid explosion of examples, so that only a predefined number of split examples with the largest weights is used for replacement of the original example.

- Classification phase

The routine *Fraction* works for each paradigm in a different way. In case of a decision tree, the example with a missing value for a given attribute A_n is split along all branches, with the weights equal to the overall relative frequencies $f_{n,j}$.

As for the decision rules, the matching ratio for a selector $x_n = V_j$ is defined by (1) as $\mu = f_{n,j}$ for a missing value of A_n. An instance with a missing value is tested with the conditions of all the rules, and is attached to the rule whose condition yields the maximum matching ratio – i.e., it is assigned to the class of this rule.

(A) Strategy Anyvalue: Any Value Matches: A missing value matches any existing attribute value, both in learning and classification. Therefore, a matching ratio μ of any selector is equal to 1 for any missing value.

It should be noticed that there is no uniform scheme in machine learning for processing the "any-value." In some systems, an example with a missing value for attribute A_n is replaced by

$J(n)$ examples in which the missing value is in turn substituted by each regular value $V_j, j = 1, \ldots, J(n)$. In other systems, the missing "anyvalue" is substituted by any first attribute value involved in a newly generated rule when covered examples are being removed from the training set; see Bruha and Franek (1996) for details.

(Ran) Strategy Random: Substitute by Random Value A missing value of an attribute A_n is substituted by a randomly selected value from the set of its values $V_j, j = 1, \ldots, J(n)$. In case of the numerical attributes, the process used in the routine *Common* is first applied, i.e., the entire numerical range is partitioned into a prespecified number of equal-length intervals. A missing value of the numerical attribute is then substituted by the mean value of a randomly selected interval.

At least two possibilities exist in the random procedure. Either

- A value is randomly chosen according to the uniform distribution – i.e., all the values have the same chance
- A value is chosen in conformity with the value distribution – i.e., the most frequent value has the greatest chance of being selected

To illustrate the difference of the strategies Anyvalue and Random, consider this scheme. Let the attribute A have three possible values, V_1, V_2, V_3 with the relative distribution [0.5, 0.3, 0.2]. (Here, of course, we consider class-sensitive distribution for the learning phase, overall one for classification.)

Strategy Anyvalue for TDIDT replaces the missing value $A = ?$ by each possible value $A = V_j$, $j = 1, 2, 3$, and these selectors (attribute-value pairs) are utilized for selecting a new node (during learning), or pushed down along an existing decision tree (classi-fication).

Strategy Anyvalue for covering algorithms: if the corresponding selector in a complex is for example, $A = V_3$ then the selector $A = ?$ in an instance is replaced by $A = V_3$, so that the matching always succeeds.

Let the pseudo-random number be for example, 0.4 in the strategy Random. Then, in the first case – i.e., uniform distribution (one can consider the relative distribution has been changed to [0.33, 0.33, 0.33]) – the missing value $A = ?$ is replaced by $A = V_2$. In the second possibility – i.e., the actual distribution – the missing value is replaced by $A = V_1$.

(M) Strategy Meta Fill In: Use Another Learning Topology for Substitution: This interesting strategy utilizes another ML algorithm in order to fill in the missing attribute values. This second (or *meta*) learning algorithm uses the remaining attribute values of a given example (instance, observation) for determining (inducing) the missing value of the attribute A_n. There are several approaches to this strategy.

The first one was designed by Breiman; it uses a *surrogate split* in order to determine the missing attribute value. We can observe that a surrogate attribute has the highest correlation with the original one.

Quinlan (1989) was the first to introduce the meta-fill-in strategy; in fact, this method was proposed by A. Shapiro during their private communication. It builds a decision tree for each attribute that attempts to derive a value of the attribute with a missing value for a given instance in terms of the values of other attributes of the given instance.

Lakshminarayan et al. (1996) introduced a more robust approach where a ML technique (namely, C4.5) is used to fill in the missing values.

Ragel and Cremilleux (1998) developed a fill-in strategy by using the association rules paradigm. It induces a set of association rules according to the entire training set. This method is able to efficiently process the missing attribute values.

Missing Value Processing Techniques in Various ML Paradigms

As mentioned above, various missing value processing techniques have been embedded into various ML paradigms. We introduce four such systems.

Quinlan (1986, 1989) applied missing value techniques into ID3, the most famous TDIDT (decision tree inducing) algorithm. His list exhibits two additional routines that were not discussed above:

- The evaluation of an attribute uses the routines I, C, M, and R (i.e., reduce the apparent information gain from evaluating an attribute by the proportion of training examples with the missing value for this attribute)
- When partitioning a training set using the selected attribute, the routines I, U, C, F, A, M were used
- The classification phase utilizes the strategies U, C, F, M, and H (i.e., halt the classification and assign the instance to the most likely class)

Quinlan then combined the above routine into triples each representing a different overall strategy; however, not all the possible combinations of these routines make sense.

His experiments revealed that the strategies starting with R or C behave reasonably accurately among them the strategy *RFF* is the best. Brazdil and Bruha (1992) improved this strategy for partitioning a training set. They combined the strategies U and F; therefore, they call it *R(UF)(UF)* strategy.

Bruha and Franek (1996) discusses the embedding of missing value strategies into the covering algorithm CN4 (Bruha and Kockova 1994), a large extension of the well-known CN2 (Clark and Niblett 1989). A condition of a decision rule has the form:

$$\text{cmplx} = S_{q1} \& \ldots \& S_{qM}$$

where $S_{qm}, m = 1, \ldots, M$, is the mth selector testing the jth value V_j of the q_mth attribute, (i.e., exhibiting the form $x_{qm} = V_j$). For the purposes of processing missing values, we need to define the *matching ratio* of the example $\mathbf{x}$ and the rule's condition *Cond*. (Bruha and Franek 1996) uses two definitions:

The product of matching ratios of its selectors:

$$\mu(x, \text{cmplx}) = w(x) \prod_{m=1}^{M} \mu(x, S_{qm}) \qquad (2)$$

or their average:

$$\mu(x, \text{cmplx}) = \frac{w(x)}{M} \sum_{m=1}^{M} \mu(x, S_{qm}), \qquad (3)$$

where $w(\mathbf{x})$ is the weight of the example $\mathbf{x}$ (1 by default), and μ on the right-hand side is the selector's matching ratio (1).

The Naive Bayes algorithm can process missing attribute values in a very simple way, because the probabilities it works with are, in fact, the relative frequencies discussed above: the class-sensitive relative frequencies $f_{r,n,j}$ (for the learning phase) and the overall relative frequencies $f_{n,j}$ (for the purposes of classification). When learning relative frequencies, all strategies can by applied. Only routine Fraction is useless because it copies the distribution of the rest of a training set. When classifying an instance with missing value A_n =?, all strategies can be applied as well. Section Fraction substitutes this instances with $J(n)$ instances by each known attribute value, and each "fractioned" instance is attached by the weight $f_{n,j}$, and classified separately.

Ragel and Cremilleux (1998) present the missing value processing strategy for the algorithm that induced ▸ association rules. Their algorithm uses a modified version of the routine *Ignore*. The instances with missing attribute values are not removed from the training database but the missing values are ignored (or "hidden").

The experiments with the above techniques for handling missing values have revealed the following. In both decision tree and decision rules inducing algorithms, the routine *Ignore* is evidently the worst strategy. An Interesting issue is that the association rule inducing algorithms use its modified version. In case of the decision tree inducing algorithms, the strategy *Fraction* is one of the best; however, the decision rules inducing algorithms found it not so efficient. The explanation for this fact is based on different ways of processing examples in these two paradigms: in TDIDT, all training examples are eventually incorporated into the decision tree generated by the learning algorithm; on the other hand, the covering paradigm algorithm generates rules that may not cover all of the examples from the training set (as some of the examples are found not to be representable).

Although the routine *Unknown* is one of the "winners" (at least in the rule inducing algorithms and Brazdil and Bruha (1992), it is not quite clear how one can interpret, on a philosophical as well as a semantic level, a branch in a decision tree or a decision rule that involves a selector with an attribute equal to "?" (missing value). Strategy Fraction can be faced by "problems": if an example/instance exhibits too many missing values, then this strategy generates too many "fractioned" examples with very negligible weights.

One can find out that each dataset has more or less its own "favorite" routine for processing missing attribute values. It evidently depends on the magnitude of noise and the source of unknownness in each dataset. The problem of a "favorite" strategy can be solved by various approaches. One possibility is to create a small "window" within a training set, and to check the efficiency of each strategy in this window, and then choose the most efficient one. Bruha (2003) discusses another possibility: investigating the advantages of utilizing the external background (domain-specific, expert) knowledge on an attribute hierarchical tree.

Also, the concept of the so-called ▸ meta-combiner (Fan et al. 1996) can be utilized. A learning algorithm processes a given training base for each strategy for missing values independently; thus, all the missing value strategies are utilized in parallel and the meta-classifier makes up its decision from the results of the base level (Bruha 2004).

The above issue – i.e., selection or combination of various strategies for missing value processing – is an open field for future research.

Mixture Model

Rohan A. Baxter
Australian Taxation Office, Sydney, NSW,
Australia

Abstract

A mixture model is a probability model for representing subpopulations within a data set. The mixture model is built up from a weighted combination of component probability distributions. Mixture models can be estimated by attribution partial membership to the component distributions to individual observations in the data set.

Synonyms

Finite mixture model; Latent class model; Mixture distribution; Mixture modeling; Mixture modeling

Definition

A mixture model is a collection of probability distributions or densities $D_1, \dots, D_k$ and mixing weights or proportions $W_1, \dots, W_k$,where k is the number of component distributions (McLachlan and Peel 2000; Lindsey 1996; Duda et al. 2000).

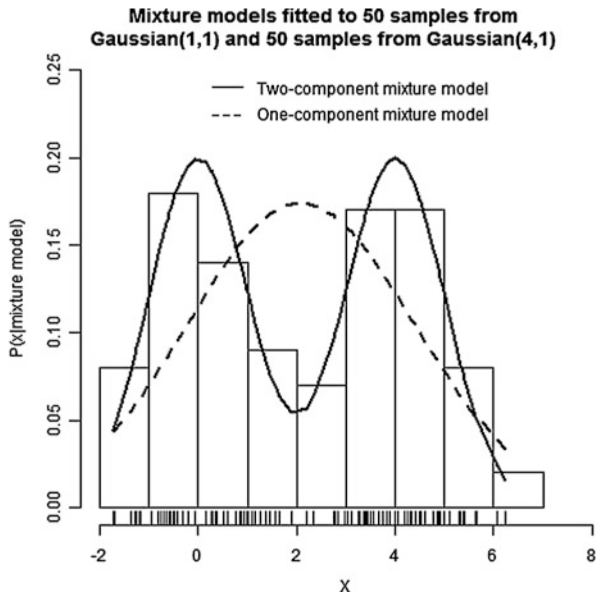
The mixture model, $P(x|D_1, \dots, D_k, w_1, \dots, w_k) = \sum_{j=1}^{k} w_j P(x|D_j)$, is a probability distribution over the data conditional on the component distributions of the mixture and their mixing weights. Mixture models can be used for density estimation, model-based clustering or unsupervised learning, and classification.

Figure 1 shows one-dimensional data plotted along the x-axis with tick marks and a histogram of that data. The probability densities of two mixture models fitted to that data are then shown. The one-component mixture model is a Gaussian density with mean around 2 and standard deviation of 2.3. The two-component mixture model has one component with mean around 0 and one component with mean around 4, which reflects how these simple example data was artificially generated. The two-component mixture model can be used for clustering by considering each of its components as a cluster and assigning cluster membership based on the relative probability of a data item belonging to that component. Data less than 2 will have higher probability of belonging to the Gaussian with mean 0 component.

Motivation and Background

Mixture models are easy and convenient to apply. They trade off good power in data representation with relative ease in building the models. When used in clustering, a mixture model will have a component distribution covering each cluster, while the mixing weights reflect the relative proportion of a cluster's population. For example, a two-component mixture model of seal skull lengths from two different seal species may have one component with relative proportion 0.3 and the other 0.7 reflecting the relative frequency of the two components.

Mixture Model, Fig. 1
Mixture model example for one-dimensional data



Estimation

In order to use mixture models, the following choices need to be made by the modeler or by the mixture model software, based on the characteristics of a particular problem domain and its datasets:

1. The type of the component distributions (e.g., Gaussian, multinomial, etc.)
2. The number of component distributions, k
3. The parameters for the component distributions (e.g., a one-dimensional Gaussian has a mean and standard deviation as parameters, and a higher dimensional Gaussian has a mean vector and covariance matrix as parameters)
4. Mixing weights, W_i
5. (Optional) component labels, c_j for each datum x_j, where $j = 1 \ldots n$ and n is the number of data

The fifth item above, component labels, are optional because they are only used in latent class mixture model frameworks where a definite component membership is part of the model specification. Other mixture model frameworks use probabilistic membership of each datum to each component distribution and so do not need explicit component labels.

The most common way of fitting distribution parameters and mixture weights is to use the expectation-maximization (EM) algorithm to find the maximum likelihood estimates. The EM algorithm is an iterative algorithm that, starting with initial guesses of parameter values, computes the mixing weights (the expectation step). The next step is to then compute the parameter values based on these weights (the maximization step). The expectation and maximization steps iterate and convergence is assured (Redner and Walker 2004). However there is no guarantee that a global optimum has been found, and so a number of random restarts may be required to find what other optima exist (Xu and Jordan 1996).

As an alternative to random restarts, a good search strategy can be to modify the current best solution, perhaps by choosing to split, merge, delete, or add component distributions at random. This can also be a way to explore mixture models with different number of components (Figueiredo and Jain 2002).

Since mixture models are a probabilistic model class, besides EM, other methods such as Bayesian methods or methods for graphical models can be used. These include Markov chain Monte Carlo inference and variational learning (Bishop 2006).

Choosing the Number of Components

The number of components in a mixture model is often unknown when used for clustering real-world data. There have been many methods for choosing the number of components. The global maximum for maximum likelihood chooses a component for every data item, which is usually undesirable. Criteria based on information theory or Bayesian model selection choose reasonable numbers of components in many domains (McLachlan and Peel 2000, Chap 6, 5). There is no universally accepted method, because there is no universally accepted optimality criteria for clustering or density estimation. The use of an infinite mixture model, by using an infinite number of components, is one way to avoid the number of component problem (Rasmussen 2000).

Types of Component Distributions

Besides Gaussian, other distributions can be used such as Poisson (for count data), von Mises (for data involving directions or angles), and Weibull. Heavy-tailed distributions require particular care because standard estimation may not work when mean or variance is infinite (Dasgupta et al. 2005).

Another commonly needed variation is a mixture model to handle a mix of continuous and categorical features (McLachlan and Peel 2000). For example, a binomial distribution can be used to model male/female gender proportions and Gaussian to model length for data relating to a seal species sample.

A further extension is to allow components to depend on covariates, leading to mixtures of regression models (McLachlan and Peel 2000). This leads to models such as mixtures of experts and hierarchical mixtures of experts (McLachlan and Peel 2000; Bishop 2006) which are flexible models for nonlinear regression. The combination of mixture models with hidden Markov models allows the modeling of dependent data (McLachlan and Peel 2000).

Large Datasets

The EM algorithm can be modified to find mixture models for very large datasets (Bradley et al. 2000). The modification allows for a single scan of the data and involves identifying compressible regions of the data.

Theory

A key issue for mixture models is learnability (Chaudri 2009). The more the component distributions overlap, the harder they are to learn. Higher dimensional data also makes learning harder. Sometimes, these problems can be overcome by increasing the data quantity, but, in extremely hard cases, this will not work (Xu and Jordan 1996; Srebo et al. 2006).

Another issue is the relationship between adequate sample size and the number of components. A pragmatic policy is to set minimum mixing weights for component distributions. For example, for a dataset of size 100, if mixing weights are required to be greater than 0.1, this implies a maximum of ten components that are possible to be learned from the data with these parameter settings.

Applications

Mixture model software is often available in the clustering or density estimation parts of general statistical and data mining software. More specialized mixture modeling software for clustering data has included Autoclass (Autoclass 2010), Snob (Snob 2010), and mclust (Mclust 2010).

Definition of Key Terms Used Above

Probability distribution: This is the probability for each value of a random variable with discrete values.

Probability density: This is a function of a continuous random variable that describes probability at a given point in the variable space.

Gaussian distribution: A bell-shaped probability density function with a peak at the mean. It has two parameters: the mean to give the location of the peak and the standard deviation to describe the width of the bell-shaped curve.

Mixing weights: These are the parameters of the mixture model giving the relative weights of each component distribution. The weights are between 0 and 1 and must sum to 1. In clustering applications, the mixing weights can be interpreted as the relative size of a cluster compared to the whole population.

Model Evaluation

Geoffrey I. Webb
Faculty of Information Technology, Monash
Clayton, Victoria, Australia

Abstract

Model evaluation is the process of assessing a property or properties of a model.

Synonyms

Evaluation of model performance; Model assessment; Assessment of model performance

Motivation and Background

It is often valuable to assess the efficacy of a model that has been learned. Such assessment is frequently relative – an evaluation of which of several alternative models is best suited to a specific application.

Processes and Techniques

There are many metrics by which a model may be assessed. The relative importance of each metric varies from application to application.

The primary considerations often relate to predictive efficacy – how useful will the predictions be in the particular context in which the model is to be deployed. Measures relating to predictive efficacy include ▶ accuracy, ▶ lift, ▶ mean absolute error, ▶ mean squared error, ▶ negative predictive value, ▶ positive predictive value, ▶ precision, ▶ recall, ▶ sensitivity, ▶ specificity, and various metrics based on ▶ ROC analysis.

Computational issues may also be important, such as a model's size or its execution time.

In many applications one of the most important considerations is the ease with which the model can be understood by the users or how consistent is it with the users' prior beliefs and understanding of the application domain.

When assessing the predictive efficacy of a model learned from data, to obtain a reliable estimate of its likely performance on new data, it is essential that it not be assessed by considering its performance on the data from which it was learned. A learning algorithm must interpolate appropriate predictions for regions of the ▶ instance space that are not included in the training data. It is probable that the inferred model will be more accurate for those regions represented in the training data than for those that are not, and hence predictions are likely to be less accurate for instances that were not included in the training data. Estimates that have been computed on the training data are called ▶ *resubstitution estimates*. For example, the error of a model on the training data from which it was learned is called resubstitution error.

Algorithm evaluation techniques such as ▶ cross-validation, ▶ holdout evaluation, and ▶ bootstrap sampling are designed to provide more reliable estimates of the accuracy of the models learned by an algorithm than would be obtained by assessing them on the training data.

Model Trees

Luís Torgo
University of Porto, Porto, Portugal

Synonyms

Functional trees, Linear regression trees, Piecewise linear models

Definition

Model trees are supervised learning methods that obtain a type of tree-based ▸ regression model, similar to ▸ regression trees, with the particularity of having functional models in the leaves instead of constants. These methods address multiple regression problems. In these problems we are usually given a training sample of n observations of a target continuous variable Y and of a vector of p predictor variables, $\mathbf{x} = X_1, \cdots, X_p$. Model trees provide an approximation of an unknown regression function $Y = f(\mathbf{x}) + \varepsilon$ with $Y \in \Re$ and $\varepsilon \approx N(0, \sigma^2)$. The leaves of these trees usually contain linear regression models, although some works also consider other types of models.

Motivation and Background

Model trees are motivated by the purpose of overcoming some of the known limitations of regression trees caused by their piecewise constant approximation. In effect, by using constants at the leaves, regression trees provide a coarse grained function approximation leading to poor accuracy in some domains. Model trees try to overcome this by using more complex models on the leaves. Trees with linear models in the leaves were first considered in Breiman and Meisel (1976) and Friedman (1979). Torgo (1997) has extended the notion of model trees to other type of models in the tree leaves, namely, kernel regression, later extended to other type of local regression models (Torgo 1999, 2000). The added complexity of the models used in the leaves increases the computational complexity of model trees when compared to regression trees and also decreases their interpretability. In this context, several works Chaudhuri et al. (1994), Dobra and Gehrke (2002), Loh (2002), Malerba et al. (2002), Natarajan and Pednault (2002), Torgo (2002), Malerba (2004), Potts and Sammut (2005), and Vogel et al. (2007) have focussed on obtaining model trees in a computationally efficient form.

Structure of Learning System

Approaches to model trees can be distinguished along two dimensions: the criterion used to select the best splits at each node, i.e., the criterion guiding the partitioning obtained by the tree, and the type of models used in the leaves. The choices along the first dimension are mainly driven by considerations of computational efficiency. In effect, the selection of the best split node involves evaluating many candidate splits. The evaluation of a binary split (the most common splits in tree-based models) consists in calculating the error reduction produced by the split, i.e.,

$$\Delta(s,t) = Err(t) - \left(\frac{n_{t_L}}{n_t} \times Err(t_L) + \frac{n_{t_R}}{n_t} \times Err(t_R) \right) \quad (1)$$

where t is a tree node with sub-nodes t_L and t_R originated by the split test s, while n_t, n_{t_L}, and n_{t_R} are the cardinalities of the respective sets of observations on each of these nodes, and $Err()$ is a function that estimates the error on a node being defined as

$$Err(t) = \frac{1}{n_t} \sum_{\langle \mathbf{x}_i, y_i \rangle \in D_t} (y_i - g(D_t))^2 \quad (2)$$

where D_t is the sample of cases in node t, n_t is the cardinality of this set, and $g(D_t)$ is a function of the cases in node t.

In standard regression trees, the function $g()$ is the average of the target variable Y, i.e., $\frac{1}{n_t} \sum_{\langle \mathbf{x}_i, y_i \rangle \in D_t} y_i$. This corresponds to assuming a constant model on each leaf of the tree. The evaluation of each candidate split requires obtaining the models at the respective left and right branches (Eq. 1). If this model is an average, rather efficient incremental algorithms can be used to evaluate all candidate splits. On the contrary, if $g()$ is a linear regression model or even other more complex models, this evaluation is not so simple, and it is computationally very demanding, as a result of which systems that use this strategy (Karalic 1992) become impractical for large problems. In this context, several authors have adopted the alternative of growing the trees assuming constant values in the leaves and then fitting the complex models on each of the obtained leaves (e.g. Quinlan 1992; Torgo 1997, 1999, 2000). This only requires fitting as many models as there are leaves in the final tree. The main drawback of this approach is that the splits for the tree nodes are selected assuming the leaves will have averages instead of the models that in effect will be used. This may lead to splits that are suboptimal for the models that will be fit on each leaf (Malerba et al. 2002; Malerba 2004). Several authors have tried to maintain the consistency of the split selection step with the models used in the leaves by proposing efficient algorithms for evaluating the different splits. In Malerba et al. (2002) and Malerba (2004) linear models are obtained in a stepwise manner during tree growth. In Chaudhuri et al. (1994), Loh (2002), and Dobra and Gehrke (2002) the computational complexity is reduced by transforming the original regression problem into a classification problem. In effect, the best split is chosen by looking at the distribution of the sign of the residuals of a linear model fitted locally. In Torgo (2002), Natarajan and Pednault (2002), and Vogel et al. (2007) the problem is addressed by proposing more efficient algorithms to evaluate all candidate splits. Finally, Potts and Sammut (2005) proposes an incremental algorithm to obtain model trees that fights the complexity of this task by imposing a limit on the number of splits that are considered for each node.

The most common form of model used in leaves is ▶ linear regression. Still, there are systems considering kernel models (Torgo 1997), local linear models (Torgo 1999), and partial linear models (Torgo 2000). These alternatives provide smoother function approximation, although with increased computational costs and less interpretable models.

▶ Pruning in model trees does not bring any additional challenges when compared to standard regression trees, and so similar methods are used for this over-fitting avoidance task. The same occurs with the use of model trees for obtaining predictions for new test cases. Each case is "dropped down" the tree from the root node, following the branches according to the logical tests in the nodes, till a leaf is reached. The model in this leaf is used to obtain the prediction for the test case.

Model-Based Clustering

Arindam Banerjee and Hanhuai Shan
University of Minnesota, Minneapolis, MN, USA

Definition

Model-based clustering is a statistical approach to data clustering. The observed (multivariate) data is assumed to have been generated from a finite mixture of component models. Each component model is a probability distribution, typically a parametric multivariate distribution. For example, in a multivariate Gaussian mixture model, each component is a multivariate Gaussian distribution. The component responsible for generating a particular observation determines the cluster to which the observation belongs. However, the component generating each observation as well as the parameters for each of the component distributions are unknown. The key learning task is to determine the component responsible for generating each observation, which in turn gives the clustering of the data. Ideally, observations generated from the same component are inferred to belong to the same cluster. In addition to inferring the component assignment of observations, most popular learning approaches also estimate the parameters of each component in the process. The strength and popularity of the methods stem from the fact that they are applicable for a wide variety of data types, such as multivariate, categorical, sequential, etc., as long as suitable component generative models can be constructed. Such methods have found applications in several domains such as text clustering, image processing, computational biology, and climate sciences.

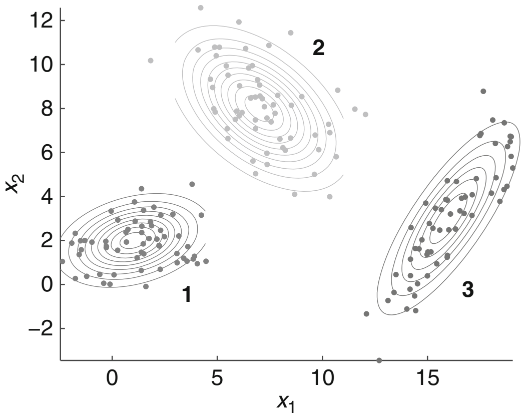
Structure of Learning System

Generative Model

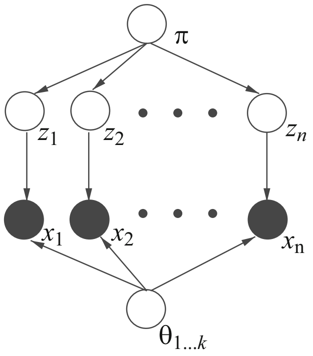
Let $X = \{x_1, \ldots, x_n\}$ be a dataset on which a k-clustering is to be performed. Let $p(x|\theta_1), \ldots, p(x|\theta_k)$ be k distributions which form the components of the mixture model from which the observed data is assumed to have been generated, and let $\pi = (\pi_1, \ldots, \pi_k)$ denote a prior distribution over the components. Then $\Theta = (\pi, \theta)$ constitutes the (unknown) parameters of the generative mixture model, where $\theta = \{\theta_1, \ldots, \theta_k\}$ and $\pi = \{\pi_1, \ldots, \pi_k\}$.

Given the model, an observation is assumed to be generated by the following two-step process: (1) randomly pick a component following the discrete distribution π over the components, i.e., the hth component is chosen with the probability of π_h; (2) the observation is sampled from the component distribution, e.g., if the hth component was chosen, we draw a sample $x \sim p(x|\ \theta_h)$. Each observation is assumed to be statistically independent so that they are all generated independently following the same two-step process.

Figure 1 gives an example of data drawn from a mixture of three ($k = 3$) 2-dimentional multivariate Gaussians. In the example, the discrete distribution over the component Gaussians is given by $\pi = (0.2, 0.3, 0.5)$. The parameter set $\theta_h, h = 1, 2, 3$ for any individual multivariate Gaussian consists of the mean vector μ_h and the



Model-Based Clustering, Fig. 1 Three 2-dimensional Gaussians



Model-Based Clustering, Fig. 2 Bayesian network for a finite mixture model

covariance matrix Σ_h. For the example, we have $\mu_1 = [1, 2], \mu_2 = [7, 8], \mu_3 = [16, 3]$, and $\Sigma_1 = \begin{bmatrix} .3 & 0.5196 \\ 0.5196 & 1 \end{bmatrix}$, $\Sigma_2 = \begin{bmatrix} 4 & -1.7321 \\ -1.7321 & 3 \end{bmatrix}$, $\Sigma_3 = \begin{bmatrix} 3 & 3.0984 \\ 3.0984 & 5 \end{bmatrix}$.

The generative process could be represented as a Bayesian network as shown in Fig. 2, where the arrows denote the dependencies among variables/parameters. In the Bayesian network, (π, θ) are the parameters of the mixture model, x_i are the observations and z_i are the latent variables corresponding to the component which generates x_i, $i = 1, \ldots, n$. To generate an observation x_i, the model first samples a latent variable z_i from the discrete distribution π, and then samples the observation x_i from component distribution $p(x|\theta_{zi})$.

Learning

Given a set of observations $X = \{x_1, \ldots, x_n\}$ assumed to have been generated from a finite mixture model, the learning task is to infer the latent variables z_i for each observation as well as estimate the model parameters $\Theta = (\pi, \theta)$. In the Gaussian mixture model example, the goal would be to infer the component responsible for generating each observation and estimate the mean and covariance for each component Gaussian as well as the discrete distribution π over the three Gaussians. After learning model parameters, the posterior probability $p(h|x_i, \Theta)$ of each observation x_i belonging to each component Gaussian gives a (soft) clustering for the observation.

The most popular approach for learning mixture models is based on maximum likelihood estimation (MLE) of the model parameters. In particular, given the set of observations X, one estimates the set of model parameters which maximizes the (log-)likelihood of observing the entire dataset X. For the finite mixture model, the likelihood of observing any data point x_i is given by

$$p(x_i|\Theta) = \sum_{h=1}^{k} \pi_h p(x_i|\theta_h). \qquad (1)$$

Since the data points in X are assumed to be statistically independent, the log-likelihood. (In practice, one typically focuses on maximizing the log-likelihood $\log p(X|\Theta)$ instead of the likelihood $p(X|\Theta)$ due to both numerical stability and analytical tractability). of observing the entire dataset X is given by

$$\log p(X|\Theta) = \log\left(\prod_{i=1}^{n} p(x_i|\pi, \theta)\right)$$
$$\sum_{i=1}^{n} \log\left(\sum_{h=1}^{k} \pi_h p(x_i|\theta_h)\right). \qquad (2)$$

A direct application of MLE is difficult since the log-likelihood cannot be directly optimized with respect to the model parameters. The standard approach to work around this issue is to use the expectation maximization (EM) algorithm which entails maximizing a tractable lower bound to the log-likelihood $\log p(X|\Theta)$. To this end, a latent variable z_i is explicitly introduced for each x_i to inform the component that x_i is generated from. The joint distribution of (x_i, z_i) is $p(x_i, z_i|\pi\theta) = \pi_{zi} p(x_i|\theta_{zi})$. Let $Z = \{z_1, \ldots, z_n\}$ denote the set of latent variables corresponding to $X = \{x_1, \ldots, x_n\}$. The joint log-likelihood of (X, Z) then becomes

$$\begin{aligned}\log p(X, Z|\Theta) &= \sum_{i=1}^{n} \log p(x_i, z_i|\Theta)\\ &= \sum_{i=1}^{n} (\log \pi_{zi} + \log p(x_i|\theta_{zi})).\end{aligned} \tag{3}$$

For a given set Z, it is easy to directly optimize (3) with respect to the parameters $\Theta = (\pi, \theta)$. However, Z is actually a random vector whose exact value is unknown. Hence, the log-likelihood $\log p(X, Z|\Theta)$ is a random variable depending on the distribution of Z. As a result, EM focuses on optimizing the following lower bound based on the expectation of $\log p(X, Z|\Theta)$ where the expectation is taken with respect to some distribution $p(Z)$ over the latent variable set Z. In particular, for any distribution $q(Z)$, we consider the lower bound

$$L(q, \Theta) = E_{z\sim q}[\log p(X, Z|\theta)] + H(q(Z)), \tag{4}$$

where the expectation on the first term is with respect to the posterior distribution $q(Z)$ and $H(q(Z))$ denotes the Shannon entropy of the latent variable set $Z \sim q(Z)$. A direct calculation shows that the difference between the true log-likelihood in (2) and the lower bound in (4) is exactly the relative entropy between $q(Z)$ and the posterior distribution $p(Z|X, \Theta)$, i.e.,

$$\begin{aligned}\log p(X|\Theta) - &L(q, \Theta)\\ &= KL(q(Z)\|p(Z|X, \Theta)) \geq 0\end{aligned} \tag{5}$$

$$\Rightarrow \log p(X|\Theta) \geq L(q, \Theta), \tag{6}$$

where $KL(||)$ denotes the KL-divergence or relative entropy. As a result, when $q(Z) = p(Z|X, \Theta)$, the lower bound is exactly equal to the log-likelihood $\log p(X|\Theta)$. EM algorithms for learning mixture models work by alternately optimizing the lower bound $L(q, \Theta)$ over q and Θ. Starting with an initial guess $\Theta^{(0)}$ of the parameters, in iteration t such algorithms perform the following two steps:

E-step Maximize $L(q, \Theta^{(t-1)})$ with respect to $q(Z)$ to obtain

$$\begin{aligned}q^{(t)}(Z) &= argmax_{q(Z)}\, L(q(Z), \Theta^{(t-1)})\\ &= p(Z|X, \Theta^{(t-1)}).\end{aligned} \tag{7}$$

M-step Maximize $L(q^{(t)}, \Theta)$ with respect to Θ, i.e.,

$$\Theta^{(t)} = arg_{\Theta} max L(q^{(t)}(Z), \Theta), \tag{8}$$

which is equivalent to

$$\Theta^{(t)} = argmax_{\Theta} \sum_{i=1}^{n} E_{zi}[\log p(x_i, z_i|\Theta)]$$

since the second term in (4) does not depend on Θ.

Model-based clustering of multivariate data is often performed by learning a Mixture of Gaussians (MoG) using the EM algorithm. In a MoG model, the parameters corresponding to each component are the mean and covariance for each Gaussian given by (μ_h, Σ_h), $h = 1, \ldots, k$. For a given dataset X, the EM algorithm for learning MoG starts with an initial guess $\Theta^{(0)}$ for the parameters where $\Theta^{(0)} = \{(\pi_h^{(0)}, \mu_h^{(0)}, \Sigma_h^{(0)}),$ $h = 1, \ldots, k\}$. At iteration t, the following updates are done:

E-step Update distributions over latent variables $z_i, i = 1, \ldots, n$ as

$$q^{(t)}(z_j = h) = p(z_j = h|x_j, \Theta^{(t-1)}) = \frac{\pi_h^{(t-1)} p(x_i|\mu_h^{(t-1)}, \Sigma_h^{(t-1)},)}{\Sigma_{h'=1}^{k} \pi_{h'}^{(t-1)} p(x_i|\mu_h^{(t-1)}, \Sigma_h^{(t-1)})}. \tag{9}$$

M-step Optimizing the lower bound over $\{(\pi_h, \mu_h, \Sigma_h), h = 1, \ldots, k\}$ yields

$$\pi_h^{(t)} = \frac{1}{n} \sum_{i=1}^{n} p(h|x_j,\ \Theta^{(t-1)}), \tag{10}$$

$$\mu_h^{(t)} = \frac{\Sigma_{i=1}^{n} x_i\, p(h|x_i, \Theta^{(t-1)})}{n\pi_h^{(t)}}, \tag{11}$$

$$\Sigma_h^{(t)} = \frac{\Sigma_{i=1}^{n} (x_i - \mu_h^{(t)})(x_i - \mu_h^{(t)})^T\, p(h|x_i, \Theta^{(t-1)})}{n\pi_h^{(t)}}. \tag{12}$$

The iterations are guaranteed to lead to monotonically non decreasing improvements of the lower bound $L(q, \Theta)$. The iterations are typically run till a suitable convergence criterion is satisfied. On convergence, one gets the estimates $\Theta = \{(\pi_h,\ \mu_h,\ \Sigma_h),\ h = 1,\ \ldots, k\}$ of the component parameters as well as the soft clustering $p(h|xi, \Theta)$ of individual data points. The alternating maximization algorithm outlined above can get stuck in a local minima or saddle point of the objective function. In general, the iterations are not guaranteed to converge to a global optima. In fact, different initializations $\Theta^{(0)}$ of parameters can yield different final results. In practice, one typically tries a set of different initializations and picks the best among them according to the final value of the lower bound obtained. Extensive empirical research has gone into devising good initialization schemes for EM algorithm in the context of learning mixture models.

Recent years have seen progress in the design and analysis of provably correct algorithms for learning mixture models for certain well behaved distributions, where the component distributions are assumed to be separated from each other in a well-defined sense. Such algorithms typically involve projecting data to a suitable lower-dimensional space where the components separate out and the clustering becomes simpler. One family of algorithms rely on random projections and are applicable to variety of problems including that of learning mixture of Gaussians. More recent developments include algorithms based on spectral projections and are applicable to any log-concave distri-butions.

Related Work

Model-based clustering is intimately related to a wide variety of centroid-based partitional clustering algorithms. In particular, the popular kmeans clustering algorithm can be viewed as a special case of learning mixture of Gaussians with a specific covariance structure. Given a dataset X, the kmeans problem is to find a partitioning $C = \{Ch, h = 1, \ldots, k\}$ of X such that the following objective is minimized:

$$J(C) = \sum_{h=1}^{k} \sum_{x \in C_h} \|x - \mu_h\|^2,$$

where μ_h is the mean of the points in C_h. Starting from an initial guess at the cluster means, the kmeans algorithm alternates between assigning points to the nearest cluster and updating the cluster means till convergence. Consider the problem of learning a mixture of Gaussians on X such that each Gaussian has a fixed covariance matrix $\sum_h = \beta I$, where I is the identity matrix and $\beta > 0$ is a constant. Then, as $\beta \to 0$, maximizing the scaled lower bound $\beta\ L(q, \Theta)$ corresponding to the mixture modeling problem becomes equivalent to minimizing the kmeans objective. Further, the EM algorithm outlined above reduces to the popular kmeans algorithm. In fact, such a reduction holds for a much larger class of centroid-based clustering algorithms based on Bregman divergences, which are a general class of divergence measures derived from convex function and have popular divergences such as squared Euclidean distance and KL-divergence as special cases. Centroid-based clustering with Bregman divergences can be viewed as a special case of learning mixtures of exponential family distributions with a reduction similar to the one from mixture of Gaussians to kmeans. Further, non linear clustering algorithms such as kernel kmeans can be viewed as a special case of learning mixture of Gaussians in a Hilbert space.

Recent years have seen generalizations of mixture models to mixed membership models and their non parametric extensions. Latent Dirichlet allocation is an example of such a mixed membership model for topic modeling in text corpora. The key novelty of mixed membership models is that they allow a different component proportions π_x for each observation x instead of a fixed proportion π as in mixture models. The added flexibility yields superior performance in certain problem domains.

Definition

Model-based reinforcement learning refers to learning optimal behavior indirectly by learning a model of the environment by taking actions and observing the outcomes that include the next state and the immediate reward. The models predict the outcomes of actions and are used in lieu of or in addition to interaction with the environment to learn optimal policies.

Motivation and Background

▶ Reinforcement Learning (RL) refers to learning to behave optimally in a stochastic environment by taking actions and receiving rewards (Sutton and Barto 1998). The environment is assumed Markovian in that there is a fixed probability of the next state given the current state and the agent's action. The agent also receives an immediate reward based on the current state and the action. Models of the next-state distribution and the immediate rewards are referred to as "action models" and, in general, are not known to the learner. The agent's goal is to take actions, observe the outcomes including rewards and next states, and learn a policy or a mapping from states to actions that optimizes some performance measure. Typically the performance measure is the expected total reward in episodic domains and the expected average reward per time step or expected discounted total reward in infinite-horizon domains.

The theory of ▸ Markov Decision Processes (MDPs) implies that under fairly general conditions, there is a stationary policy, i.e., a time-invariant mapping from states to actions, which maximizes each of the above reward measures. Moreover, there are MDP solution algorithms, e.g., value iteration and policy iteration (Puterman 1994), which can be used to solve the MDP exactly given the action models. Assuming that the number of states is not exceedingly high, this suggests a straightforward approach for model-based reinforcement learning. The models can be learned by interacting with the environment by taking actions, observing the resulting states and rewards, and estimating the parameters of the action models through maximum likelihood methods. Once the models are estimated to a desired accuracy, the MDP solution algorithms can be run to learn the optimal policy.

One weakness of the above approach is that it seems to suggest that a fairly accurate model needs to be learned over the entire domain to learn a good policy. Intuitively it seems that we should be able to get by without learning highly accurate models for suboptimal actions. A related problem is that the method does not suggest how best to explore the domain, i.e., which states to visit and which actions to execute to quickly learn an optimal policy. A third issue is one of scaling these methods, including model learning, to very large state spaces with billions of states.

The remaining sections outline some of the approaches explored in the literature to solve these problems.

Theory and Methods

Systems that solve MDPs using value-based methods can take advantage of models in at least two ways. First, with an accurate model, they can use offline learning algorithms that directly solve the modeled MDPs. Second, in an online setting, they can use the estimated models to guide exploration and action selection. Algorithms have been developed that exploit MDP models in each of these ways. We describe some such algorithms below.

Common approaches to solving MDPs given a model are value or policy iteration (Sutton and Barto 1998; Kaelbling et al. 1996). In these approaches, the algorithms start with a randomly initialized value function or policy. In value iteration, the algorithm loops through the state space, updating the value estimates of each state using Bellman backups, until convergence. In policy iteration, the algorithm calculates the value of the current policy and then loops through the state space, updating the current policy to be greedy with respect to the backed up values. This is repeated until the policy converges.

When the model is unknown but being estimated as learning progresses, we could use value or policy iteration in the inner loop: after updating our current model estimate using an observed sample from the MDP, we could solve the updated MDP offline and take an action based on the solution. However, this is computationally very expensive. To gain efficiency, algorithms such as ▸ Adaptive Real-time Dynamic Programming (ARTDP) (Barto et al. 1995) and DYNA (Sutton 1990) perform one or more Bellman updates using the action models after each real-world action and corresponding update to either a state-based or state-action-based value function. Other approaches, such as prioritized sweeping (Moore and Atkeson 1993) and Queue-Dyna (Peng and Williams 1993), have considered the problem of intelligently choosing which states to update after each iteration.

A different approach to discovering the optimal policy is to use algorithms that calculate the gradient of the utility measure with respect to some adjustable policy parameters. The standard policy gradient approaches that estimate the gradient from immediate rewards suffer from high variance due to the stochasticity of the domain and the policy. Wang and Dietterich propose a model-based policy gradient algorithm that alleviates this problem by learning a partial model of the domain (Wang and Dietterich 2003). The partial model is solved to yield the value function of the current policy and the expected number of visits to each state, which are then used to derive the gradient of the policy in closed form. The authors observe that their approach converges in many fewer exploratory steps compared with model-free policy gradient algorithms in a number of domains including a real-world resource-controlled scheduling problem.

One of the many challenges in model-based reinforcement learning is that of efficient exploration of the MDP to learn the dynamics and the rewards. In the "Explicit Explore and Exploit" or E^3 algorithm, the agent explicitly decides between exploiting the known part of the MDP and optimally trying to reach the unknown part of the MDP (exploration) (Kearns and Singh 2002). During exploration, it uses the idea of "balanced wandering," where the least executed action in the current state is preferred until all actions are executed a certain number of times. In contrast, the R-Max algorithm implicitly chooses between exploration and exploitation by using the principle of "optimism under uncertainty" (Brafman and Tennenholtz 2002). The idea here is to initialize the model parameters optimistically so that all unexplored actions in all states are assumed to reach a fictitious state that yields maximum possible reward from then on regardless of which action is taken. Both these algorithms are guaranteed to find models whose approximate policies are close to the optimal with high probability in time polynomial in the size and mixing time of the MDP.

Since a table-based representation of the model is impractical in large state spaces, efficient model-based learning depends on compact parameterization of the models. Dynamic Bayesian networks offer an elegant way to represent action models compactly by exploiting conditional independence relationships and have been shown to lead to fast convergence of models (Tadepalli and Ok 1998). In some cases, choosing an appropriate prior distribution over model parameters can be important and lead to faster learning. In recent work, the acquisition of a model prior has been investigated in a multitask setting (Wilson et al. 2007). In this work, the authors use a hierarchical Bayesian model to represent classes of MDPs. Given observations from a new MDP, the algorithm uses the model to infer an appropriate class (creating a new class if none seem appropriate). It then uses the distributions governing the inferred class as a prior to guide exploration in the new MDP. This approach is able to significantly speed up the rate of convergence to optimal policy as more environments are seen.

In recent work, researchers have explored the possibility of using approximate models coupled with policy gradient approaches to solve hard control problems (Abbeel et al. 2006). In this work, the approximate model is used to calculate gradient directions for the policy parameters. When searching for an improved policy, however, the real environment is used to calculate the utility of each intermediate policy. Observations from the environment are also used to update the approximate model. The authors show that their approach improves upon model-based algorithms which only used the approximate model while learning.

Applications

In this section, we describe some domains where model-based reinforcement learning has been applied.

Model-based approaches have been commonly used in RL systems that play two-player games (Tesauro 1995; Baxter et al. 1998). In such systems, the model corresponds to legal moves in the game. Such models are easy to acquire and can be used to perform lookahead search on the game tree. For example, the TD-LEAF(λ) system (Baxter et al. 1998) uses the values at the leaves of an expanded game tree at some depth to update the estimate of the value of the current state. After playing a few hundred chess games, this algorithm was able to reach the play level of a US Master.

Model-based reinforcement learning has been used in a spoken dialog system (Singh et al.

1999). In this application, a dialog is modeled as a turn-based process, where at each step the system speaks a phrase and records certain observations about the response and possibly receives a reward. The system estimates a model from the observations and rewards and uses value iteration to compute optimal policies for the estimated MDP. The authors show empirically that, among other things, the system finds sensible policies and is able to model situations that involve "distress features" that indicate the dialog is in trouble.

It was shown that in complex real-world control tasks such as pendulum swing-up task on a real anthropomorphic robot arm, model-based learning is very effective in learning from demonstrations (Atkeson and Schaal 1997). A model is learned from the human demonstration of pendulum swing up, and an optimal policy is computed using a standard approach in control theory called linear quadratic regulation. Direct imitation of the human policy would not work in this case due to the small differences in the tasks and the imperfections of the robot controller. On the other hand, model-based learning was able to learn successfully from short demonstrations of pendulum swing up. However, on a more difficult swing-up task that includes pumping, model-based learning by itself was inadequate due to the inaccuracies in the model. They obtained better results by combining model-based learning with learning appropriate task parameters such as the desired pendulum target angle at an intermediate stage where the pendulum was at its highest point.

In more recent work, model-based RL has been used to learn to fly a remote-controlled helicopter (Abbeel et al. 2007). Again, the use of model-free approaches is very difficult, because almost any random exploratory action results in an undesirable outcome (i.e., a crash). To learn a model, the system bootstraps from a trajectory that is observed by watching an expert human fly the desired maneuvers. In each step, the system learns a model with the observed trajectory and finds a controller that works in simulation with the model. This controller is then tried with the real helicopter. If it fails to work well, the model is refined with the new observations and the process is repeated. Using this approach, the system is able to learn a controller that can repeatedly perform complex aerobatic maneuvers, such as flips and rolls.

Model-based RL has also been applied to other domains, such as robot juggling (Schaal and Atkeson 1994) and job-shop scheduling (Zhang and Dietterich 1995). Some work has also been done that compares model-free and model-based RL methods (Atkeson and Santamaria 1997). From their experiments, the authors conclude that, for systems with reasonably simple dynamics, model-based RL is more data efficient, finds better policies, and handles changing goals better than model-free methods. On the other hand, model-based methods are subject to errors due to inaccurate model representations.

Future Directions

Representing and learning richer action models for stochastic domains that involve relations, numeric quantities, and parallel, hierarchical, and durative actions is a challenging open problem. Efficient derivation of optimal policies from such rich representations of action models is another problem that is partially explored in ► symbolic dynamic programming. Constructing good policy languages appropriate for a given action model or class of models might be useful to accelerate learning near-optimal policies for MDPs.

Multi-agent Learning

Yoav Shoham and Rob Powers
Stanford University, Stanford, CA, USA

Definition

Multi-agent learning (MAL) refers to settings in which multiple agents learn simultaneously. Usually defined in a game theoretic setting, specifically in repeated games or stochastic games, the key feature that distinguishes multi-agent learning from single-agent learning is that in the former the learning of one agent impacts the learning of others. As a result, neither the problem definition for multi-agent learning nor the algorithms offered follow in a straightforward way from the single-agent case. In this first of two entries on the subject, we focus on the problem definition.

Background

The topic of multi-agent learning (MAL henceforth) has a long history in game theory, almost as long as the history of game theory itself (another more recent term for the area within game theory is *interactive learning*). In artificial intelligence (AI), the history of *single*-agent learning is of course as rich if not richer; one need not look further than this encyclopedia for evidence. And while it is only in recent years that AI has branched into the multi-agent aspects of learning, it has done so with something of a vengeance. If in 2003 one could describe the AI literature on MAL by enumerating the relevant articles, today this is no longer possible. The leading conferences routinely feature articles on MAL, as do the journals (We acknowledge a simplification of history here. There is definitely MAL work in AI that predates the last few years, though the relative deluge is indeed recent. Similarly, we focus on AI since this is where most of the action is these days, but there are also other areas in computer science that feature MAL material; we mean to include that literature here as well).

While the AI literature maintains a certain flavor that distinguishes it from the game theoretic literature, the commonalities are greater than the differences. Indeed, alongside the area of mechanism design and perhaps the computational questions surrounding solution concepts such as the Nash equilibrium, MAL is today arguably one of the most fertile interaction grounds between computer science and game theory. The key aspect of MAL, which ties the work together and which distinguishes it from single-agent learning, is the fact that in MAL one cannot separate the process of learning from the process of teaching.

The learning of one agent causes it to change its behavior; this causes other agents to adapt their behavior, which in turn causes the first agent to keep adapting too. Such reciprocal – or interactive – learning calls not only for different types of learning algorithms but also for different yardsticks by which to evaluate learning. For this reason, the literature on MAL can be confusing. Not only do the learning techniques vary, but the goal of learning and the evaluation measures are diverse and often left only implicit.

We will couch our discussion in the formal setting of *stochastic games* (aka *Markov games*). Most of the MAL literature adopts this setting, and indeed most of it focuses on the even more narrow class of *repeated games*. Furthermore, stochastic games also generalize *Markov decision problems* (MDPs), the setting from which much of the relevant learning literature in AI originates. These are defined as follows.

A stochastic game can be represented as a tuple: $(N, S, \vec{A}, \vec{R}, T)$. N is a set of agents indexed $1, \ldots, n$. S is a set of n-agent stage games. $\vec{A} = A_1, \ldots, A_n$, with A_i the set of actions (or pure strategies) of agent i (note that we assume the agent has the same strategy space in all games; this is a notational convenience, but not a substantive restriction). $\vec{R} = R_1, \ldots, R_n$, with $R_i : S \times \vec{A} \to \mathcal{R}$ giving the immediate reward function of agent i for stage game S. $T : S \times \vec{A} \to \Pi(S)$ is a stochastic transition function, specifying the probability of the next stage game to be played based on the game just played and the actions taken in it.

We also need to define a way for each agent to aggregate the set of immediate rewards received in each state. For finitely repeated games, we can simply use the sum or average, while for infinite games, the most common approaches are to use either the limit average or the sum of discounted awards $\sum_{t=1}^{\infty} \delta^t r_t$, where r_t is the reward received at time t.

A repeated game is a stochastic game with only one stage game, while an MDP is a stochastic game with only one agent. (Note: While most of the MAL literature lives happily in this setting, we would be remiss not to acknowledge the literature that does not. Certainly, one could discuss learning in the context of extensive-form games of incomplete and/or imperfect information. Even farther afield, interesting studies of learning exist in large population games and evolutionary models, particularly *replicator dynamics (RD)* and *evolutionary stable strategies (ESS)*.)

What is there to learn in stochastic games? Here we need to be explicit about some aspects of stochastic games that were glossed over so far. Do the agents know the stochastic game, including the stage games and the transition probabilities? If not, do they at least know the specific game being played at each stage, or only the actions available to them? What do they see after each stage game has been played – only their own rewards, or also the actions played by the other agent(s)? Do they perhaps magically see the other agent(s)' mixed strategy in the stage game? And so on.

In general, games may be known or not, play may be observable or not, and so on. We will focus on known, fully observable games, where the other agent's strategy (or agents' strategies) is not known a priori (though in some cases, there is a prior distribution over it). In our restricted setting, there are two possible things to learn. First, the agent can learn the opponent's (or opponents') strategy (or strategies), so that the agent can then devise the best (or at least a good) response. Alternatively, the agent can learn a strategy of his own that does well against the opponents, without explicitly learning the opponent's strategy. The first is sometimes called *model-based learning* and the second *model-free learning*.

In broader settings, there is more to learn. In particular, with unknown games, one can learn the game itself. Some will argue that the restricted setting is not a true learning setting, but (a) much of the current work on MAL, particularly in game theory, takes place in this setting, and (b) the foundational issues we wish to tackle surface already here. In particular, our comments are intended to also apply to the work in the AI literature on games with unknown payoffs, work which builds on the success of learning in unknown MDPs. We will have more to say about the nature of "learning" in the setting of stochastic games in the following sections.

Problem Definition

When one examines the MAL literature, one can identify several distinct agendas at play, which are often left implicit and conflated. A prerequisite for success in the field is to be very explicit about the problem being addressed. Here we list five distinct coherent goals of MAL research. They each have a clear motivation and a success criterion. They can be caricatured as follows:

1. Computational
2. Descriptive
3. Normative
4. Prescriptive, cooperative
5. Prescriptive, noncooperative

The first agenda is computational in nature. It views learning algorithms as an iterative way to compute properties of the game, such as solution concepts. As an example, fictitious play was originally proposed as a way of computing a sample Nash equilibrium for zero-sum games, and replicator dynamics has been proposed for computing a sample Nash equilibrium in symmetric games. These tend not to be the most efficient computation methods, but they do sometimes constitute quick-and-dirty methods that can easily be understood and implemented.

The second agenda is descriptive – it asks how natural agents learn in the context of other learners. The goal here is to investigate formal models of learning that agree with people's behavior (typically, in laboratory experiments) or possibly with the behaviors of other agents (e.g., animals or organizations). This problem is clearly an important one and when taken seriously calls for strong justification of the learning dynamics being studied. One approach is to apply the experimental methodology of the social sciences.

The centrality of equilibria in game theory underlies the third agenda we identify in MAL, which for lack of a better term we called normative and which focuses on determining which sets of learning rules are in equilibrium with each other. More precisely, we ask which repeated game strategies are in equilibrium; it just so happens that in repeated games, most strategies embody a learning rule of some sort. For example, we can ask whether fictitious play and Q-learning, appropriately initialized, are in equilibrium with each other in a repeated Prisoner's Dilemma game.

The last two agendas are prescriptive; they ask how agents *should* learn. The first of these involves distributed control in dynamic systems. There is sometimes a need or desire to decentralize the control of a system operating in a dynamic environment, and in this case, the local controllers must adapt to each other's choices. This direction, which is most naturally modeled as a repeated or stochastic common-payoff (or "team") game. Proposed approaches can be evaluated based on the value achieved by the joint policy and the resources required, whether in terms of computation, communication, or time required to learn the policy. In this case, there is rarely a role for equilibrium analysis; the agents have no freedom to deviate from the prescribed algorithm.

In our final agenda, termed "prescriptive, noncooperative," we ask how an agent should act to obtain high reward in the repeated (and, more generally, stochastic) game. It thus retains the design stance of AI, asking how to design an optimal (or at least effective) agent for a given environment. It just so happens that this environment is characterized by the types of agents inhabiting it, agents who may do some learning of their own. The objective of this agenda is to identify effective strategies for environments of interest. An effective strategy is one that achieves a high reward in its environment, where one of the main characteristics of this environment is the selected class of possible opponents. This class of opponents should itself be motivated as being reasonable and containing opponents of interest. Convergence to an equilibrium is not a goal in and of itself.

Stanford University, Stanford, CA, USA

Definition

Multi-agent learning (MAL) refers to settings in which multiple agents learn simultaneously. Usually defined in a game theoretic setting, specifically in repeated games or stochastic games, the key feature that distinguishes MAL from single-agent learning is that in the former the learning of one agent impacts the learning of others. As a result, neither the problem definition for multi-agent learning nor the algorithms offered follow in a straightforward way from the single-agent case. In this second of two entries on the subject, we focus on algorithms.

Some MAL Techniques

We will discuss three classes of techniques – one representative of work in game theory, one more typical of work in artificial intelligence (AI), and one that seems to have drawn equal attention from both communities.

Model-Based Approaches

The first approach to learning we discuss, which is common in the game theory literature, is the model-based one. It adopts the following general scheme:

1. Start with some model of the opponent's strategy.
2. Compute and play the best response.
3. Observe the opponent's play and update your model of his/her strategy.
4. Go to step 2.

Among the earliest, and probably the best-known, instance of this scheme is *fictitious play*. The model is simply a count of the plays by the opponent in the past. The opponent is assumed to be playing a stationary strategy, and the observed frequencies are taken to represent the opponent's mixed strategy. Thus after five repetitions of the Rochambeau game (R) in which the opponent played (R, S, P, R, P), the current model of his/her mixed strategy is $R = 0.4$, $P = 0.4$, $S = 0.2$.

There exist many variants of the general scheme, for example, those in which one does not play the exact best response in step 2. This is typically accomplished by assigning a probability of playing each pure strategy, assigning the best response the highest probability, but allowing some chance of playing any of the strategies. A number of proposals have been made of different ways to assign these probabilities such as *smooth fictitious play* and *exponential fictitious play*.

A more sophisticated version of the same scheme is seen in *rational learning*. The model is a distribution over the repeated-game strategies. One starts with some prior distribution; for example, in a repeated Rochambeau game, the prior could state that with probability 0.5 the opponent repeatedly plays the equilibrium strategy of the stage game, and, for all $k > 1$, with probability 2^{-k} she plays R k times and then reverts to the repeated equilibrium strategy. After each play, the model is updated to be the posterior obtained by Bayesian conditioning of the previous model. For instance, in our example, after the first non-R play of the opponent, the posterior places probability 1 on the repeated equilibrium play.

Model-Free Approaches

An entirely different approach that has been commonly pursued in the AI literature is the model-free one, which avoids building an explicit model of the opponent's strategy. Instead, over time one learns how well one's own various possible actions fare. This work takes place under the general heading of *reinforcement learning* (we note that the term is used somewhat differently in the game theory literature), and most approaches have their roots in the Bellman equations. We start our discussion with the familiar single-agent *Q-learning* algorithm for computing an optimal policy in an unknown Markov Decision Problem (MDP).

$$\begin{aligned} Q(s,a) &\leftarrow (1-\alpha_t)Q(s,a) + \alpha_t[R(s,a) \\ &\quad + \gamma V(s')] \\ V(s) &\leftarrow \max_{a \in A} Q(s,a). \end{aligned}$$

As is well known, with certain assumptions about the way in which actions are selected at each state over time and constraints on the learning rate schedule, α_t, Q-learning can be shown to converge to the optimal value function V^*.

The Q-learning algorithm can be extended to the multi-agent stochastic game setting by having each agent simply ignore the other agents and pretend that the environment is passive:

$$\begin{aligned} Q_i(s,a_i) &\leftarrow (1-\alpha_t)Q_i(s,a_i) + \alpha_t[R_i(s,\mathbf{a}) \\ &\quad + \gamma V_i(s')] \\ V_i(s) &\leftarrow \max_{a_i \in A_i} Q_i(s,a_i). \end{aligned}$$

Several authors have tested variations of the basic Q-learning algorithm for MAL. However, this approach ignores the multi-agent nature of the setting entirely. The Q-values are updated without regard for the actions selected by the other agents. While this can be justified when the opponents' distributions of actions are stationary, it can fail when an opponent may adapt its choice of actions based on the past history of the game.

The first step in addressing this problem is to define the Q-values as a function of all the agents' actions:

$$\begin{aligned} Q_i(s,\mathbf{a}) &\leftarrow (1-\alpha)Q_i(s,\mathbf{a}) \\ &\quad + \alpha[R_i(s,\mathbf{a}) + \gamma V_i(s')]. \end{aligned}$$

We are, however, left with the question of how to update V, given the more complex nature of the Q-values.

For (by definition, two-player) zero-sum stochastic games (SGs), the *minimax-Q* learning algorithm updates V with the minimax of the Q-values:

$$\begin{aligned} V_1(s) \leftarrow \max_{P_1 \in \Pi(A_1)} \min_{a_2 \in A_2} \sum_{a_1 \in A_1} P_1(a_1) \\ Q_1(s,(a_1,a_2)). \end{aligned}$$

Later work proposed other update rules for the Q and V functions focusing on the special case of common-payoff (or "team") games. A stage game is common-payoff if at each outcome all agents receive the same payoff. The payoff is, in general, different in different outcomes, and thus the agents' problem is that of coordination; indeed, these are also called *games of pure coordination.*

The work on zero-sum and common-payoff games continues to be refined and extended; much of this work has concentrated on probably optimal trade-offs between exploration and exploitation in unknown, zero-sum games. Another work attempted to extend the "Bellman heritage" to general-sum games (as opposed to zero-sum or common-payoff games), but the results here have been less conclusive.

Regret Minimization Approaches

Our third and final example of prior work in MAL is no-regret learning. It is an interesting example for two reasons. First, it has some unique properties that distinguish it from the work above. Second, both the AI and game theory communities appear to have converged on it independently. The basic idea goes back to early work on how to evaluate the success of learning rules in the mid-1950s and has since been extended and rediscovered numerous times over the years under the names of universal consistency, no-regret learning, and the Bayes' envelope. The following algorithm is a representative of this body of work. We start by defining the *regret*, $r_i^t(a_j, s_i)$ of agent i for playing the sequence of actions s_i instead of playing action a_j, given that the opponents played the sequence s_{-i}.

$$r_i^t(a_j, s_i | s_{-i}) = \sum_{k=1}^{t} R\left(a_j, s_{-i}^k\right) - R\left(s_i^k, s_{-i}^k\right).$$

The agent then selects each of its actions with probability proportional to max $\left(r_i^t(a_j, s_i), 0\right)$ at each time step $t + 1$.

Some Typical Results

One sees at least three kinds of results in the literature regarding the learning algorithms presented above and others similar to them. These are:

1. Convergence of the strategy profile to an (e.g., Nash) equilibrium of the stage game in self-play (i.e., when all agents adopt the learning procedure under consideration).
2. Successful learning of an opponent's strategy (or opponents' strategies).
3. Obtaining payoffs that exceed a specified threshold.

Each of these types comes in many flavors; here are some examples. The first type is perhaps the most common in the literature, in both game theory and AI. For example, while fictitious play does not in general converge to a Nash equilibrium of the stage game, the distribution of its play can be shown to converge to an equilibrium in zero-sum games, 2 × 2 games with generic payoffs, or games that can be solved by iterated elimination of strictly dominated strategies. Similarly in AI, minimax-Q learning is proven to converge in the limit to the correct Q-values for any zero-sum game, guaranteeing convergence to a Nash equilibrium in self-play. This result makes the standard assumptions of infinite exploration and the conditions on learning rates used in proofs of convergence for single-agent Q-learning.

Rational learning exemplifies results of the second type. The convergence shown is to correct beliefs about the opponent's repeated game strategy; thus it follows that, since each agent adopts a best response to their beliefs about the other agent, in the limit the agents will converge to a Nash equilibrium of the repeated game. This is an impressive result, but it is limited by two factors: the convergence depends on a very strong assumption of absolute continuity; and the beliefs converged to are correct only with respect to the aspects of history that are observable given the strategies of the agents. This is an involved topic, and the reader is referred to the literature for more details.

The literature on no-regret learning provides an example of the third type of result and has perhaps been the most explicit about the criteria for evaluating learning rules. For example, one pair of criteria that have been suggested is as follows. The first criterion is that the learning rule should be "safe," which is defined as the requirement that the learning rule must guarantee at least the minimax payoff of the game. (The minimax payoff is the maximum expected value a player can guarantee against any possible opponent.) The second criterion is that the rule should be "consistent." In order to be "consistent," the learning rule must guarantee that it does at least as well as the best response to the empirical distribution of play when playing against an opponent whose play is governed by independent draws from a fixed distribution. "Universal consistency" is then defined as the requirement that a learning rule does at least as well as the best response to the empirical distribution regardless of the actual strategy the opponent is employing (this implies both safety and consistency). The requirement of “universal consistency” is in fact equivalent to requiring that an algorithm exhibits *no-regret*, generally defined as follows, against all opponents.

$$\forall \epsilon > 0, \left(\lim_{t\to\inf}\left[\frac{1}{t}\max_{a_j\in A_i} r_i^t(a_j, s_i|s_{-i})\right] < \epsilon\right)$$

In both game theory and artificial intelligence, a large number of algorithms have been shown to satisfy universal consistency or no-regret requirements.

MultiBoosting

Geoffrey I. Webb
Faculty of Information Technology, Monash
University, Victoria, Australia

Definition

MultiBoosting (Webb 2000) is an approach to ▶ multistrategy ensemble learning that combines features of ▶ AdaBoost and ▶ Bagging. The insight underlying MultiBoosting is that the primary effect of AdaBoost is ▶ bias reduction, while the primary effect of bagging is ▶ variance reduction. By combining the two techniques, it is possible to obtain both bias and variance reduction, the cumulative effect often being a greater reduction in error than can be obtained with the equivalent amount of computation by either AdaBoost or Bagging alone. Viewed from another perspective, as the size of an ensemble formed by either AdaBoost or Bagging is increased, each successive addition to the ensemble has decreasing effect. Thus, if the benefit of the first few applications of AdaBoost can be combined with the benefit of the first few applications of Bagging, the combined benefit may be greater than simply increasing the number of applications of one or the other.

Algorithm

MultiBoosting operates by dividing the ensemble of classifiers that is to be created into a number of subcommittees. Each of these subcommittees is formed by Wagging (Baner and Kohavi 1999), MultiBoosting. Tablel MultiBoost Algorithm

MultiBoost
input:

- S_0, a sequence of m labeled examples $\langle(x_1, y_1), \ldots, (x_m, y_m)\rangle$ with labels $y_j \in Y$.
- base learning algorithm *BaseLearn*.
- integer T specifying the number of iterations.
- vector of integers I_i specifying the iteration at which each subcommittee $i \geq 1$ should terminate.

```
1.  $S_1 = S_0$ with instance weights assigned to be 1.
2.  set $k = 1$.
3.  For $t = 1$ to $T$
4.    If $I_k = t$ then
5.    reweight $S_t$ .
6.    increment $k$.
7.  $C_t = BaseLearn(S')$.
8.  $\epsilon_t = \frac{\Sigma_{x_j \in S_t : C_t(x_j) \neq y_j} weight(x_j)}{m}$.
9.  if $\epsilon_t > 0.5$ then
10.   reweight $S_t$.
11.   increment $k$.
12.   go to 7.
13. otherwise if $\epsilon_t = 0$ then
14.   set $\beta_t$ to $10^{-10}$
15.   reweight $S_t$.
16.   increment $k$.
17. otherwise,
18.   $\beta_t = \frac{\epsilon_t}{(1-\epsilon_t)}$.
19.   $S_{t+1} = S_t$.
20.   For each $x_j \in S_{t+1}$,
21.     divide $weight\ (x_j)$ by $2\epsilon_t$ if $C_t(x_j) \neq y_j$ and
      $2\ (1 - \epsilon_t)$ otherwise.
22.     if $weight\ (x_j) < 10^{-8}$, set $weight\ (x_j)$ to $10^{-8}$
```

Output the final classifier: $C^*(x) = argmax_{y \in Y} \sum_{t; C_t(x)=y} log \frac{1}{\beta_t}$.

a variant of Bagging that utilizes weighted instances and, hence, is more readily integrated with AdaBoost. The ensemble is formed by applying AdaBoost to these subcommittees. The resulting algorithm is presented in Table 1. The learned ensemble classifier is C, and the tth member of the ensemble is C_t. Each S_t is a vector of n weighted training objects whose weights always sum to n. The weights change from turn to turn (the turns indicated by the subscript t). The base training algorithm *BaseLearn* should more heavily penalize errors on training instances with higher weights. ε_t is the weighted error of C_t on S_i. β_t is a weight assigned to the tth classifier, Ct. The operation reweight S_t sets the weights of the objects in S_t to random values drawn from the continuous Poisson distribution and then standardizes them to sum to n. The code set with a grey background is the code added to AdaBoost in order to create MultiBoost.

Multiple-instance learning

Definition

Multiple-Instance (MI) learning is an extension of the standard supervised learning setting. In standard supervised learning, the input consists of a set of labeled instances each described by an attribute vector. The learner then induces a concept that relates the label of an instance to its attributes. In MI learning, the input consists of labeled examples (called "bags") consisting of *multisets* of instances, each described by an attribute vector, and there are constraints that relate the label of each bag to the unknown labels of each instance. The MI learner then induces a concept that relates the label of a bag to the attributes describing the instances in it. This setting contains supervised learning as a special case: if each bag contains exactly one instance, it reduces to a standard supervised learning problem.

Motivation and Background

The MI setting was introduced by Dietterich et al. (1997) in the context of drug activity prediction. Drugs are typically molecules that fulfill some desired function by binding to a target. If we wish to learn the characteristics responsible for binding, a possible representation of the problem is to represent each molecule as a set of low energy shapes or *conformations*, and describe each conformation using a set of attributes. Each such bag of conformations is given a label corresponding to whether the molecule is active or inactive. To learn a classification model, an algorithm assumes that every instance in a bag labeled negative is actually negative, whereas at least one instance in a bag labeled positive is actually positive with respect to the underlying concept.

From a theoretical viewpoint, MI learning occupies an intermediate position between standard propositional supervised learning and first-order relational learning. Supervised learning is a special case of MI learning, while MI learning is a special case of first-order learning. It has been argued that the MI setting is a key transition between standard supervised and relational learning DeRaedt (1998). At the same time, theoretical results exist that show that, under certain assumptions, certain concept classes that are probably approximately correct (PAC)-learnable (see PAC Learning) in a supervised setting remain PAC-learnable in an MI setting. Thus, the MI setting is able to leverage some of the rich representational power of relational learners while not sacrificing the efficiency of propositional learners. Figure 1 illustrates the relationships between standard supervised learning, MI learning, and relational learning.

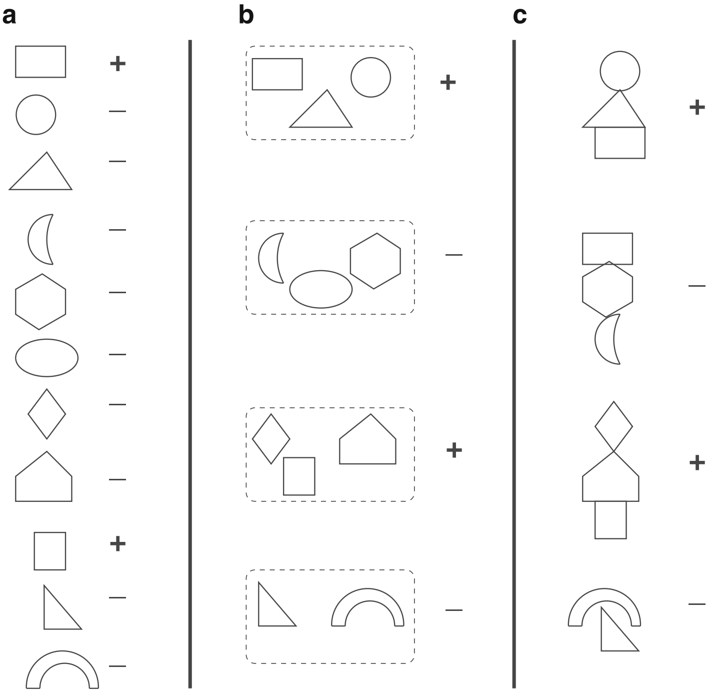
Since its introduction, a wide variety of tasks have been formulated as MI learning problems. Many new algorithms have been developed, and well-known supervised learning algorithms extended, to learn MI concepts. A great deal of work has also been done to understand what kinds of concepts can and cannot be learned efficiently in this setting. In the following sections, we discuss the theory, methods, and applications of MI learning in more detail.

Structure of the Problem

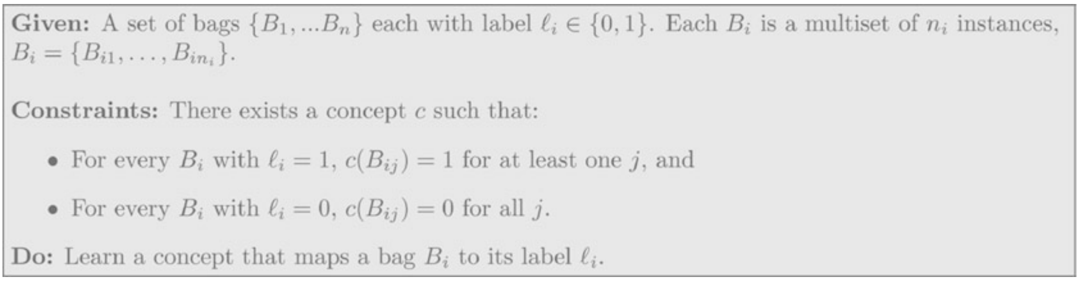
The general MI classification task in shown in Fig. 2. The MI regression task is defined analogously by substituting a real-valued response for the classification label. In this case, the constraint used by the learning algorithm is that the response of any bag is equal to the response of at least one of the instances in it, for example, it could be equal to the largest response over all the instances.

Notice the following problem characteristics:

- The number of instances in each bag can vary independently of other bags. This implies in particular that an MI algorithm must be able to handle bags with as few as one instance (this is a supervised learning setting) to bags with large numbers of instances.
- The number of instances in any positive bag that are "truly positive" could be many more than one – in fact, the definition does not rule



Multi-Instance Learning, Fig. 1 The relationship between supervised, multiple-instance (MI), and relational learning. (a) In supervised learning, each example (geometric figure) is labeled. A possible concept that explains the example labels shown is "the figure is a rectangle." (b) In MI learning, bags of examples are labeled. A possible concept that explains the bag labels shown is "the bag contains at least one figure that is a rectangle." (c) In relational learning, objects of arbitrary structure are labeled. A possible concept that explains the object labels shown is "the object is a stack of three figures and the bottom figure is a rectangle"



Given: A set of bags $\{B_1, ...B_n\}$ each with label $\ell_i \in \{0,1\}$. Each B_i is a multiset of n_i instances, $B_i = \{B_{i1}, \ldots, B_{in_i}\}$.

Constraints: There exists a concept c such that:

- For every B_i with $\ell_i = 1$, $c(B_{ij}) = 1$ for at least one j, and
- For every B_i with $\ell_i = 0$, $c(B_{ij}) = 0$ for all j.

Do: Learn a concept that maps a bag B_i to its label ℓ_i.

Multi-Instance Learning, Fig. 2 Statement of the multiple-instance classification problem

out the case where *all* instances in a positive bag are "truly positive."

- The problem definition does not specify how the instances in any bag are related to each other.

Theory and Methods

In this section we discuss some of the key algorithms and theoretical results in MI learning. We first discuss the methods and results for MI classification. Then we discuss the work on MI regression.

Multiple-Instance Classification

Axis-Parallel Rectangles (APRs) are a concept class that early work in MI classification focused on. These generative concepts specify upper and lower bounds for all numeric attributes describing each instance. An APR is said to "cover" an instance if the instance lies within it. An APR covers a bag if it covers at least one instance within it. The learning algorithm tries to find an APR such that it covers all positive bags and does not cover any negative bags.

An algorithm called "iterated-discrimination" was proposed by Dietterich et al. (1997) to learn APRs from MI data. This algorithm has two phases. In the first phase, it iteratively chooses a set of “relevant” attributes and grows an APR using this set. This phase results in the construction of a very “tight” APR that covers just positive bags. In the second phase, the algorithm expands this APR so that with high probability a new positive instance will fall within the APR. The key steps of the algorithm are outlined below. Note that initially, all attributes are considered to be “relevant.”

The algorithm starts by choosing a random instance in a positive bag. Let us call this instance I_1. The smallest APR covering this instance is a point. The algorithm then expands this APR by finding the smallest APR that covers any instance from a yet uncovered positive bag; call the newly covered instance I_2. This process is continued, identifying new instances $I_3, \ldots, I_k$, until all positive bags are covered. At each step, the APR is “backfitted” in a way that is reminiscent of the later Expectation-Maximization (EM) approaches: each earlier choice is revisited, and I_j is replaced with an instance from the same bag that minimizes the current APR (which may or may not be the same as the one that minimized it at step j).

This process yields an APR that imposes maximally tight bounds on all attributes and covers all positive bags. Based on this APR, a new set of “relevant” attributes is selected as follows. An attribute’s relevance is determined by how strongly it discriminates against negative instances, i.e., given the current APR bounds, how many negative instances the attribute excludes. Features are then chosen iteratively and greedily according to how relevant they are until all negative instances have been excluded. This yields a subset of (presumably relevant) attributes. The APR growth procedure in the previous paragraph is then repeated, with the size of an APR redefined as its size along relevant attributes only. The APR growth and attribute selection phases are repeated until the process converges.

The APR thus constructed may still be too tight, as it fits narrowly around the positive bags in the dataset. In the second phase of the algorithm, the APR bounds are further expanded using a kernel density estimate approach. Here, a probability distribution is constructed for each relevant attribute using Gaussian distributions centered at each instance in a positive bag. Then, the bounds on that attribute are adjusted so that with high probability, any positive instance will lie within the expanded APR.

Theoretical analyses of APR concepts have been performed along with the empirical approach, using Valiant’s “probably approximately correct” (PAC) learning model (Valiant 1984). In early work (Long and Tan 1998), it was shown that if each instance was drawn according to a fixed, unknown product distribution over the rational numbers, independently from every other instance, then an algorithm could PAC-learn APRs. Later, this result was improved in two ways (Auer et al. 1998). First, the restriction that the individual instances in each bag come from a product distribution was removed. Instead, each instance is generated by an arbitrary probability distribution (though each instance in a bag is still generated independently and identically distributed (iid) according to that one distribution). Second, the time and sample complexities for PAC-learning APRs were improved. Specifically, the algorithm described in this work PAC-learns APRs in

$$O\left(\frac{d^3n^2}{\epsilon^2}\log\frac{nd\log(1/\delta)}{\epsilon}\log\frac{d}{\delta}\right)$$

using

$$O\left(\frac{d^2n^2}{\epsilon^2}\log\frac{d}{\delta}\right)$$

time-labeled training bags. Here, d is the dimension of each instance, n is the (largest) number of instances per training bag, and ε and δ are parameters to the algorithm. A variant of this algorithm was empirically evaluated and found to be successful (Auer 1997).

Diverse Density (Maron 1998; Maron and Lozano-Pérez 1998) is a probabilistic generative framework for MI classification. The idea behind this framework is that, given a set of positive and negative bags, we wish to learn a concept that is “close” to at least one instance from each positive bag, while remaining “far” from every instance in every negative bag. Thus, the concept must describe a region of instance space that is "dense" in instances from positive bags, and is also "diverse" in that it describes every positive bag. More formally, let

$$DD(t) = \frac{1}{Z}\left(\prod_i \Pr(t|B_i^+)\prod_i \Pr(t|B_i^-)\right),$$

where t is a candidate concept, B_i^+ represents the ith positive bag, and B_i^- represents the ith negative bag. We seek a concept that maximizes $DD(t)$. The concept generates the instances of a bag, rather than the bag itself. To score a concept with respect to a bag, we combine t's probabilities for instances using a function based on noisy-OR Pearl (1998):

$$\Pr(t|B_i^+)\infty(1 - \prod_j (1 - \Pr(B_{ij}^+ \in t))) \quad (1)$$

$$\Pr(t|B_i^-)\infty \prod_j (1 - \Pr(B_{ij}^- \in t)) \quad (2)$$

Here, the instances B_{ij}^+ and B_{ij}^- belonging to t are the "causes" of the "event" that "t is the target." The concept class investigated by Maron (1998) is the class of generative Gaussian models, which are parameterized by the mean μ and a "scale" $s = \frac{1}{2\sigma^2}$:

$$\Pr(B_{ij} \in t)\infty e^{-\sum_k (s_k (B_{ijk} - \mu_k)^2)},$$

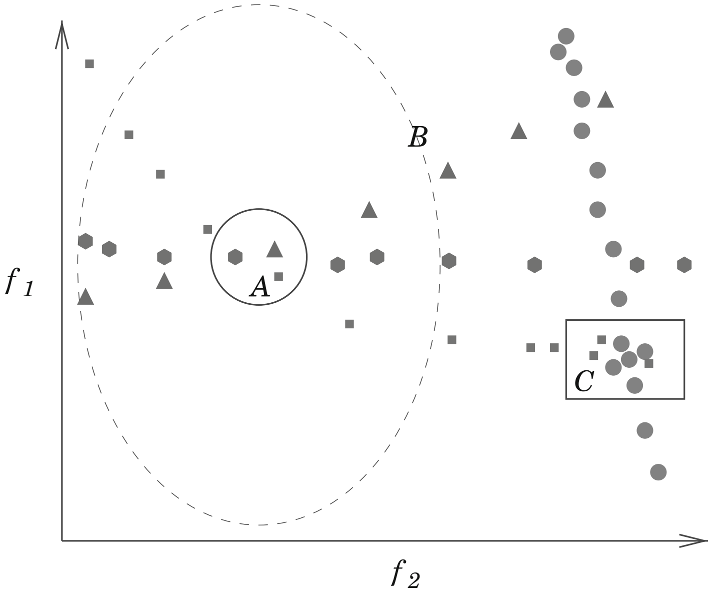
where k ranges over attributes. Figure 3 illustrates a concept that Diverse Density might learn when applied to an MI dataset.

Diverse Density with k disjuncts is a variant of Diverse Density that has also been investigated (Maron 1998). This is a class of disjunctive Gaussian concepts, where the probability of an instance belonging to a concept is given by the maximum probability of belonging to any of the disjuncts.

EM-DD (Zhang and Goldman 2001) is an example of a class of algorithms that try to identify the "cause" of a bag's label using EM. These algorithms sometimes assume that there is a single instance in each bag that is responsible for the bag's label (though variants using "soft EM" are possible). The key idea behind this approach is as follows: from each positive bag, we take a random instance and assume that this instance is the relevant one. We learn a hypothesis from these relevant instances and all negative bags. Next, for each positive bag, we replace the current relevant instance by the instance most consistent with the learned hypothesis (which will initially not be the chosen instance in general). We then relearn the hypothesis with these new instances. This process is continued until the set of chosen instances does not change (or alternatively, the objective function of the classifier reaches a fixed point). This procedure has the advantage of being computationally efficient, since the learning algorithm only uses one instance from each positive bag. This approach has also been used in MI regression described later.

"Upgraded" supervised learning algorithms can be used in a MI setting by suitably modifying their objective functions. Below, we summarize some of the algorithms that have been derived in this way.

1. ▶ Decision Tree induction algorithms have been adapted to the MI setting (Blockeel et al. 2005). The standard algorithm measures the quality of a split on an attribute by considering the class label distribution in the child nodes produced. In the MI case, this distribution is uncertain, because the true instance labels in positive bags are unknown. However, some rules have been identified that lead to empirically good MI trees: (1) use an asymmetric heuristic that favors early creation of pure positive (rather than negative) leaves, (2) once a positive leaf has been created, remove all other instances of the bags covered by this leaf; (3) abandon the depth-first or breadth-first order in which nodes are usually split, adopting a best-first strategy instead (indeed, because of (2), the result of tree learning is now sensitive to the order in which the nodes are split).
2. ▶ Artificial Neural Networks have been adapted to the MI setting by representing



Multi-Instance Learning, Fig. 3 An illustration of the concept that Diverse Density searches for on a simple MI dataset with three positive bags and one negative bag, where each instance (represented by the geometric figures) is described by two attributes, f_1 and f_2. Each type of figure represents one bag, i.e., all triangles belong to one bag, all circles belong to a second bag, and so forth. The bag containing the red circles is negative, while the other bags are positive. Region C is a region of high density, because several instances belong to that region. Region A is a region of high "Diverse Density," because several instances *from different positive bags* belong to that region, and no instances from negative bags are nearby. Region B shows a concept that might be learned if the learning algorithm assumed that all instances in every positive bag are positive (Figure adapted from Maron 1998)

the bag classifier as a network that combines several copies of a smaller network, which represents the instance classifier, with a smooth approximation of the *max* combining function (Ramon and DeRaedt 2000). Weight update rules for a backpropagation algorithm working on this network have been derived. Later work on MI neural networks has been performed independently by others (Zhou and Zhang 2002).

3. ▶ Logistic Regression has been adapted to the MI setting by using it as an instance-based classifier and combining the instance-level probabilities using functions like softmax (Ray and Craven 2005) and arithmetic and geometric averages (Xu and Frank 2004).
4. The k-Nearest Neighbor algorithm has been adapted to the MI setting by using set-based distance metrics, such as variants based on the Hausdorff distance. However, this alone does not solve the problem – it is possible for a positive bag to be mistakenly classified negative if it contains a "true negative" instance that happens to be much closer to negative instances in other negative bags. To solve this, a "Citation-kNN" (Wang and Zucker 2000) approach has been proposed that also considers, for each bag B, the labels of those bags for which B is a nearest neighbor.
5. ▶ Support Vector Machines have been adapted to the MI setting in several ways. In one method, the constraints in the quadratic program for SVMs is modified to account for the fact that certain instance labels are unknown but have constraints relating them (Andrews et al. 2003). In another method, new kernels are designed for MI data by modifying standard supervised SVM kernels (Gartner et al. 2002) or designing new kernels (Tao et al. 2004). The modification allows these MI ker-

nels to distinguish between positive and negative bags if the supervised kernel could distinguish between ("true") positive and negative instances.

6. ► Rule learning algorithms have been adapted to the MI setting in two ways. One method has investigated upgrading a supervised rule-learner, the ripper system (Cohen 1995), to the MI setting by modifying its objective function to account for bags and addressing several issues that resulted. Another method has investigated using general purpose relational algorithms, such as foil (Quinlan 1990) and tilde (Blockeel and De Raedt 1998), and providing them with an appropriate ► inductive bias so that they learn the MI concepts. Further, it has been observed that techniques from MI learning can also be used inside relational learning algorithms (Alphonse and Matwin 2002).

A large-scale empirical analysis of several such propositional supervised learning algorithms and their MI counterparts has been performed (Ray and Craven 2005). This analysis concludes that (1) no single MI algorithm works well across all problems. Thus, different inductive biases are suited to different problems, (2) some MI algorithms consistently perform better than their supervised counterparts but others do not (hence for these biases there seems room for improvement), and (3) assigning a larger weight to false positives than to false negatives is a simple but effective method to adapt supervised learning algorithms to the MI setting. It was also observed that the advantages of MI learners may be more pronounced if they would be evaluated on the task of labeling individual instances rather than bags.

Along with "upgrading" supervised learning algorithms, a *theoretical analysis of supervised learners* learning with MI data has been carried out (Blum and Kalai 1998). In particular, the MI problem has been related to the problem of learning in the presence of classification noise (i.e., each training example's label is flipped with some probability $< 1/2$). This implies that any concept class that is PAC-learnable in the presence of such noise is also learnable in the MI learning model when each instance of a bag is drawn iid. Since many concept classes are learnable under this noise assumption (using e.g., *statistical queries* Kearns 1998), Blum and Kalai's result implies PAC learnability of many concept classes. Further, they improved on previous learnability results (Auer et al. 1998) by reducing the number of training bags required for PAC learning by about a factor of n with only an increase in time complexity of about $\log n/\varepsilon$.

Besides these positive results, a *negative learnability result* describing when it is hard to learn concepts from MI data is also known (Auer et al. 1998). Specifically, if the instances of each bag are allowed collectively to be generated according to an arbitrary distribution, learning from MI examples is as hard as PAC-learning disjunctive normal form (DNF) formulas from single-instance examples, which is an open problem in learning theory that is believed to be hard. Further, it has been showed that if an efficient algorithm exists for the non-iid case that outputs as its hypothesis an axis-parallel rectangle, then NP = RP (Randomized Polynomial time, see e.g., Papadimitriou 1994), which is very unlikely.

Learning from structured MI data has received some attention (McGovern and Jensen 2003). In this work, each instance is a graph, and a bag is a set of graphs (e.g., a bag could consist of certain subgraphs of a larger graph). To learn the concepts in this structured space, the authors use a modified form of the Diverse Density algorithm discussed above. As before, the concept being searched for is a point (which corresponds to a graph in this case). The main modification is the use of the size of the maximal common subgraph to estimate the probability of a concept – i.e., the probability of a concept given a bag is estimated as proportional to the size of the maximal common subgraph between the concept and any instance in the bag.

Multiple-Instance Regression

Regression problems in an MI setting have received less attention than the classification problem. Two key directions have been explored in this setting. One direction extends the well-known standard ▸ linear regression method to the MI setting. The other direction considers extending various MI classification methods to a regression setting.

In *MI Linear Regression* (Ray and Page 2001) (referred to as multiple-instance regression in the cited work), it is assumed that the hypothesis underlying the data is a linear model with Gaussian noise on the value of the dependent variable (which is the response). Further, it is assumed that it is sufficient to model one instance from each bag, i.e., that there is some *primary* instance which is responsible for the real-valued label. Ideally, one would like to find a hyperplane that minimizes the squared error with respect to these primary instances. However, these instances are unknown during training. The authors conjecture that, given enough data, a good approximation to the ideal is given by the "best-fit" hyperplane, defined as the hyperplane that minimizes the training set squared error by fitting one instance from each bag such that the response of the fitted instance most closely matches the bag response. This conjecture will be true if the nonprimary instances are not a better fit to a hyperplane than the primary instances. However, exactly finding the "best-fit" hyperplane is intractable. It is shown that the decision problem "Is there a hyperplane which perfectly fits one instance from each bag?" is *NP*-complete for arbitrary numbers of bags, attributes, and at most three instances per bag. Thus, the authors propose an approximation algorithm which iterates between choosing instances and learning linear regression models that best fit them, similar to the EM-DD algorithm described earlier.

Another direction has explored *extending MI classification algorithms* to the regression setting. This approach (Dooly et al. 2002) uses algorithms like Citation-kNN and Diverse Density to learn real-valued concepts. To predict a real value, the approach uses the average of the nearest neighbor responses or interprets the Gaussian "probability" as a real number for Diverse Density.

Recent work has analyzed the Diverse Density-based regression in the *online* model (Angluin 1988; Littlestone 1988) (see ▸ online learning). In the online model, learning proceeds in *trials*, where in each trial a single example is selected adversarially and given to the learner for classification. After the learner predicts a label, the true label is revealed and the learner incurs a *loss* based on whether its prediction was correct. The goal of the online learner is to minimize the loss over all trials. Online learning is harder than PAC learning in that there are some PAC-learnable concept classes that are not online learnable.

In the regression setting above (Dooly et al. 2006), there is a point concept, and the label of each bag is a function of the distance between the concept and the point in the bag closest to the target. It is shown that similar to Auer et al.'s lower bound, learning in this setting using labeled bags alone is as hard as learning DNF. They then define an *MI membership query* (MI-MQ) in which an adversary defines a bag $B = \{p_1, \ldots, p_n\}$ and the learner is allowed to ask an oracle for the label of bag $B + \vec{v} = \{p_1 + \vec{v}, \ldots, p_n + \vec{v}\}$ for any d-dimensional vector $\vec{v}$. Their algorithm then uses this MI-MQ oracle to online learn a real-valued MI concept in time $O(dn^2)$.

Applications

In this section, we describe domains where MI learning problems have been formulated.

Drug activity was the motivating application for the MI representation (Dietterich et al. 1997). Drugs are typically molecules that fulfill some desired function by binding to a target. In this domain, we wish to predict how strongly a given molecule will bind to a target. Each molecule is a three-dimensional entity and takes on multiple shapes or *conformations* in solution. We know that for every molecule showing activity, at least one of its low energy conformations possesses the right shape for interacting with the target. Similarly, if the molecule does not show drug-like activity, none of its conformations possess the right shape for interaction. Thus, each molecule is represented as a bag, where each instance is a low energy conformation of the molecule. A well-known example from this domain is the MUSK dataset. The positive class in this data consists of molecules that smell "musky." This dataset has two variants, MUSK1 and MUSK2, both with similar numbers of bags, with MUSK2 having many more instances per bag.

Content-Based Image Retrieval is another domain where the MI representation has been used (Maron and Lozano-Pérez 1998; Zhang et al. 2002). In this domain, the task is to find images that contain objects of interest, such as tigers, in a database of images. An image is represented by a bag. An instance in a bag corresponds to a segment in the image, obtained by some segmentation technique. The underlying assumption is that the object of interest is contained in (at least) one segment of the image. For example, if we are trying to find images of mountains in a database, it is reasonable to expect most images of mountains to have certain distinctive segments characteristic of mountains. An MI learning algorithm should be able to use the segmented images to learn a concept that represents the shape of a mountain and use the learned concept to collect images of mountains from the database.

The *identification of protein families* has been framed as an MI problem (Tao et al. 2004). The objective in that work is to classify given protein sequences according to whether they belong to the family of thioredoxin-fold proteins. The given proteins are first aligned with respect to a motif that is known to be conserved in the members of the family. Each aligned protein is represented by a bag. A bag is labeled positive if the protein belongs to the family, and negative otherwise. An instance in a bag corresponds to a position in a fixed length sequence around the conserved motif. Each position is described by a vector of attributes; each attribute describes the properties of the amino acid at that position, and is smoothed using the same properties from its neighbors.

Text Categorization is another domain that has used the MI representation (Andrews et al. 2003; Ray and Craven 2005). In this domain, the task is to classify a document as belonging to a certain category or not. Often, whether the document belongs to the specified category is the function of a few passages in the document. These passages are however not labeled with the category information. Thus, a document could be represented as a set of passages. We assume that each positive document (i.e., that belongs to the specified category) has at least one passage that contains words that indicate category membership. On the other hand, a negative document (that does not belong to the category) has no passage that contain words indicating category membership. This formulation has been used to classify whether MEDLINE documents should be annotated with specific MeSH terms (Andrews et al.) and to determine if specific documents should be annotated with terms from the Gene Ontology (Ray and Craven 2005).

Time-series data from the hard drives have been used to define an MI problem (Murray et al. 2005). The task here is to distinguish drives that fail from others. Each hard drive is a bag. Each instance in the bag is a fixed-size window over timepoints when the drive's state was measured using certain attributes. In the training set, each drive is labeled according to whether it failed during a window of observation. An interesting aspect to prediction in this setting is that it is done online, i.e., the algorithm learns a classifier for instances, which is applied to each instance as it becomes available in time. The authors learn a naïve Bayes model using an EM-based approach to solve this problem.

Discovering useful subgoals in reinforcement learning has been formulated as an MI problem (McGovern and Barto 2001). Imagine that a robot has to get from one room to another by passing through a connecting door. If the robot knew of the existence of the door, it could decompose the problem into two simpler subproblems to be solved separately: getting from the initial location in the first room to the door, and then getting from the door to its destination. How could the robot discover such a "useful subgoal?" One approach formulates this as an MI problem. Each trajectory of the robot, where the robot starts at the source and then moves for some number of time steps, is considered to be a bag. An instance in a bag is a state of the world, that records observations such as, "is the robot's current location a door?" Trajectories that reach the destination are positive, while those that do not are negative. Given this data, we can learn a classifier that predicts which states are more likely to be seen on successful trajectories than on unsuccessful ones. These states are taken to be useful subgoals. In the previous example, the MI algorithm could learn that the state "location is a door" is a useful subgoal, since it appears on all successful trajectories, but infrequently on unsuccessful ones.

Future Directions

MI learning remains an active research area. One direction that is being explored relaxes the "Constraints" in Fig. 2 in different ways (Tao et al. 2004; Weidmann et al. 2003). For example, one could consider constraints where at least a certain number (or fraction) of instances have to be positive for a bag to be labeled positive. Similarly, it may be the case that a bag is labeled positive only if it does not contain a specific instance. Such relaxations are often studied as "generalized multiple-instance learning."

One such generalization of MI learning has been formally studied under the name "geometric patterns." In this setting, the target concept consists of a collection of APRs, and a bag is labeled positive if and only if (1) each of its points lies in a target APR, and (2) every target APR contains a point. Noise-tolerant PAC algorithms (Goldman and Scott 1999) and online algorithms (Goldman et al. 2001) have been presented for such concept classes. These algorithms make no assumptions on the distribution used to generate the bags (e.g., instances might not be generated by an iid process). This does not violate Auer et al.'s lower bound since these algorithms do not scale with the dimension of the input space.

Another recent direction explores the connections between MI and semi-supervised learnings. Semi-supervised learning generally refers to learning from a setting where some instance labels are unknown. MI learning can be viewed as one example of this setting. Exploiting this connection between MI learning and other methods for semi-supervised learning, recent work (Rahmani and Goldman 2006) proposes an approach where an MI problem is transformed into a semi-supervised learning problem. An advantage of the approach is that it automatically also takes into account unlabeled bags.

Abstract

Multi-label learning is an important machine learning setting where each example is associated with multiple class labels simultaneously. Firstly, definition, motivation and background, and learning system structure for multi-label learning are introduced. Secondly, multi-label evaluation measures and the issue of label correlation are discussed. Thirdly, basic ideas and technical details on four representative multi-label learning algorithms are considered. Lastly, theory, extensions, and future challenges on multi-label learning are introduced.

Definition

Multi-label learning is an extension of the standard supervised learning setting. In contrast to standard supervised learning where one training example is associated with a single class label, in multi-label learning, one training example is associated with *multiple* class labels simultaneously. The multi-label learner induces a function that is able to assign multiple proper labels (from a given label set) to unseen instances. Multi-label learning reduces to standard supervised learning by restricting the number of class labels per instance to one.

Motivation and Background

Most classification learning approaches treat the class values as disjoint – each object may belong only to a single class, such as *on* or *off*. Some applications, however, have categories that are not mutually exclusive – a single object may belong to multiple classes (Zhang and Zhou 2014). For instance, in text categorization, a news document on presidential election can cover multiple topics such as *politics*, *economics*, *diplomacy*, and *TV debate* (Schapire and Singer 2000); in image classification, a natural scene image can contain multiple sceneries such as the *sky*, *sea*, *boat*, and *beach* (Boutell et al. 2004). Actually, multi-label objects are often encountered in many applications such as bioinformatics, multimedia content annotation, information retrieval, and web mining (Zhang and Zhou 2014).

The goal of multi-label learning is to induce a function that can predict a subset of labels for an unseen instance from a given label set. Research into this important problem emerged in early 2000 and significant research progress has followed (Zhang and Zhou 2014).

Structure of Learning System

Let $\mathcal{X} = \mathcal{R}^d$ denote the d-dimensional instance space and $\mathcal{Y} = \{y_1, y_2, \ldots, y_q\}$ denote the label space consisting of q class labels. Given the multi-label training set $\mathcal{D} = \{(\boldsymbol{x}_i, Y_i) \mid 1 \le i \le m\}$, the task of multi-label learning is to learn a function $h : \mathcal{X} \mapsto 2^{\mathcal{Y}}$ mapping from the instance space to the *powerset* of the label space. For each multi-label training example $(\boldsymbol{x}_i, Y_i)$, $\boldsymbol{x}_i \in \mathcal{X}$ is a d-dimensional feature vector and $Y_i \subseteq \mathcal{Y}$ is the set of class labels associated with $\boldsymbol{x}_i$. The learned function $h(\cdot)$ predicts the proper label set for any unseen instance $\boldsymbol{x}$ as $h(\boldsymbol{x}) \subseteq \mathcal{Y}$.

An alternative model to $h(\cdot)$ returned by most multi-label learning systems corresponds to a real-valued function $f : \mathcal{X} \times \mathcal{Y} \mapsto \mathbb{R}$. Here, $f(\boldsymbol{x}, y)$ can be regarded as the predictive *confidence* of $y \in \mathcal{Y}$ being a proper label for $\boldsymbol{x}$. In other words, for the multi-label example $(\boldsymbol{x}, Y)$, the predictive output $f(\boldsymbol{x}, y')$ on *relevant* label

$y' \in Y$ should be larger than the predictive output $f(\boldsymbol{x}, y'')$ on *irrelevant* label $y'' \notin Y$, i.e., $f(\boldsymbol{x}, y') > f(\boldsymbol{x}, y'')$. By referring to a threshold function $t : \mathcal{X} \mapsto \mathbb{R}$, $h(\cdot)$ can be derived from the real-valued function $f(\cdot, \cdot)$ by: $h(\boldsymbol{x}) = \{y \mid f(\boldsymbol{x}, y) > t(\boldsymbol{x}), y \in \mathcal{Y}\}$.

Evaluation Measures

In standard supervised learning, popular measures used to evaluate the learning performance include *accuracy*, *precision*, *recall*, etc. In multi-label learning, however, these single-label evaluation measures cannot be adopted directly due to the multi-label nature of the data. Therefore, a number of evaluation measures have been designed for multi-label learning. These measures can be roughly categorized into two groups, i.e., *example-based* measures and *label-based* measures (Zhang and Zhou 2014). Example-based measures evaluate the generalization performance of the learned multi-label predictor on each test example separately and then return the mean value across the test set; label-based measures evaluate the generalization performance of the predictor on each class label separately and then return the macro-/micro-averaging value across all class labels.

Let $\mathcal{S} = \{(\boldsymbol{x}_i, Y_i) \mid 1 \leq i \leq p\}$ denote the multi-label test set, and $h(\cdot)$ (or equivalently $f(\cdot, \cdot)$) denote the learned multi-label predictor. Typical example-based measures include:

- *Subset Accuracy*: $\frac{1}{p}\sum_{i=1}^{p}[\![h(\boldsymbol{x}_i) = Y_i]\!]$. This measure evaluates the proportion of test examples whose predicted label set coincides with the ground-truth label set. Here, $[\![\pi]\!]$ returns 1 if predicate π holds and 0 otherwise.
- *Hamming Loss*: $\frac{1}{p}\sum_{i=1}^{p}\frac{1}{q}|h(\boldsymbol{x}_i)\Delta Y_i|$. This measure evaluates the proportion of misclassified instance-label pairs, i.e., a relevant label is missed or an irrelevant label is predicted. Here, Δ stands for the symmetric difference between two sets and $|\cdot|$ measures the cardinality of a set.
- *One-Error*: $\frac{1}{p}\sum_{i=1}^{p}[\![\arg\max_{y\in\mathcal{Y}} f(\boldsymbol{x}_i, y) \notin Y_i]\!]$. This measure evaluates the proportion of test examples whose top-1 predicted label fails to be a relevant label.
- *Coverage*: $\frac{1}{p}\sum_{i=1}^{p}\max_{y\in Y_i} rank_f(\boldsymbol{x}_i, y) - 1$. This measure evaluates the number of steps needed to move down the ranked label list so as to cover all relevant labels of the test example. Here, $rank_f(\boldsymbol{x}, y)$ returns the rank of class label y within label space $\mathcal{Y}$ according to the descending order specified by $f(\boldsymbol{x}, \cdot)$.
- *Ranking Loss*: $\frac{1}{p}\sum_{i=1}^{p}\frac{1}{|Y_i||\bar{Y}_i|}|\{(y', y'')| f(\boldsymbol{x}, y') \leq f(\boldsymbol{x}_i, y''),\ (y', y'') \in Y_i \times \bar{Y}_i\}|$. This measure evaluates the proportion of incorrectly ordered label pairs, i.e., an irrelevant label yields larger output value than a relevant label. Here, $\bar{Y}_i$ is the complementary set of Y_i in $\mathcal{Y}$.
- *Average Precision*: $\frac{1}{p}\sum_{i=1}^{p}\frac{1}{|Y_i|}\sum_{y\in Y_i} \frac{|\{y' | rank_f(\boldsymbol{x}_i, y') \leq rank_f(\boldsymbol{x}_i, y), y' \in Y_i\}|}{rank_f(\boldsymbol{x}_i, y)}$. This measure evaluates the average proportion of labels ranked higher than a relevant label $y \in Y_i$ that are also relevant.

For *hamming loss*, *one-error*, *coverage*, and *ranking loss*, the smaller the value, the better the generalization performance. For other example-based measures, the larger the value, the better the performance.

For label-based measures, to characterize the binary classification performance of the predictor on each label $y_j \in \mathcal{Y}$, four basic quantities regarding the test examples are commonly used: TP_j (#true positive), FP_j (#false positive), TN_j (#true negative), and FN_j (#false negative). It is evident that most binary classification measures can be derived based on these quantities. Let $B(TP_j, FP_j, TN_j, FN_j)$ denote a certain binary classification measure, label-based multi-label measures can be defined in either of the following ways:

- *Macro-B*: $\frac{1}{q}\sum_{j=1}^{q} B(TP_j, FP_j, TN_j, FN_j)$. This multi-label measure is derived by assuming equal importance for each label.
- *Micro-B*: $B(\sum_{j=1}^{q} TP_j, \sum_{j=1}^{q} FP_j, \sum_{j=1}^{q} TN_j, \sum_{j=1}^{q} FN_j)$. This multi-label measure is derived by assuming equal importance for each example.

Among popular choices of $B \in \{accuracy, precision, recall, F\}$, the larger the macro-/micro-B value, the better the performance.

Label Correlation

The major challenge of learning from multi-label data lies in the potentially tremendous-sized output space. Here, the number of possible *label sets* to be predicted grows exponentially as the number of class labels increases. For example, a label space with a moderate number of 20 class labels will lead to more than 1 million (i.e., 2^{20}) possible label sets. Thus, many label sets will rarely have examples appearing in the training set, leading to poor performance if they are learned separately.

To deal with the challenge of huge output space, a common practice is to exploit the *label correlation* to facilitate the learning process (Zhang and Zhou 2014). For instance, the probability of an image having label *Africa* would be high if we know it already has labels *grassland* and *lions*; a document is unlikely to be labeled as *recreation* if it is related to *legislation* and *police*. Actually, the fundamental issue distinguishing multi-label learning from traditional supervised learning lies in the fact that in multi-label learning it is crucial to exploit the label relations.

A widely-used strategy is to estimate the correlation among labels directly from the training examples based on the assumed correlation model. Based on the *order of correlations* being modeled, the estimation techniques can be roughly categorized into three categories:

(a) First-order techniques tackling multi-label learning task in a *label-by-label* style and thus ignoring the coexistence of other labels, such as decomposing the multi-label learning problem into a number of independent binary classification problems (one per label) (Boutell et al. 2004; Zhang and Zhou 2007)
(b) Second-order techniques tackling multi-label learning task by considering *pairwise* correlations between labels, such as the ranking between relevant and irrelevant labels (Elisseeff and Weston 2002; Schapire and Singer 2000)
(c) High-order techniques tackling multi-label learning task by considering high-order correlations among labels, such as assuming the correlations among all labels (Read et al. 2011) or random subsets of labels (Tsoumakas et al. 2011)

Another strategy is to adopt domain knowledge about label relations as input to the multi-label learning algorithms. One conventional source of domain knowledge corresponds to the label hierarchies (or taxonomies) available in some applications such as text classification (Rousu et al. 2005). There is also a recent strategy which tries to discover and exploit label relations during the procedure of learning the multi-label predictors (Zhang and Zhou 2014).

Learning Algorithms

To design learning algorithms for multi-label data, two complementary philosophies naturally arise. On one hand, *algorithm adaptation* methods work by fitting algorithms to data, i.e., adapting popular standard supervised learning algorithms to deal with multi-label data. On the other hand, *problem transformation* methods work by fitting data to algorithms, i.e., transforming multi-label data to accommodate other well-established learning frameworks. During the past decade, lots of algorithms have been developed following these philosophies (Zhang and Zhou 2014). This section briefly introduces four representative algorithms, including algorithm adaptation methods ML-KNN (multi-label k-nearest neighbor) (Zhang and Zhou 2007) and RANK-SVM (ranking support vector machine) (Elisseeff and Weston 2002), as well as problem transformation methods CC (classifier chain) (Read et al. 2011) and RAKEL (random k-labelsets) (Tsoumakas et al. 2011). These algorithms are simply chosen to manifest the essentials of two key design philosophies, which by no means exclude the importance of other multi-label learning algorithms.

ML-KNN adapts the *k-nearest neighbor* technique to deal with multi-label data (Zhang and Zhou 2007). Specifically, the *maximum a posteriori* (MAP) rule is utilized to make prediction for unseen instance by reasoning with the labeling information from its neighbors. Given the multi-label training set $\mathcal{D}$ and unseen instance $\boldsymbol{x}$, let $\mathcal{N}(\boldsymbol{x})$ denote the set of k nearest neighbors of $\boldsymbol{x}$ identified in $\mathcal{D}$. Accordingly, the following statistics can be calculated based on the labeling information of the neighbors in $\mathcal{N}(\boldsymbol{x})$: $C_j = \sum_{(\boldsymbol{x}_i, Y_i) \in \mathcal{N}(\boldsymbol{x})} [\![y_j \in Y_i]\!]$. Namely, C_j records the number of neighbors which take the j-th class label y_j as their relevant label. Let $P(H_j \mid C_j)$ represent the posterior probability that the event of H_j (i.e., $\boldsymbol{x}$ has y_j as its relevant label) holds under the condition of C_j (i.e., $\boldsymbol{x}$ has exactly C_j neighbors with relevant label y_j). Similarly, let $P(\neg H_j \mid C_j)$ represent the posterior probability that H_j does not hold under the same condition. Based on the MAP rule, the label set for $\boldsymbol{x}$ is predicted by

$$Y = \{y_j \mid P(H_j \mid C_j) > P(\neg H_j \mid C_j),\ 1 \le j \le q\} \qquad (1)$$

According to the Bayes rule, we have $P(H_j \mid C_j) \propto P(H_j) \cdot P(C_j \mid H_j)$ and $P(\neg H_j \mid C_j) \propto P(\neg H_j) \cdot P(C_j \mid \neg H_j)$. Therefore, it suffices to make prediction by estimating the prior probabilities $\{P(H_j),\ P(\neg H_j)\}$ and the likelihoods $\{P(C_j \mid H_j),\ P(C_j \mid \neg H_j)\}$. These probabilistic terms can be estimated from the training set via the *frequency counting* strategy (Zhang and Zhou 2007). In general, ML-KNN assumes label independence in its learning procedure and optimizes the evaluation measure of hamming loss (or equivalently macro-/micro-accuracy).

RANK-SVM adapts *large margin* methods to deal with multi-label data (Elisseeff and Weston 2002). Specifically, a set of linear classifiers are optimized to minimize the empirical ranking loss. Given the learning system with q linear classifiers $\mathcal{W} = \{(\boldsymbol{w}_j, b_j) \mid 1 \le j \le q\}$, its margin over each multi-label training example $(\boldsymbol{x}_i, Y_i)$ corresponds to

$$\gamma_i = \min_{(y_j, y_k) \in Y_i \times \bar{Y}_i} \frac{\langle \boldsymbol{w}_j - \boldsymbol{w}_k, \boldsymbol{x}_i \rangle + b_j - b_k}{||\boldsymbol{w}_j - \boldsymbol{w}_k||} \qquad (2)$$

Here, $\langle \cdot, \cdot \rangle$ returns the inner product between two vectors. Conceptually, Eq. (2) considers the signed L_2-distance of $\boldsymbol{x}_i$ to the decision hyperplane of every relevant-irrelevant label pair (y_j, y_k): $\langle \boldsymbol{w}_j - \boldsymbol{w}_k, \boldsymbol{x} \rangle + b_j - b_k = 0$, and then returns the minimum as the margin on $(\boldsymbol{x}_i, Y_i)$. Accordingly, the margin of the learning system on the whole training set $\mathcal{D}$ is $\min_{(\boldsymbol{x}_i, Y_i) \in \mathcal{D}} \gamma_i$. Under the ideal case that the learning system can properly rank every relevant-irrelevant label pair for each training example, the large margin optimization problem turns out to be

$$\begin{aligned} \min_{\mathcal{W}} \quad & \max_{1 \le j < k \le q} ||\boldsymbol{w}_j - \boldsymbol{w}_k||^2 \\ \text{s.t.}: \quad & \langle \boldsymbol{w}_j - \boldsymbol{w}_k, \boldsymbol{x}_i \rangle + b_j - b_k \ge 1 \\ & 1 \le i \le m,\ (y_j, y_k) \in Y_i \times \bar{Y}_i \end{aligned} \qquad (3)$$

By approximating `max` by `sum` and introducing slack variables to accommodate violated constraints, Eq. (3) can be re-formulated as

$$\begin{aligned} \min_{\{\mathcal{W}, \Xi\}} \quad & \sum_{j=1}^{q} ||\boldsymbol{w}_j||^2 + C \sum_{i=1}^{m} \frac{1}{|Y_i||\bar{Y}_i|} \sum_{(y_j, y_k) \in Y_i \times \bar{Y}_i} \xi_{ijk} \\ \text{s.t.}: \quad & \langle \boldsymbol{w}_j - \boldsymbol{w}_k, \boldsymbol{x}_i \rangle + b_j - b_k \ge 1 - \xi_{ijk} \\ & \xi_{ijk} \ge 0,\ 1 \le i \le m,\ (y_j, y_k) \in Y_i \times \bar{Y}_i \end{aligned} \qquad (4)$$

Here, $\Xi = \{\xi_{ijk} \mid 1 \le i \le m, (y_j, y_k) \in Y_i \times \bar{Y}_i\}$ is the set of slack variables. The first objective term in Eq. (4) corresponds to the margin of the learning system, whereas the second objective term corresponds to the empirical ranking loss. The solution to Eq. (4) can be found by invoking standard *quadratic programming* (QP) procedure in its primal form or incorporating kernel trick in its dual form. The label set for unseen instance is predicted by thresholding the output of each classifier in $\mathcal{W}$. In general, RANK-SVM assumes second-order label correlations (relevant-irrelevant label pair) in its learning procedure and optimizes the evaluation measure of ranking loss.

CC transforms the multi-label learning problem into a chain of *binary* classification problems. Specifically, subsequent classifiers in the chain are built upon the predictions of preceding ones. Without loss of generality, suppose all the class labels in $\mathcal{Y}$ are ordered in a chain: $y_1 \succ y_2 \succ \cdots \succ y_q$. For the j-th class label y_j in the chain, a corresponding binary training set can be constructed by taking the relevancy of each preceding label as an extra feature to the instance:

$$\mathcal{D}_j = \left\{\left([\boldsymbol{x}_i, \mathbf{pre}^i_j], \phi(Y_i, y_j)\right) \mid 1 \leq i \leq m\right\}$$
$$\text{where } \mathbf{pre}^i_j = (\phi(Y_i, y_1), \ldots, \phi(Y_i, y_{j-1}))^{\mathrm{T}} \tag{5}$$

Here, $\phi(Y, y) = [\![y \in Y]\!]$ represents the binary assignment of class label y w.r.t. label set Y. As shown in Eq. (5), each instance $\boldsymbol{x}_i$ is appended with an extra feature vector $\mathbf{pre}^i_j$ representing the relevancy of those labels preceding y_j. After that, a binary classifier $g_j : \mathcal{X} \times \{0,1\}^{j-1} \mapsto \{0,1\}$ can be induced for y_j by utilizing some binary learning algorithm $\mathcal{B}$, i.e., $g_j \hookleftarrow \mathcal{B}(\mathcal{D}_j)$. For unseen instance $\boldsymbol{x}$, its label set is predicted by traversing the classifier chain iteratively. The predicted binary assignment of y_j on $\boldsymbol{x}$, denoted as $\lambda^{\boldsymbol{x}}_j$, are recursively determined by

$$\lambda^{\boldsymbol{x}}_1 = g_1(\boldsymbol{x})$$
$$\lambda^{\boldsymbol{x}}_j = g_j([\boldsymbol{x}, \lambda^{\boldsymbol{x}}_1, \ldots, \lambda^{\boldsymbol{x}}_{j-1}]) \quad (2 \leq j \leq q) \tag{6}$$

Therefore, the predicted label set corresponds to: $Y = \{y_j \mid \lambda^{\boldsymbol{x}}_j = 1,\ 1 \leq j \leq q\}$. Evidently, the chaining order over the class labels has significant influence on the effectiveness of CC. To account for the effect of chaining order, an *ensemble* of classifier chains can be built with diverse random chaining orders. In general, CC assumes high-order label correlations (among all labels) in its learning procedure and optimizes the evaluation measure of hamming loss (or equivalently macro-/micro-accuracy).

RAKEL transforms the multi-label learning problem into an ensemble of *multi-class* classification problems. Specifically, each component learner in the ensemble is generated by considering a random subset of $\mathcal{Y}$. Let $\mathcal{S}_k \subset \mathcal{Y}$ denote a k-labelset which contains k random class labels in $\mathcal{Y}$. Accordingly, let $\sigma_{\mathcal{S}_k} : 2^{\mathcal{S}_k} \mapsto \mathcal{N}$ denote the injective function mapping from the power set of $\mathcal{S}_k$ to natural numbers. In view of $\mathcal{S}_k$, a corresponding multi-class training set can be constructed by shrinking the original label space $\mathcal{Y}$ into $\mathcal{S}_k$:

$$\mathcal{D}_{\mathcal{S}_k} = \left\{\left(\boldsymbol{x}_i, \sigma_{\mathcal{S}_k}(Y_i \cap \mathcal{S}_k)\right) \mid 1 \leq i \leq m\right\} \tag{7}$$

Here, the set of newly transformed labels in $\mathcal{D}_{\mathcal{S}_k}$ corresponds to $\Gamma_{\mathcal{S}_k} = \{\sigma_{\mathcal{S}_k}(Y_i \cap \mathcal{S}_k) \mid 1 \leq i \leq m\}$. As shown in Eq. (7), each instance $\boldsymbol{x}_i$ is transformed into a multi-class single-label example by mapping the intersection between Y_i and $\mathcal{S}_k$ into a new label in $\Gamma_{\mathcal{S}_k}$. After that, a multi-class classifier $g_{\mathcal{S}_k} : \mathcal{X} \mapsto \Gamma_{\mathcal{S}_k}$ can be induced for $\mathcal{S}_k$ by utilizing some multi-class learning algorithm $\mathcal{M}$, i.e., $g_{\mathcal{S}_k} \hookleftarrow \mathcal{M}(\mathcal{D}_{\mathcal{S}_k})$. To entirely explore the original label space $\mathcal{Y}$ with k-labelsets, an ensemble of n random k-labelsets $\mathcal{S}^{(r)}_k$ $(1 \leq r \leq n)$ can be created where each of them leads to a multi-class classifier $g_{\mathcal{S}^{(r)}_k}(\cdot)$. For unseen instance $\boldsymbol{x}$, its label set is predicted by referring to the following two quantities:

$$\tau(\boldsymbol{x}, y_j) = \sum_{r=1}^{n} \left[\!\!\left[y_j \in \mathcal{S}^{(r)}_k \right]\!\!\right]$$
$$\mu(\boldsymbol{x}, y_j) = \sum_{r=1}^{n} \left[\!\!\left[y_j \in \sigma^{-1}_{\mathcal{S}^{(r)}_k}\left(g_{\mathcal{S}^{(r)}_k}(\boldsymbol{x})\right) \right]\!\!\right] \tag{8}$$

Conceptually, $\tau(\boldsymbol{x}, y_j)$ counts the *maximum* number of votes that y_j can receive from the ensemble, whereas $\mu(\boldsymbol{x}, y_j)$ counts the *actual* number of votes that y_j does receive from the ensemble. Therefore, the predicted label set corresponds to: $Y = \{y_j \mid \mu(\boldsymbol{x}, y_j)/\tau(\boldsymbol{x}, y_j) > 0.5,\ 1 \leq j \leq q\}$. In general, CC assumes high-order label correlations (among subsets of labels) in its learning procedure and optimizes the evaluation measure of subset accuracy (measured w.r.t. k-labelset).

It is worth mentioning that many multi-label learning algorithms mainly work under the scenarios where the label space $\mathcal{Y}$ contains moderate number (tens or hundreds) of class labels. Nonetheless, in many applications the number of class labels in $\mathcal{Y}$ can be huge. For instance, a web page may be annotated with relevant labels from the pool of more than one million Wikipedia categories. In such case, the computational complexity of many multi-label learning algorithms might be prohibitively high. Even for binary decomposition, which is the simplest way to learn from multi-label data, building one independent classifier for each label is still too computational demanding given the huge number of class labels. Therefore, specific strategies need to be employed to handle huge number of labels. One feasible strategy is to find a low-dimensional embedding of the original label space by exploiting the sparsity of relevant labels, where the classification model is built within the embedded label space (Weston et al. 2011). Another strategy is to partition the original label space into different clusters based on tree structure, where the classification model is built within each leaf node (Agrawal et al. 2013).

Theory

Multi-label loss functions are usually *non-convex* and *discontinuous*, making them difficult to optimize directly. Therefore, in practice, most learning algorithms resort to optimizing (convex) *surrogate* loss functions. There are several theoretical studies about the *consistency* of surrogate loss functions, i.e., whether the expected risk of surrogate loss of a learner converges to the Bayes risk of multi-label loss as the training set size increases. Recently, a necessary and sufficient condition has been provided for the consistency of multi-label learning based on surrogate loss functions (Gao and Zhou 2011).

For *hamming loss*, the state-of-the-art multi-label learning approaches are proven to be inconsistent (Gao and Zhou 2011). For *ranking loss*, it has been shown that none pairwise convex surrogate loss defined on label pairs can be consistent; therefore, the *partial ranking loss* is introduced for multi-label learning, and some pairwise consistent surrogate loss function are provided (Gao and Zhou 2011). The univariate convex surrogate loss defined on single label can be consistent with partial ranking loss based on a reduction to the bipartite ranking problem (Dembczyński et al. 2012) although the reduction relaxes the original target.

Extensions

Multi-instance multi-label learning (MIML) (Zhou et al. 2012) tries to induce a function $h_{\text{MIML}} : 2^{\mathcal{X}} \mapsto 2^{\mathcal{Y}}$ from a training set $\{(X_i, Y_i) \mid 1 \leq i \leq m\}$, where $X_i \subseteq \mathcal{X}$ is a set of instances and Y_i is the set of class labels associated with X_i. The major difference between MIML and multi-label learning lies in the fact that each example in MIML is represented by a set of instances rather than a single instance. This framework is suitable to tasks involving complicated objects with inherent structures; e.g., a text document can be represented by a set of instances each corresponds to a section or paragraph. In addition to exploit the structural information for learning the predictor, MIML also offers the possibility of discovering the relation between semantic meanings and input patterns; e.g., it is possible to discover that the document owes a specific tag because of its several special paragraphs.

Superset label learning (SLL) (Liu and Dietterich 2012) tries to induce a function $h_{SLL} : \mathcal{X} \mapsto \mathcal{Y}$ from a training set $\{(\boldsymbol{x}_i, S_i) \mid 1 \leq i \leq m\}$, where $\boldsymbol{x}_i \in \mathcal{X}$ is an instance and $S_i \subseteq \mathcal{Y}$ is the set of candidate labels associated with $\boldsymbol{x}_i$ such that the (unknown) ground-truth label y_i belongs to S_i. The major difference between SLL and multi-label learning lies in the fact that each example in SLL is associated with multiple *candidate* labels among which only one label is valid. This framework is suitable to tasks where superset labeling information is readily available; e.g., a face in an image can be associated with all the names mentioned in the image's surrounding texts where only one name is valid.

Label distribution learning (LDL) (Geng et al. 2013) tries to induce a function $f_{\text{LDL}} : \mathcal{X} \mapsto \mathcal{P}(\mathcal{Y})$ from a training set $\{(\boldsymbol{x}_i, \mathcal{D}_i) \mid 1 \leq i \leq m\}$, where $\boldsymbol{x}_i$ is an instance and $\mathcal{D}_i = \{d_i^1, d_i^2, \cdots, d_i^q\}$ is the probability mass of the q labels associated with $\boldsymbol{x}_i$ such that $d_i^j \geq 0$ (1 $\leq$

$j \leq q$) and $\sum_{j=1}^{q} d_i^j = 1$. The major difference between LDL and multi-label learning lies in the fact that the associated labeling information for each example in LDL is real-valued probability mass rather than discrete-valued binary labels. This framework is suitable to tasks where the degree of labeling importance is inherently different; e.g., entities appearing in a natural scene have different importance in implying its scenic concepts.

Future Challenges

There are many research challenges to be addressed in the future. Firstly, label relations play a critical role in multi-label learning; however, there lacks principled mechanism for label relation exploitation. Secondly, it is generally difficult to get accurate and complete label annotations, particularly when each example has many labels. Thus, it is important to develop multi-label learning approaches that can learn from partially labeled data. Moreover, multi-label data usually suffers from inherent class imbalance and unequal misclassification costs; taking these properties into full consideration is desirable.

Multi-objective Optimization

Synonyms

MOO; Multi-criteria optimization; Vector optimization

Definition

Multi-criteria optimization is concerned with the optimization of a vector of objectives, which can be the subject of a number of constraints or bounds. The goal of multi-objective optimization is usually to find or to approximate the set of Pareto-optimal solutions. A solution is Pareto-optimal if it cannot be improved in one objective without getting worse in another one.

Definition

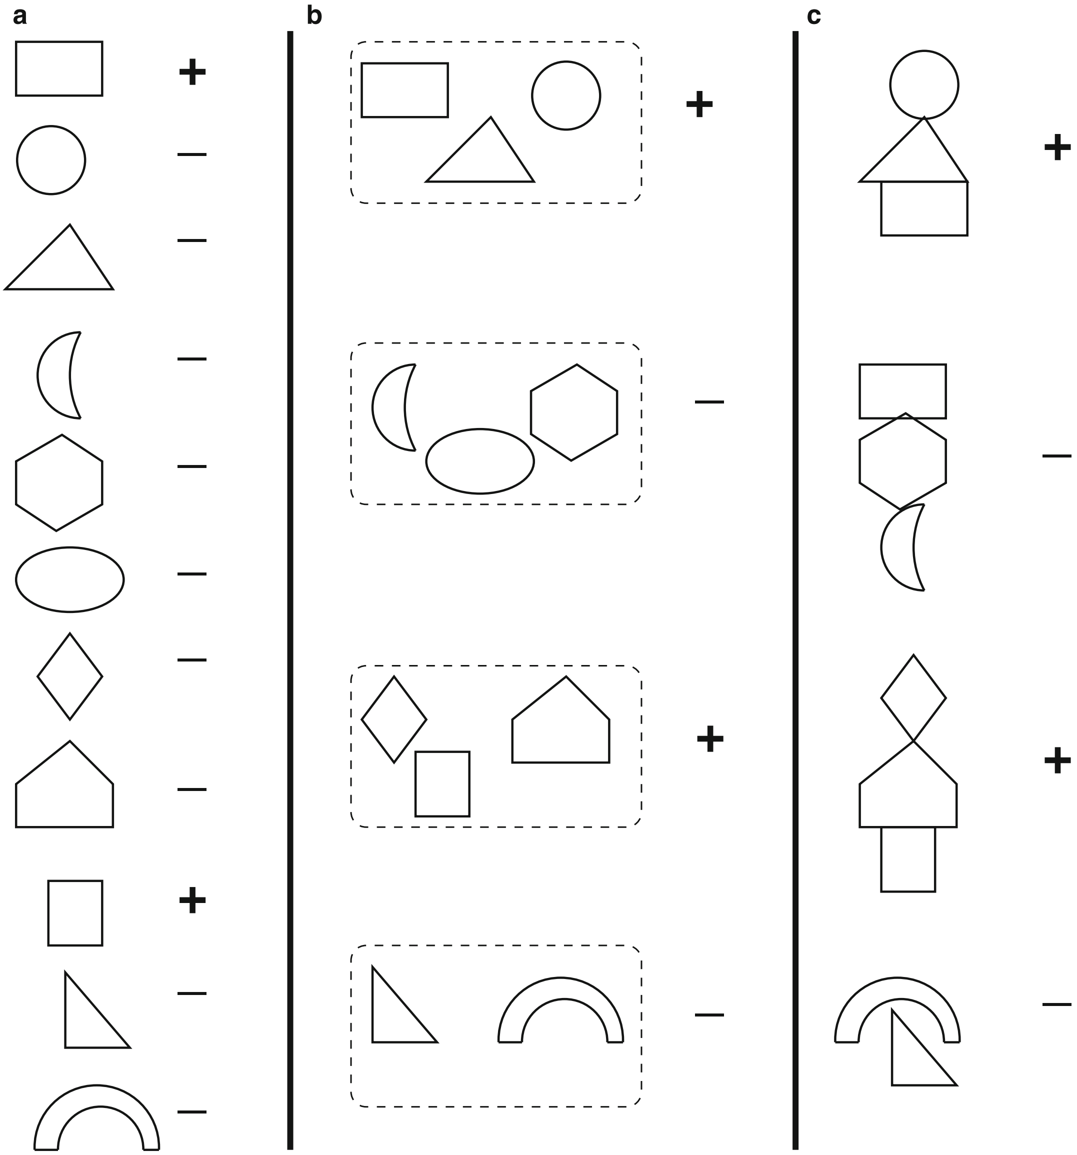
Multiple-instance (MI) learning is an extension of the standard supervised learning setting. In standard supervised learning, the input consists of a set of labeled instances each described by an attribute vector. The learner then induces a concept that relates the label of an instance to its attributes. In MI learning, the input consists of labeled examples (called “bags”) consisting of *multisets* of instances, each described by an attribute vector, and there are constraints that relate the label of each bag to the unknown labels of each instance. The MI learner then induces a concept that relates the label of a bag to the attributes describing the instances in it. This setting contains supervised learning as a special case: if each bag contains exactly one instance, it reduces to a standard supervised learning problem.

Motivation and Background

The MI setting was introduced by Dietterich et al. (1997) in the context of drug activity prediction. Drugs are typically molecules that fulfill some desired function by binding to a target. If we wish to learn the characteristics responsible for binding, a possible representation of the problem is to represent each molecule as a set of low-energy shapes or *conformations* and describe each conformation using a set of attributes. Each such bag of conformations is given a label corresponding to whether the molecule is active or inactive. To learn a classification model, an algorithm assumes that every instance in a bag labeled negative is actually negative, whereas at least one instance in a bag labeled positive is actually positive with respect to the underlying concept.

From a theoretical viewpoint, MI learning occupies an intermediate position between standard propositional supervised learning and first-order relational learning. Supervised learning is a special case of MI learning, while MI learning is a special case of first-order learning. It has been argued that the MI setting is a key transition between standard supervised and relational learning (DeRaedt 1998). At the same time, theoretical results exist that show that, under certain assumptions, certain concept classes that are probably approximately correct (PAC)-learnable (see PAC learning) in a supervised setting remain PAC-learnable in an MI setting. Thus, the MI setting is able to leverage some of the rich representational power of relational learners while not sacrificing the efficiency of propositional learners. Figure 1 illustrates the relationships between standard supervised learning, MI learning, and relational learning.

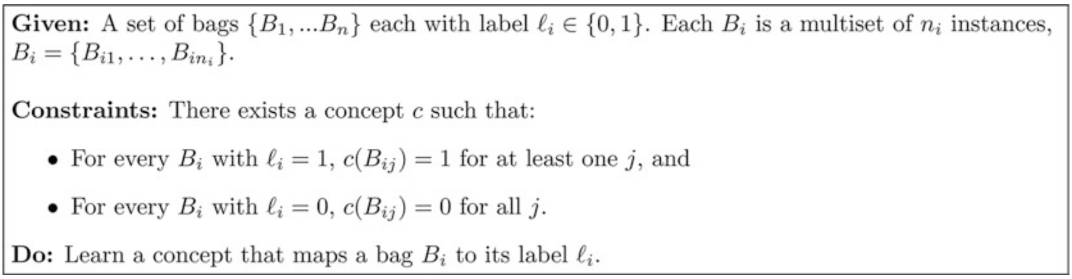
Since its introduction, a wide variety of tasks have been formulated as MI learning problems. Many new algorithms have been developed, and well-known supervised learning algorithms extended, to learn MI concepts. A great deal of work has also been done to understand what kinds of concepts can and cannot be learned efficiently in this setting. In the following sections, we discuss the theory, methods, and applications of MI learning in more detail.



Multiple-Instance Learning, Fig. 1 The relationship between supervised, multiple-instance (MI), and relational learning. (**a**) In supervised learning, each example (geometric figure) is labeled. A possible concept that explains the example labels shown is "the figure is a rectangle." (**b**) In MI learning, bags of examples are labeled. A possible concept that explains the bag labels shown is "the bag contains at least one figure that is a rectangle." (**c**) In relational learning, objects of arbitrary structure are labeled. A possible concept that explains the object labels shown is "the object is a stack of three figures and the bottom figure is a rectangle"

Structure of the Problem

The general MI classification task is shown in Fig. 2. The MI regression task is defined analogously by substituting a real-valued response for the classification label. In this case, the constraint used by the learning algorithm is that the response of any bag is equal to the response of at least one of the instances in it, for example, it could be equal to the largest response over all the instances.



Given: A set of bags $\{B_1, ...B_n\}$ each with label $\ell_i \in \{0,1\}$. Each B_i is a multiset of n_i instances, $B_i = \{B_{i1}, \ldots, B_{in_i}\}$.

Constraints: There exists a concept c such that:

- For every B_i with $\ell_i = 1$, $c(B_{ij}) = 1$ for at least one j, and
- For every B_i with $\ell_i = 0$, $c(B_{ij}) = 0$ for all j.

Do: Learn a concept that maps a bag B_i to its label ℓ_i.

Multiple-Instance Learning, Fig. 2 Statement of the multiple-instance classification problem

Notice the following problem characteristics:

- The number of instances in each bag can vary independently of other bags. This implies in particular that an MI algorithm must be able to handle bags with as few as one instance (this is a supervised learning setting) to bags with large numbers of instances.
- The number of instances in any positive bag that are "truly positive" could be many more than one – in fact, the definition does not rule out the case where *all* instances in a positive bag are "truly positive."
- The problem definition does not specify how the instances in any bag are related to each other.

Theory and Methods

In this section, we discuss some of the key algorithms and theoretical results in MI learning. We first discuss the methods and results for MI classification. Then we discuss the work on MI regression.

Multiple-Instance Classification

Axis-parallel rectangles (APRs) are a concept class that early work in MI classification focused on. These generative concepts specify upper and lower bounds for all numeric attributes describing each instance. An APR is said to "cover" an instance if the instance lies within it. An APR covers a bag if it covers at least one instance within it. The learning algorithm tries to find an APR such that it covers all positive bags and does not cover any negative bags.

An algorithm called "iterated discrimination" was proposed by Dietterich et al. (1997) to learn APRs from MI data. This algorithm has two phases. In the first phase, it iteratively chooses a set of "relevant" attributes and grows an APR using this set. This phase results in the construction of a very "tight" APR that covers just positive bags. In the second phase, the algorithm expands this APR so that with high probability, a new positive instance will fall within the APR. The key steps of the algorithm are outlined below. Note that initially, all attributes are considered to be "relevant."

The algorithm starts by choosing a random instance in a positive bag. Let us call this instance I_1. The smallest APR covering this instance is a point. The algorithm then expands this APR by finding the smallest APR that covers any instance from a yet uncovered positive bag; call the newly covered instance I_2. This process is continued, identifying new instances $I_3, \ldots, I_k$, until all positive bags are covered. At each step, the APR is "backfitted" in a way that is reminiscent of the later Expectation-Maximization (EM) approaches: each earlier choice is revisited, and I_j is replaced with an instance from the same bag that minimizes the current APR (which may or may not be the same as the one that minimized it at step j).

This process yields an APR that imposes maximally tight bounds on all attributes and covers all positive bags. Based on this APR, a new set of "relevant" attributes is selected as follows. An attribute's relevance is determined by how strongly it discriminates against negative instances, i.e., given the current APR bounds, how many negative instances the attribute excludes. Features are then chosen iteratively and greedily according to how relevant they are until all negative instances have been excluded. This yields a subset of (presumably relevant) attributes. The APR growth procedure in the previous paragraph is then repeated, with the size of an APR redefined as its size along relevant attributes only. The APR growth and attribute selection phases are repeated until the process converges.

The APR thus constructed may still be too tight, as it fits narrowly around the positive bags in the dataset. In the second phase of the algorithm, the APR bounds are further expanded using a kernel density estimate approach. Here, a probability distribution is constructed for each relevant attribute using Gaussian distributions centered at each instance in a positive bag. Then, the bounds on that attribute are adjusted so that with high probability, any positive instance will lie within the expanded APR.

Theoretical analyses of APR concepts have been performed along with the empirical approach, using Valiant's "probably approximately correct" (PAC)-learning model (Valiant 1984). In early work (Long and Tan 1998), it was shown that if each instance was drawn according to a fixed, unknown product distribution over the rational numbers, independently from every other instance, then an algorithm could PAC-learn APRs. Later, this result was improved in two ways (Auer et al. 1998). First, the restriction that the individual instances in each bag come from a product distribution was removed. Instead, each instance is generated by an arbitrary probability distribution (though each instance in a bag is still generated independently and identically distributed (iid) according to that one distribution). Second, the time and sample complexities for PAC-learning APRs were improved. Specifically, the algorithm described in this work PAC-learns APRs in

$$O\left(\frac{d^3n^2}{\epsilon^2}\log\frac{nd\log(1/\delta)}{\epsilon}\log\frac{d}{\delta}\right)$$

using

$$O\left(\frac{d^2n^2}{\epsilon^2}\log\frac{d}{\delta}\right)$$

time-labeled training bags. Here, d is the dimension of each instance, n is the (largest) number of instances per training bag, and ϵ and δ are parameters to the algorithm. A variant of this algorithm was empirically evaluated and found to be successful (Auer 1997).

Diverse Density (Maron 1998; Maron and Lozano-Pérez 1998) is a probabilistic generative framework for MI classification. The idea behind this framework is that, given a set of positive and negative bags, we wish to learn a concept that is "close" to at least one instance from each positive bag, while remaining "far" from every instance in every negative bag. Thus, the concept must describe a region of instance space that is "dense" in instances from positive bags and is also "diverse" in that it describes every positive bag. More formally, let

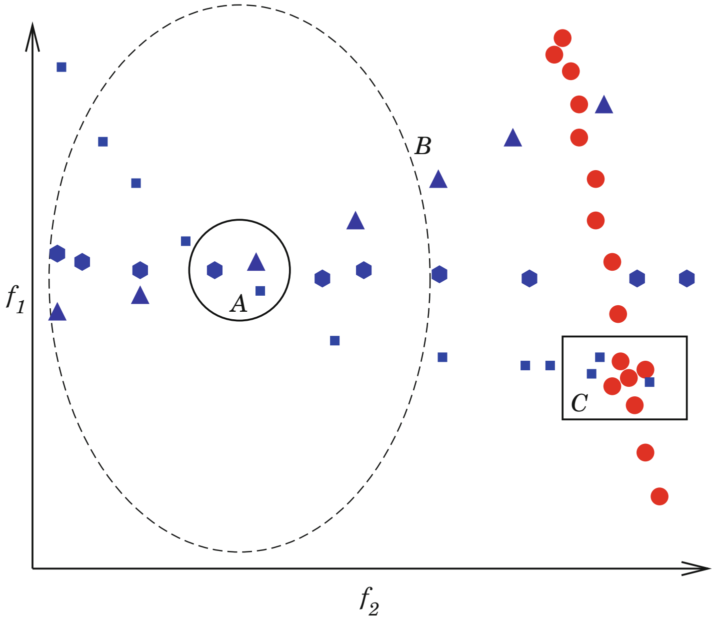
$$DD(t) = \frac{1}{Z}\left(\prod_i \Pr\left(t|B_i^+\right)\prod_i \Pr\left(t|B_i^-\right)\right),$$

where t is a candidate concept, B_i^+ represents the ith positive bag, and B_i^- represents the ith negative bag. We seek a concept that maximizes $DD(t)$. The concept generates the instances of a bag, rather than the bag itself. To score a concept with respect to a bag, we combine t's probabilities for instances using a function based on noisy-OR (Pearl 1998):

$$\Pr(t|B_i^+) \propto \left(1-\prod_j\left(1-\Pr\left(B_{ij}^+\in t\right)\right)\right) \tag{1}$$

$$\Pr\left(t|B_i^-\right) \propto \prod_j\left(1-\Pr\left(B_{ij}^-\in t\right)\right) \tag{2}$$

Here, the instances B_{ij}^+ and B_{ij}^- belonging to t are the "causes" of the "event" that "t is the target." The concept class investigated by Maron (1998) is the class of generative Gaussian models, which



Multiple-Instance Learning, Fig. 3 An illustration of the concept that Diverse Density searches for on a simple MI dataset with three positive bags and one negative bag, where each instance (represented by the geometric figures) is described by two attributes, f_1 and f_2. Each type of figure represents one bag, i.e., all *triangles* belong to one bag, all *circles* belong to a second bag, and so forth. The bag containing the *red circles* is negative, while the other bags are positive. Region C is a region of high density, because several instances belong to that region. Region A is a region of high "Diverse Density," because several instances *from different positive bags* belong to that region, and no instances from negative bags are nearby. Region B shows a concept that might be learned if the learning algorithm assumed that all instances in every positive bag are positive (Figure adapted from Maron and Lozano-Pérez (1998))

are parameterized by the mean μ and a "scale" $s = \frac{1}{2\sigma^2}$:

$$\Pr(B_{ij} \in t) \propto e^{-\sum_k \left(s_k (B_{ijk} - \mu_k)^2\right)},$$

where k ranges over attributes. Figure 3 illustrates a concept that Diverse Density might learn when applied to an MI dataset.

Diverse Density with k disjuncts is a variant of Diverse Density that has also been investigated (Maron 1998). This is a class of disjunctive Gaussian concepts, where the probability of an instance belonging to a concept is given by the maximum probability of belonging to any of the disjuncts.

EM-DD (Zhang and Goldman 2001) is an example of a class of algorithms that try to identify the "cause" of a bag's label using EM. These algorithms sometimes assume that there is a single instance in each bag that is responsible for the bag's label (though variants using "soft EM" are possible). The key idea behind this approach is as follows: from each positive bag, we take a random instance and assume that this instance is the relevant one. We learn a hypothesis from these relevant instances and all negative bags. Next, for each positive bag, we replace the current relevant instance by the instance most consistent with the learned hypothesis (which will initially not be the chosen instance in general). We then relearn the hypothesis with these new instances. This process is continued until the set of chosen instances does not change (or alternatively, the objective function of the classifier reaches a fixed point). This procedure has the advantage of being computationally efficient, since the learning algorithm only uses one instance from each positive bag. This approach has also been used in MI regression described later.

"Upgraded" supervised learning algorithms can be used in an MI setting by suitably modifying their objective functions. Below, we summarize some of the algorithms that have been derived in this way.

1. ▸ *Decision Tree induction* algorithms have been adapted to the MI setting (Blockeel et al. 2005). The standard algorithm measures the quality of a split on an attribute by considering the class label distribution in the child nodes produced. In the MI case, this distribution is uncertain, because the true instance labels in positive bags are unknown. However, some rules have been identified that lead to empirically good MI trees: (1) use an asymmetric heuristic that favors early creation of pure positive (rather than negative) leaves; (2) once a positive leaf has been created, remove all other instances of the bags covered by this leaf; (3) abandon the depth-first or breadth-first order in which nodes are usually split, adopting a best-first strategy instead (indeed, because of (2), the result of tree learning is now sensitive to the order in which the nodes are split).
2. ▸ *Artificial Neural Networks* have been adapted to the MI setting by representing the bag classifier as a network that combines several copies of a smaller network, which represents the instance classifier, with a smooth approximation of the *max* combining function (Ramon and DeRaedt 2000). Weight update rules for a backpropagation algorithm working on this network have been derived. Later work on MI neural networks has been performed independently by others (Zhou and Zhang 2002).
3. ▸ *Logistic Regression* has been adapted to the MI setting by using it as an instance-based classifier and combining the instance-level probabilities using functions like softmax (Ray and Craven 2005) and arithmetic and geometric averages (Xu and Frank 2004).
4. The ▸ *k-Nearest Neighbor* algorithm has been adapted to the MI setting by using set-based distance metrics, such as variants based on the Hausdorff distance. However, this alone does not solve the problem – it is possible for a positive bag to be mistakenly classified negative if it contains a "true negative" instance that happens to be much closer to negative instances in other negative bags. To solve this, a "Citation-kNN" (Wang and Zucker 2000) approach has been proposed that also considers, for each bag B, the labels of those bags for which B is a nearest neighbor.
5. ▸ *Support Vector Machines* have been adapted to the MI setting in several ways. In one method, the constraints in the quadratic program for SVMs is modified to account for the fact that certain instance labels are unknown but have constraints relating them (Andrews et al. 2003). In another method, new kernels are designed for MI data by modifying standard supervised SVM kernels (Gartner et al. 2002) or designing new kernels (Tao et al. 2004). The modification allows these MI kernels to distinguish between positive and negative bags if the supervised kernel could distinguish between ("true") positive and negative instances.
6. ▸ *Rule learning algorithms* have been adapted to the MI setting in two ways. One method has investigated upgrading a supervised rule-learner, the RIPPER system (Cohen 1995), to the MI setting by modifying its objective function to account for bags and addressing several issues that resulted. Another method has investigated using general-purpose relational algorithms, such as FOIL (Quinlan 1990) and TILDE (Blockeel and De Raedt 1998), and providing them with an appropriate ▸ inductive bias so that they learn the MI concepts. Further, it has been observed that techniques from MI learning can also be used inside relational learning algorithms (Alphonse and Matwin 2002).

A large-scale empirical analysis of several such propositional supervised learning algorithms and their MI counterparts has been performed (Ray and Craven 2005). This analysis concludes that (1) no single MI algorithm works well across all problems (thus, different inductive biases are suited to different problems), (2) some MI algorithms consistently perform better than their supervised counterparts but others do not (hence, for these biases, there seems room for improvement), and (3) assigning a larger weight to false positives than to false negatives is a simple but effective method to adapt supervised learning algorithms to the MI setting. It was also observed that the advantages of MI learners may be more pronounced if they would be evaluated on the task of labeling individual instances rather than bags.

Along with "upgrading" supervised learning algorithms, a *theoretical analysis of supervised learners* learning with MI data has been carried out (Blum and Kalai 1998). In particular, the MI problem has been related to the problem of learning in the presence of classification noise (i.e., each training example's label is flipped with some probability $<1/2$). This implies that any concept class that is PAC-learnable in the presence of such noise is also learnable in the MI learning model when each instance of a bag is drawn iid. Since many concept classes are learnable under this noise assumption (using, e.g., *statistical queries* Kearns 1998), Blum and Kalai's result implies PAC learnability of many concept classes. Further, they improved on previous learnability results (Auer et al. 1998) by reducing the number of training bags required for PAC learning by about a factor of n with only an increase in time complexity of about $\log n/\epsilon$.

Besides these positive results, a *negative learnability result* describing when it is hard to learn concepts from MI data is also known (Auer et al. 1998). Specifically, if the instances of each bag are allowed collectively to be generated according to an arbitrary distribution, learning from MI examples is as hard as PAC-learning disjunctive normal form (DNF) formulas from single-instance examples, which is an open problem in learning theory that is believed to be hard. Further, it has been shown that if an efficient algorithm exists for the non-iid case that outputs as its hypothesis an axis-parallel rectangle, then NP = RP (Randomized Polynomial time; see, e.g., Papadimitriou 1994), which is very unlikely.

Learning from structured MI data has received some attention (McGovern and Jensen 2003). In this work, each instance is a graph, and a bag is a set of graphs (e.g., a bag could consist of certain subgraphs of a larger graph). To learn the concepts in this structured space, the authors use a modified form of the Diverse Density algorithm discussed above. As before, the concept being searched for is a point (which corresponds to a graph in this case). The main modification is the use of the size of the maximal common subgraph to estimate the probability of a concept – i.e., the probability of a concept given a bag is estimated as proportional to the size of the maximal common subgraph between the concept and any instance in the bag.

Multiple-Instance Regression

Regression problems in an MI setting have received less attention than the classification problem. Two key directions have been explored in this setting. One direction extends the well-known standard ▶ linear regression method to the MI setting. The other direction considers extending various MI classification methods to a regression setting.

In *MI linear regression* (Ray and Page 2001) (referred to as multiple-instance regression in the cited work), it is assumed that the hypothesis underlying the data is a linear model with Gaussian noise on the value of the dependent variable (which is the response). Further, it is assumed that it is sufficient to model one instance from each bag, i.e., that there is some *primary* instance which is responsible for the real-valued label. Ideally, one would like to find a hyperplane that minimizes the squared error with respect to these primary instances. However, these instances are unknown during training. The authors conjecture that, given enough data, a good approximation to the ideal is given by the "best-fit" hyperplane, defined as the hyperplane that minimizes the training set squared error by fitting one instance from each bag such that the response of the fitted instance most closely matches the bag response. This conjecture will be true if the nonprimary instances are not a better fit to a hyperplane than the primary instances. However, exactly finding the "best-fit" hyperplane is intractable. It is shown that the decision problem "Is there a hyperplane which perfectly fits one instance from each bag?" is NP-complete for arbitrary numbers of bags, attributes, and at most three instances per bag. Thus, the authors propose an approximation algorithm which iterates between choosing instances and learning linear regression models that best fit them, similar to the EM-DD algorithm described earlier.

Another direction has explored *extending MI classification algorithms* to the regression setting. This approach (Dooly et al. 2002) uses algorithms like Citation-kNN and Diverse Density to learn real-valued concepts. To predict a real value, the approach uses the average of the nearest neighbor responses or interprets the Gaussian "probability" as a real number for Diverse Density.

Recent work has analyzed the Diverse Density-based regression in the *online* model (Angluin 1988; Littlestone 1988) (see ▸ Online Learning). In the online model, learning proceeds in *trials*, where in each trial a single example is selected adversarially and given to the learner for classification. After the learner predicts a label, the true label is revealed and the learner incurs a *loss* based on whether its prediction was correct. The goal of the online learner is to minimize the loss over all trials. Online learning is harder than PAC learning in that there are some PAC-learnable concept classes that are not online learnable.

In the regression setting above (Dooly et al. 2006), there is a point concept, and the label of each bag is a function of the distance between the concept and the point in the bag closest to the target. It is shown that similar to Auer et al.'s lower bound, learning in this setting using labeled bags alone is as hard as learning DNF. They then define an *MI membership query* (MI-MQ) in which an adversary defines a bag $B = \{p_1, \ldots, p_n\}$ and the learner is allowed to ask an oracle for the label of bag $B + \vec{v} = \{p_1 + \vec{v}, \ldots, p_n + \vec{v}\}$ for any d-dimensional vector $\vec{v}$. Their algorithm then uses this MI-MQ oracle to online learn a real-valued MI concept in time $O(dn^2)$.

Applications

In this section, we describe domains where MI learning problems have been formulated.

Drug activity was the motivating application for the MI representation (Dietterich et al. 1997). Drugs are typically molecules that fulfill some desired function by binding to a target. In this domain, we wish to predict how strongly a given molecule will bind to a target. Each molecule is a three-dimensional entity and takes on multiple shapes or *conformations* in solution. We know that for every molecule showing activity, at least one of its low-energy conformations possesses the right shape for interacting with the target. Similarly, if the molecule does not show drug-like activity, none of its conformations possess the right shape for interaction. Thus, each molecule is represented as a bag, where each instance is a low-energy conformation of the molecule. A well-known example from this domain is the MUSK dataset. The positive class in this data consists of molecules that smell "musky." This dataset has two variants, MUSK1 and MUSK2, both with similar numbers of bags, with MUSK2 having many more instances per bag.

Content-Based Image Retrieval is another domain where the MI representation has been used (Maron and Lozano-Pérez 1998; Zhang et al. 2002). In this domain, the task is to find images that contain objects of interest, such as tigers, in a database of images. An image is represented by a bag. An instance in a bag corresponds to a segment in the image, obtained by some segmentation technique. The underlying assumption is that the object of interest is contained in (at least) one segment of the image. For example, if we are trying to find images of mountains in a database, it is reasonable to expect most images of mountains to have certain distinctive segments characteristic of mountains. An MI learning algorithm should be able to use the segmented images to learn a concept that represents the shape of a mountain and use the learned concept to collect images of mountains from the database.

The *identification of protein families* has been framed as an MI problem (Tao et al. 2004). The objective in that work is to classify given protein sequences according to whether they belong to the family of thioredoxin-fold proteins. The given proteins are first aligned with respect to a motif that is known to be conserved in the members of the family. Each aligned protein is represented by a bag. A bag is labeled positive if the protein belongs to the family, and negative otherwise. An instance in a bag corresponds to a position in a fixed length sequence around the conserved motif. Each position is described by a vector of attributes; each attribute describes the properties of the amino acid at that position and is smoothed using the same properties from its neighbors.

Text Categorization is another domain that has used the MI representation (Andrews et al. 2003; Ray and Craven 2005). In this domain, the task is to classify a document as belonging to a certain category or not. Often, whether the document belongs to the specified category is the function of a few passages in the document. These passages are however not labeled with the category information. Thus, a document could be represented as a set of passages. We assume that each positive document (i.e., that belongs to the specified category) has at least one passage that contains words that indicate category membership. On the other hand, a negative document (that does not belong to the category) has no passage that contains words indicating category membership. This formulation has been used to classify whether MEDLINE documents should be annotated with specific MeSH terms (Andrews et al.) and to determine if specific documents should be annotated with terms from the Gene Ontology (Ray and Craven 2005).

Time-series data from the hard drives have been used to define an MI problem (Murray et al. 2005). The task here is to distinguish drives that fail from others. Each hard drive is a bag. Each instance in the bag is a fixed-size window over timepoints when the drive's state was measured using certain attributes. In the training set, each drive is labeled according to whether it failed during a window of observation. An interesting aspect to prediction in this setting is that it is done online, i.e., the algorithm learns a classifier for instances, which is applied to each instance as it becomes available in time. The authors learn a naïve Bayes model using an EM-based approach to solve this problem.

Discovering useful subgoals in reinforcement learning has been formulated as an MI problem (McGovern and Barto 2001). Imagine that a robot has to get from one room to another by passing through a connecting door. If the robot knew of the existence of the door, it could decompose the problem into two simpler subproblems to be solved separately: getting from the initial location in the first room to the door and then getting from the door to its destination. How could the robot discover such a "useful subgoal?" One approach formulates this as an MI problem. Each trajectory of the robot, where the robot starts at the source and then moves for some number of time steps, is considered to be a bag. An instance in a bag is a state of the world, which records observations such as "is the robot's current location a door?" Trajectories that reach the destination are positive, while those that do not are negative. Given this data, we can learn a classifier that predicts which states are more likely to be seen on successful trajectories than on unsuccessful ones. These states are taken to be useful subgoals. In the previous example, the MI algorithm could learn that the state "location is a door" is a useful subgoal, since it appears on all successful trajectories, but infrequently on unsuccessful ones.

Future Directions

MI learning remains an active research area. One direction that is being explored relaxes the "constraints" in Fig. 2 in different ways (Tao et al. 2004; Weidmann et al. 2003). For example, one could consider constraints where at least a certain number (or fraction) of instances have to be positive for a bag to be labeled positive. Similarly, it may be the case that a bag is labeled positive only if it does not contain a specific instance. Such relaxations are often studied as "generalized multiple-instance learning."

One such generalization of MI learning has been formally studied under the name "geometric patterns." In this setting, the target concept consists of a collection of APRs, and a bag is labeled positive if and only if (1) each of its points lies in a target APR and (2) every target APR contains a point. Noise-tolerant PAC algorithms (Goldman and Scott 1999) and online algorithms (Goldman et al. 2001) have been presented for such concept classes. These algorithms make no assumptions on the distribution used to generate the bags (e.g., instances might not be generated by an iid process). This does not violate Auer et al.'s lower bound since these algorithms do not scale with the dimension of the input space.

Another recent direction explores the connections between MI and semi-supervised learnings. Semi-supervised learning generally refers to learning from a setting where some instance labels are unknown. MI learning can be viewed as one example of this setting. Exploiting this connection between MI learning and other methods for semi-supervised learning, recent work (Rahmani and Goldman 2006) proposes an approach where an MI problem is transformed into a semi-supervised learning problem. An advantage of the approach is that it automatically also takes into account unlabeled bags.

Naïve Bayes

Geoffrey I. Webb
Faculty of Information Technology, Monash University, Victoria, Australia

Synonyms

Idiot's Bayes; Simple Bayes

Definition

Naïve Bayes is a simple learning algorithm that utilizes ▶ Bayes' rule together with a strong assumption that the attributes are conditionally independent given the class. While this independence assumption is often violated in practice, naïve Bayes nonetheless often delivers competitive classification accuracy. Coupled with its computational efficiency and many other desirable features, this leads to naïve Bayes being widely applied in practice.

Motivation and Background

Naïve Bayes provides a mechanism for using the information in sample data to estimate the posterior probability $\mathrm{P}(y|\mathbf{x})$ of each class y given an object $\mathbf{x}$. Once we have such estimates, we can use them for ▶ classification or other decision support applications.

Naïve Bayes' features include the following:

- *Computational efficiency*: ▶ training time is linear with respect to both the number of ▶ training examples and the number of ▶ attributes, and ▶ classification time is linear with respect to the number of attributes and unaffected by the number of training examples.
- *Low variance*: because naïve Bayes does not directly fit the posterior distribution, it has low variance, albeit at the cost of high ▶ bias.
- *Incremental learning*: naïve Bayes operates from estimates of low-order probabilities that are derived from the training data. These can readily be updated as new training data are acquired.
- *Direct prediction of posterior probabilities.*
- *Robustness in the face of noise*: naïve Bayes always uses all attributes for all predictions and hence is relatively insensitive to ▶ noise in the examples to be classified. Because it uses probabilities, it is also relatively insensitive to noise in the training data.
- *Robustness in the face of missing values*: because naïve Bayes always uses all attributes for all predictions, if one attribute value is missing, information from other attributes is still used, resulting in graceful degradation in performance. It is also relatively insensitive to

C. Sammut, G.I. Webb (eds.), *Encyclopedia of Machine Learning and Data Mining*,
DOI 10.1007/978-1-4899-7687-1

missing attribute values in the training data due to its probabilistic framework.

Structure of Learning System

Naïve Bayes is a form of Bayesian network classifier based on ▶ Bayes' rule:

$$P(y|\mathbf{x}) = P(y)P(\mathbf{x}|y)/P(\mathbf{x}) \qquad (1)$$

together with an assumption that the attributes are conditionally independent given the class. For ▶ attribute-value data, this assumption entitles

$$P(\mathbf{x}|y) = \prod_{i=1}^{n} P(x_i|y) \qquad (2)$$

where x_i is the value of the ith attribute in $\mathbf{x}$ and n is the number of attributes:

$$P(\mathbf{x}) = \prod_{i=1}^{k} P(c_i)P(\mathbf{x}|c_i) \qquad (3)$$

where k is the number of classes and c_i is the ith class. Thus, (1) can be calculated by normalizing the numerators of the right-hand side of the equation.

The resulting classifier uses a linear model, equivalent to that used by ▶ logistic regression, differing only in the manner in which the parameters are chosen.

For ▶ categorical attributes, the required probabilities $P(y)$ and $P(x_i|y)$ are normally derived from frequency counts stored in arrays whose values are calculated by a single pass through the training data at training time. These arrays can be updated as new data are acquired, supporting ▶ incremental learning. Probability estimates are usually derived from the frequency counts using smoothing functions such as the ▶ Laplace estimate or an m-estimate.

For ▶ numeric attributes, either the data are discretized (see ▶ discretization) or probability density estimation is employed.

In ▶ text mining, two variants of naïve Bayes are often employed (McCallum and Nigam 1998). The *multivariate Bernoulli model* utilizes naïve Bayes as described above, with each document represented as a vector of binary variables, each representing the presence or absence of a specific word. However, only the words that are present in a document are considered when calculating the probabilities for that document.

In contrast, the *multinomial model* uses information about the number of times a word appears in a document. It treats each occurrence of a word in a document as a separate event. These events are assumed independent of each other. Hence the probability of a document given a class is the product of the probabilities of each word event given the class.

Definition

In a data collection M, the *nearest neighbor* to a data object q is the data object M_i, which minimizes dist (q, M_i), where dist is a *distance measure* defined for the objects in question. Note that the fact that the object M_i is the nearest neighbor to q does not imply that q is the nearest neighbor to M_i.

Motivation and Background

Nearest neighbors are useful in many machine learning and data mining tasks, such as ▶ classification, ▶ anomaly detection and motif discovery and in more general tasks such as spell checking, vector quantization, plagiarism detection, web search, and recommender systems.

The naive method to find the nearest neighbor to a point q requires a linear scan of all objects in M. Since this may be unacceptably slow for large datasets and/or computationally demanding distance measures, there is a huge amount of literature on speeding up nearest neighbor searches (query-by-content). The fastest methods depend on the distance measure used, whether the data is disk resident or in main memory, and the structure of the data itself. Many methods are based on the R-tree (Guttman 1984) or one of its variants (Manolopoulos et al. 2005). However, in recent years there has been an increased awareness that for many applications approximate nearest neighbors may suffice. This has led to the development of techniques like *locality sensitive hashing*, which finds high-quality approximate nearest neighbors in constant time.

The definition of nearest neighbor allows for the definition of one of the simplest classification schemes, the *nearest neighbor classifier*.

The major database (SIGMOD, VLDB, and PODS) and data mining (SIGKDD, ICDM, and SDM) conferences typically feature several papers on novel distance measures and techniques for speeding up nearest neighbor search. Pavel et al.'s book provides an excellent overview on the state-of-the-art techniques in nearest neighbor searching.

Negative Correlation Learning

Synonyms

NC-learning; NCL

Definition

Negative correlation learning (Liu and Yao 1999) is an ▶ ensemble learning technique. It can be used for regression or classification problems, though with classification problems the models must be capable of producing posterior probabilities. The model outputs are combined with a uniformly weighted average. The squared error is augmented with a penalty term which takes into account the diversity of the ensemble. The error for the ith model is,

$$E(f_i(x)) = \frac{1}{2}(f_i(x) - d)^2 - \lambda(f_i(x) - \bar{f}(x))^2. \qquad (1)$$

The coefficient λ determines the balance between optimizing individual accuracy, and optimizing ensemble diversity. With $\lambda = 0$, the models are trained independently, with no emphasis on diversity. With $\lambda = 1$, the models are tightly coupled, and the ensemble is trained as a single unit. Theoretical studies (Brown et al. 2006) have shown that NC works by directly optimizing the ▸ bias-variance-covariance trade-off, thus it explicitly *manages* the ensemble diversity. When the complexity of the individuals is sufficient to have high individual accuracy, NC provides little benefit. When the complexity is low, NC with a well-chosen λ can provide significant performance improvements. Thus the best situation to make use of the NC framework is with a large number of low accuracy models.

Negative Predictive Value

Negative Predictive Value (NPV) is defined as a ratio of true negatives to the total number of negatives predicted by a model. This is defined with reference to a special case of the ▸ confusion matrix with two classes – one designated the *positive* class and the other the *negative* class – as indicated in Table 1.

Negative Predictive Value, Table 1 The outcomes of classification into positive and negative classes

		Assigned class	
		Positive	Negative
Actual class	Positive	True positive (TP)	False negative (FN)
	Negative	False positive (FP)	True negative (TN)

NPV can then be defined in terms of true negatives and false negatives as follows.

$$\text{NPV} = \text{TN}/(\text{TN} + \text{FN})$$

University of Texas at Austin, Austin, TX, USA

Abstract

Neuroevolution is a method for modifying neural network weights, topologies, or ensembles in order to learn a specific task. Evolutionary computation is used to search for network parameters that maximize a fitness function that measures performance in the task. Compared to other neural network learning methods, neuroevolution is highly general, allowing learning without explicit targets, with nondifferentiable activation functions, and with recurrent networks. It can also be combined with standard neural network learning to, e.g., model biological adaptation. Neuroevolution can also be seen as a policy search method for reinforcement learning problems, where it is well suited to continuous domains and to domains where the state is only partially observable.

Synonyms

Evolving neural networks; Genetic neural networks

Motivation and Background

The primary motivation for neuroevolution is to be able to train neural networks in sequential decision tasks with sparse reinforcement information. Most neural network learning is concerned with supervised tasks, where the desired behavior is described in terms of a corpus of input-output examples. However, many learning tasks in the real world do not lend themselves to the supervised learning approach. For example, in game playing, vehicle control, and robotics, the optimal actions at each point in time are not always known; only after performing several actions it is possible to get information about how well they worked, such as winning or losing the game. Neuroevolution makes it possible to find a neural network that optimizes such behavior given only sparse information about how well the networks are doing, without direct information about what exactly they should be doing.

The main benefit of neuroevolution compared to other reinforcement learning (RL) methods is that it allows representing continuous state and action spaces and disambiguating hidden states naturally. Network activations are continuous, and the network generalizes well between continuous values, largely avoiding the state explosion problem that plagues many reinforcement learning approaches. Recurrent networks can encode memories of past states and actions, making it possible to learn in partially observable Markov decision process (POMDP) environments that are difficult for many RL approaches.

Compared to other neural network learning methods, neuroevolution is highly general. As long as the performance of the networks can be evaluated over time and the behavior of the network can be modified through evolution, it can be applied to a wide range of network architectures, including those with nondifferentiable activation functions and recurrent and higher-order connections. While most neural learning algorithms focus on modifying the weights only, neuroevolution can be used to optimize other aspects of the networks as well, including activation functions and network topologies.

Neuroevolution allows combining evolution over a population of solutions with lifetime learning in individual solutions: the evolved networks can each learn further through, e.g., backpropagation or Hebbian learning. The approach is therefore well suited to understanding biological adaptation and for building artificial life systems.

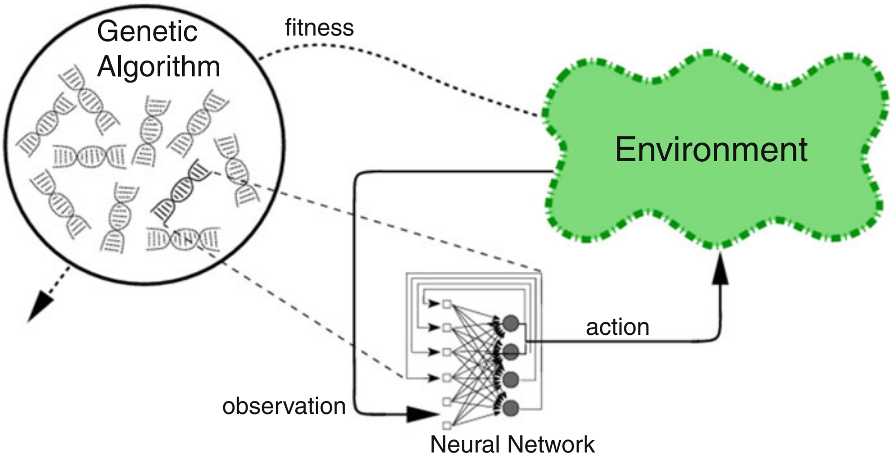
Structure of the Learning System

Basic Methods

In neuroevolution, a population of genetic encodings of neural networks is evolved in order to find a network that solves the given task. Most neuroevolution methods follow the usual generate-and-test loop of evolutionary algorithms (Fig. 1). Each encoding in the population (a genotype) is chosen in turn and decoded into the corresponding neural network (a phenotype). This network is then employed in the task and its performance over time measured, obtaining a fitness value for the corresponding genotype. After all members of the population have been evaluated in this manner, genetic operators are used to create the next generation of the population. Those encodings with the highest fitness are mutated and crossed over with each other, and the resulting offspring replaces the genotypes with the lowest fitness in the population. The process therefore constitutes an intelligent parallel search toward better genotypes and continues until a network with a sufficiently high fitness is found.

Several methods exist for evolving neural networks depending on how the networks are encoded. The most straightforward encoding, sometimes called conventional neuroevolution (CNE), is formed by concatenating the numerical values for the network weights (either binary or floating point) (Floreano et al. 2008; Yao 1999; Schaffer et al. 1992). This encoding allows evolution to optimize the weights of a fixed neural network architecture, an approach that is easy to implement and is practical in many domains.

In more challenging domains, the CNE approach suffers from three problems: The method may cause the population to converge before a solution is found, making further progress difficult (i.e., premature convergence); similar networks, such as those where the order of nodes is different, may have different encodings, and much effort is wasted in trying to optimize them in parallel (i.e., competing conventions); a large number of parameters need



Neuroevolution, Fig. 1 **Evolving Neural Networks.** A population of genetic neural network encodings (genotypes) is first created. At each iteration of evolution (generation), each genotype is decoded into a neural network (phenotype), which is evaluated in the task, resulting in a fitness value for the genotype. Crossover and mutation among the genotypes with the highest fitness are then used to generate the next generation to be optimized at once, which is difficult through evolution.

More sophisticated encodings have been devised to alleviate these problems. One approach is to run the evolution at the level of solution components instead of full solutions. That is, instead of a population of complete neural networks, a population of network fragments, neurons, or connection weights is evolved (Moriarty et al. 1999; Gomez et al. 2008; Potter and Jong 2000). Each individual is evaluated as part of a full network, and its fitness reflects how well it cooperates with other individuals in forming a full network. Specifications for how to combine the components into a full network can be evolved separately, or the combination can be based on designated roles for subpopulations. In this manner, the complex problem of finding a solution network is broken into several smaller subproblems; evolution is forced to maintain diverse solutions, and competing conventions and the number of parameters is drastically reduced.

Another approach is to evolve the network topology, in addition to the weights. The idea is that topology can have a large effect on function and evolving appropriate topologies can achieve good performance faster than evolving weights only (Angeline et al. 1994; Floreano et al. 2008; Yao 1999; Stanley and Miikkulainen 2004). Since topologies are explicitly specified, competing conventions are largely avoided. It is also possible to start evolution with simple solutions and gradually make them more complex, a process that takes place in biology and is a powerful approach in machine learning in general. Speciation according to the topology can be used to avoid premature convergence and to protect novel topological solutions until their weights have been sufficiently optimized.

All of the above methods map the genetic encoding directly to the corresponding neural network, i.e., each part of the encoding corresponds to a part of the network and vice versa. Indirect encoding, in contrast, specifies a process through which the network is constructed, such as cell division or generation through a grammar or through patterns generated by another neural network (Floreano et al. 2008; Yao 1999; Stanley and Miikkulainen 2003; Gruau and Whitley 1993; Stanley et al. 2009). Such an encoding can be highly compact and also take advantage of modular solutions. The same structures can be repeated with minor modifications, as they often are in biology. It is, however, difficult to optimize solutions produced by indirect encoding, and realizing its full potential is still future work.

Another approach is to evolve an ensemble of neural networks to solve the task together, instead of a single network (Liu et al. 2000). This approach takes advantage of the diversity in the population: Different networks learn different parts or aspects of the training data, and together the whole ensemble can perform better than a single network. Diversity can be created through speciation and negative correlation, encouraging useful specializations to emerge. The approach can be used to design ensembles for classification problems, but it can also be extended to control tasks.

Extensions

The basic mechanisms of neuroevolution can be augmented in several ways, making the process more efficient and extending it to various applications. One of the most basic ones is incremental evolution or shaping: Evolution is began on a simple task, and once that is mastered, the solutions are evolved further on a more challenging task and, through a series of such transfer steps, eventually on the actual goal task itself (Gomez et al. 2008). Shaping can be done by changing the environment, such as increasing the speed of the opponents, or by changing the fitness function, e.g., by rewarding gradually more complex behaviors. It is often possible to solve challenging tasks by approaching them incrementally even when they cannot be solved directly.

Many extensions to evolutionary computation methods apply particularly well to neuroevolution. First, intelligent mutation techniques such as those employed in evolutionary strategies are effective because the weights often have suitable correlations (Igel 2003). Second, networks can be evolved through coevolution (Stanley and Miikkulainen 2004; Chellapilla and Fogel 1999). A coevolutionary arms race can be established, e.g., based on complexification of network topology: As the network becomes gradually more complex, evolution is likely to elaborate on existing behaviors instead of replacing them. Third, behavioral diversity and novelty can be defined naturally in terms of network behavior, leading to methods that discover novel solutions (Lehman and Stanley 2010; Mouret and Doncieux 2012).

On the other hand, several extensions utilize the special properties of the neural network phenotype. For instance, neuron activation functions, initial states, and learning rules can be evolved to fit the task (Floreano et al. 2008; Yao 1999; Schaffer et al. 1992). It is possible to evolve modular network architectures, e.g., as a separate mutation or through minimizing wiring length, and thus discover how complex behavior arises from a combination of low-level behaviors (Clune et al. 2013; Schrum 2014). Most significantly, evolution can be combined with other neural network learning methods (Floreano et al. 2008). In such approaches, evolution usually provides the initial network, which then adapts further during its evaluation in the task. The adaptation can take place through Hebbian learning, thereby strengthening those existing behaviors that are invoked often during evaluation. Alternatively, supervised learning such as backpropagation can be used, provided targets are available. Even if the optimal behaviors are not known, such training can be useful: Networks can be trained to imitate the most successful individuals in the population, or part of the network can be trained in a related task such as predicting the next inputs or evaluating the utility of actions based on values obtained through Q-learning. The weight changes may be encoded back into the genotype, implementing Lamarckian evolution; alternatively, they may affect selection through the Baldwin effect, i.e., networks that learn well will be selected for reproduction even if the weight changes themselves are not inherited (Ackley and Littman 1992; Gruau and Whitley 1993; Bryant and Miikkulainen 2007).

There are also several ways to bias and direct the learning system using human knowledge. For instance, human-coded rules can be encoded in partial network structures and incorporated into the evolving networks as structural mutations. Such knowledge can be used to implement initial behaviors in the population, or it can serve as advice during evolution (Miikkulainen et al. 2006). In cases where rule-based knowledge is not available, it may still be possible to obtain examples of human behavior. Such examples can then be incorporated into evolution, either as components of fitness or by explicitly training the evolved solutions toward human behavior through, e.g., backpropagation (Bryant and Miikkulainen 2007). Similarly, knowledge about the task and its components can be utilized in designing effective shaping strategies. In this manner, human expertise can be used to bootstrap and guide evolution in difficult tasks, as well as direct it toward the desired kinds of solutions.

Applications

Neuroevolution methods are powerful especially in continuous domains of reinforcement learning and those that have partially observable states. For instance, in the benchmark task of balancing the inverted pendulum without velocity information (making the problem partially observable), the advanced methods have been shown to find solutions two orders of magnitude faster than value function-based reinforcement learning methods (measured by number of evaluations, Gomez et al. 2008). They can also solve harder versions of the problem, such as balancing two poles simultaneously.

The method is powerful enough to make many real-world applications of reinforcement learning possible. The most obvious area is adaptive, nonlinear control of physical devices. For instance, neural network controllers have been evolved to drive mobile robots, automobiles, and even rockets (Valsalam et al. 2013; Togelius and Lucas 2006; Gomez and Miikkulainen 2003; Nolfi and Floreano 2000; Bongard 2011). The control approach have been extended to optimize systems such as chemical processes, manufacturing systems, and computer systems. A crucial limitation with current approaches is that the controllers usually need to be developed in simulation and transferred to the real system. Evolution is strongest as an off-line learning method where it is free to explore potential solutions in parallel.

Evolution of neural networks is a natural tool for problems in artificial life. Because networks implement behaviors, it is possible to design neuroevolution experiments on how behaviors such as foraging, pursuit and evasion, hunting and herding, collaboration, and even communication may emerge in response to environmental pressure (Werner and Dyer 1992; Nolfi and Floreano 2000). It is possible to evolve the morphology and control together to create agents with natural movement (Lessin et al. 2013; Bongard 2011) and to analyze the evolved circuits and understand how they map to function, leading to insights into biological networks (Keinan et al. 2006). The evolutionary behavior approach is also useful for constructing characters in artificial environments, such as games and simulators. Non-player characters in current video games are usually scripted and limited; neuroevolution can be used to evolve complex behaviors for them and even adapt them in real time (Miikkulainen et al. 2006; Risi and Togelius 2014).

Programs and Data

Software for the NEAT method for evolving network weights and topologies, and for the ESP and CoSyNE methods for evolving neurons and weights to form networks, is available at nn.cs.utexas.edu/?neuroevolution. Software for HyperNEAT indirect neuroevolution method is available at eplex.cs.ucf.edu/hyperNEATpage.

PyBrain (pybrain.org) and Sferes2 (github.com/jbmouret/sferes2) are general machine learning and evolutionary computation packages that include neuroevolution methods.

The OpenNERO software for evolving intelligent multiagent behavior in simulated environments is at http://opennero.googlecode.com.

Definition

Neurons carry out the computational operations of a network; together with connections (see ▶ Topology of a Neural Network, ▶ Weight), they constitute the neural network. Computational neurons are highly abstracted from their biological counterparts. In most cases, the neuron forms a weighted sum of a large number of inputs (activations of other neurons), applies a nonlinear transfer function to that sum, and broadcasts the resulting output activation to a large number of other neurons. Such activation models the firing rate of the biological neuron, and the nonlinearity is used to limit it to a certain range (e.g., 0 or 1 with a threshold, $(0, 1)$ with a sigmoid, $(-1, 1)$ with a hyperbolic tangent, or $(0, \infty)$ with an exponential function). Each neuron may also have a bias weight, i.e., a weight from a virtual neuron that is always maximally activated, which the learning algorithm can use to adjust the input sum quickly into the most effective range of the nonlinearity. Alternatively to firing rate neurons, the firing events (i.e., spikes or action potentials) of the neuron can be represented explicitly. In such an integrate-and-fire approach, each spike causes a change in the neuron's membrane potential that decays over time; an output spike is generated if the potential exceeds a threshold (see ▶ Biological Learning: Synaptic Plasticity, Hebb Rule and Spike Timing Dependent Plasticity). In contrast, networks such as ▶ self-organizing maps and ▶ radial basis function networks abstract the firing rate further into a measure of similarity (or distance) between the neuron's input weight vector and the vector of input activities. Learning in neural networks usually takes place by adjusting the weights on the input connections of the neuron, and can also include adjusting the parameters of the nonlinear transfer function, or the neuron's connectivity with other neurons. In this manner, the neuron converges information from other neurons, makes a simple decision based on it, broadcasts the result widely, and adapts.

No-Free-Lunch Theorem

A theorem establishing that performance on test data cannot be deduced from performance on training data. It follows that the justification for any particular learning algorithm must be based on an assumption that nature is uniform in some way. Since different machine learning algorithms make such different assumptions, no-free-lunch theorems have been used to argue that it not possible to deduce that any algorithm is superior to any other from first principles. Thus "good" algorithms are those whose ▶ inductive bias matches the way the world happens to be.

Nogood Learning

Nogood learning is a ▶ deductive learning technique used for the purpose of ▶ intelligent backtrackings in constraint satisfaction. The approach analyzes failures at backtracking points and derives sets of variable bindings, or *nogoods*, that will never lead to a solution. These nogood constraints can then be used to prune later search nodes.

Noise

The training data for a learning algorithm is said to be *noisy* if the data contain errors. Errors can be of two types:

- A *measurement error* occurs when some attribute values are incorrect or inaccurate. Note that measurement of physical properties by continuous values is always subject to some error.
- In supervised learning, *classification error* means that a training example has an incorrect class label.

In addition to errors, training examples may have ▶ missing attribute values. That is, the values of some attribute values are not recorded.

Noisy data can cause learning algorithms to fail to converge to a concept description or to build a concept description that has poor classification accuracy on unseen examples. This is often due to ▶ over fitting.

For methods to minimize the effects of noise, see ▶ Overfitting.

Nominal Attribute

A **nominal attribute** assumes values that classify data into mutually exclusive (nonoverlapping), exhaustive, unordered categories. See ▶ Attribute and ▶ Measurement Scales.

Nonstandard Criteria in Evolutionary Learning

Introduction

Machine learning (ML), primarily concerned with extracting models or hypotheses from data, comes into three main flavors: ▶ supervised learning also known as ▶ classification or ▶ regression (Bishop 2006; Duda et al. 2001; Han and Kamber 2000), ▶ unsupervised learning also known as ▶ clustering (Ben-David et al. 2005), and ▶ reinforcement learning (Sutton and Barto 1998).

All three types of problems can be viewed as optimization problems. The ML core task is to define a *learning criterion* (i.e., the function to be optimized) such that it enforces (i) the statistical relevance of the solution; (ii) the well-posedness of the underlying optimization problem. Since evolutionary computation (see ▶ Evolutionary Algorithms) makes it possible to handle ill-posed optimization problems, the field of evolutionary learning (Holland 1986) has investigated quite a few nonstandard learning criteria and search spaces. Only supervised ML will be considered in the following. Unsupervised learning has hardly been touched upon in the evolutionary computation (EC) literature; regarding reinforcement learning, the interested reader is referred to the entries related to ▶ evolutionary robotics and control.

The entry will first briefly summarize the formal background of supervised ML and its two mainstream approaches for the last decade, namely support vector machines (SVMs) (Cristianini and Shawe-Taylor 2000; Schölkopf et al. 1998; Vapnik 1995) and ensemble learning (Breiman 1998; Dietterich 2000; Schapire 1990). Thereafter and without pretending to exhaustivity, this entry will illustrate some innovative variants of these approaches in the literature, building upon the evolutionary freedom of setting and tackling optimization problems.

Nonstandard Criteria in Evolutionary Learning, Table 1 Excerpt of a dataset in a failure identification problem (binary classification). Instance space X is the cross product of all attribute domains: for example, attribute *Temperature* ranges in R, attribute *Material* ranges in $\{Ni, Fe, \ldots\}$. *Label space* Y *is binary*

	Temperature	Material	Aging	Label
$\mathbf{x}_1$	118.2	Ni	No	Failure
$\mathbf{x}_2$	76.453	Fe	Yes	OK

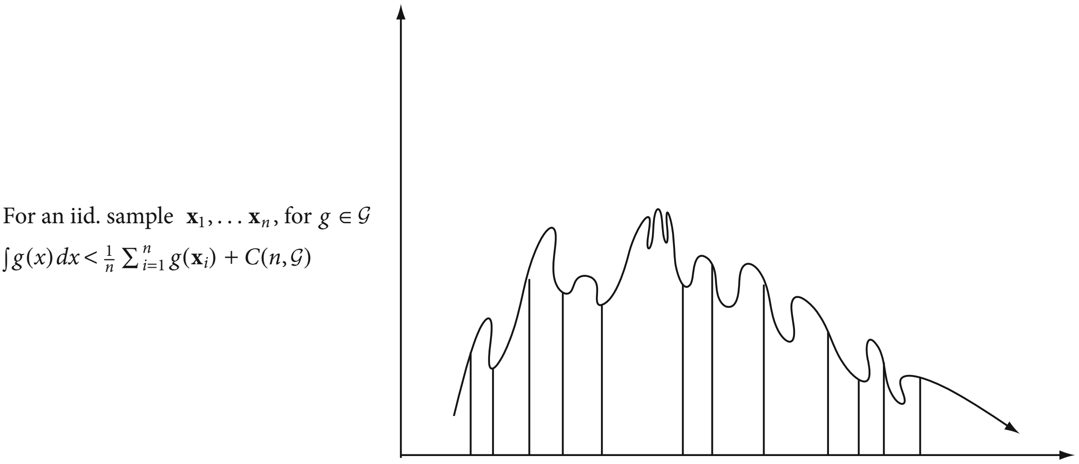
Formal Background

Supervised learning exploits a dataset $\mathcal{E} = \{(\mathbf{x}_i, y_i), \mathbf{x}_i \in X, y_i, \in Y, i = 1 \ldots n\}$, where X stands for the instance space (e.g., $\mathbb{R}^d$), Y is the label space, and $(\mathbf{x}_i, y_i)$ is a labeled example, as depicted in Table 1. Supervised learning is referred to as *classification* (respectively *regression*) when Y is a finite set (respectively when $Y = \mathbb{R}$).

The ML goal is to find a hypothesis or classifier $h : X \mapsto Y$ such that $h(x)$ is "sufficiently close" to the true label y of x for any x ranging in the instance domain. It is generally assumed that the available examples are independently and identically distributed (iid) after a probability distribution P_{XY} on $X \times Y$. Letting $\ell(y', y)$ denote the loss incurred by labeling $\mathbf{x}$ as y' instead of its true label y, the learning criterion is most naturally defined as the expectation of the loss, or *generalization error*, to be minimized, where $\mathcal{H}$ denotes the hypothesis space:

$$\text{Find } h^* = arg\ \min\{\mathcal{F}(h) = \int \ell(h(x), y) dP(x, y), h \in \mathcal{H}\}$$

The generalization error however is not computable, since the joint distribution P_{XY} of in-



For an iid. sample $\mathbf{x}_1, \ldots \mathbf{x}_n$, for $g \in \mathcal{G}$
$\int g(x)\,dx < \frac{1}{n} \sum_{i=1}^{n} g(\mathbf{x}_i) + C(n, \mathcal{G})$

Nonstandard Criteria in Evolutionary Learning, Fig. 1 Bounding the integral from the empirical average depending on the uniform sample size and the class of functions $\mathcal{G}$ at hand

stances and labels is unknown; only its approximation on the training set, referred to as *empirical error*, can be computed as follows:

$$\mathcal{F}_e(h) = \frac{1}{n} \sum_{i=1}^{n} \ell(h(\mathbf{x}_i), y_i)$$

Using results from the theory of measure and integration, the generalization error is upper bounded by the empirical error, plus a term reflecting the number of examples and the regularity of the hypothesis class (Fig. 1).

Note that minimizing the empirical error alone leads to the infamous *overfitting* problem: while the predictive accuracy on the training set is excellent, the error on a (disjoint) test set is much higher. All learning criteria thus involve a trade-off between the empirical error and a so-called regularization term, providing good guarantees (upper bound) on the generalization error.

In practice, learning algorithms also involve hyper-parameters (e.g., the weight of the regularization term). These are adjusted using cross-validation using a grid search (EC approaches have also been used to find optimal learning hyperparameters, ranging from the topology of neural nets (Miikkulainen et al. 2003), to the kernel parameters in SVM (Friedrichs and Igel 2005; Mierswa 2006) The dataset is divided into K subsets with same class distribution; hypothesis h_i is learned from the training set made of all subsets except the i-th and the empirical error of h_i is measured on the ith subset. An approximation of the generalization error is provided by the average of the h_i errors when $i = 1 \ldots K$, referred to as cross-fold error, and the hyperparameter setting is empirically determined to minimize the cross-fold error.

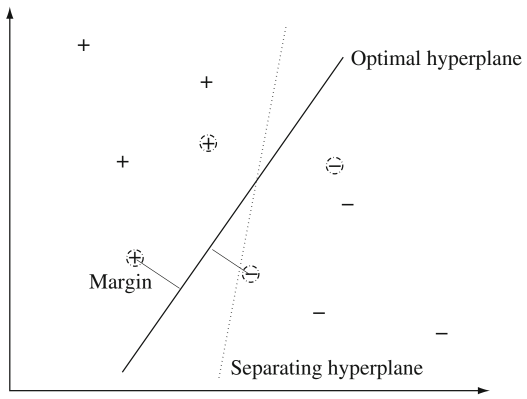
Support Vector Machines

Considering a real-valued instance space $(X = \mathbb{R}^D)$, a linear ▸ support vector machine (SVM) (Boser et al. 1992) constructs the separating hyperplane (where $< a, b >$ stands for the dot product of vectors a and b):

$$h(\mathbf{x}) = < w, \mathbf{x} > +b$$

which maximizes the margin that is, the minimal distance between the examples and the hyperplane, when such separating hyperplanes exists (Fig. 2). A slightly more complex formulation, involving the so-called slack variables $\mathbf{x}i_i$, is defined to deal with noise (Cortes and Vapnik 1995).

The function to be optimized, the L_2 norm of the hyperplane normal vector w, is quadratic; using Lagrange multipliers to account for the constraints gives rise to the so-called dual formulation. Let us call *support vectors* those examples



without noise

$$\text{Minimize } \tfrac{1}{2}||w||^2$$

s.t. for $i = 1$ to n

$$y_i(< w, \mathbf{x}_i > +b) \geq 1$$

with noise

$$\text{Minimize } \tfrac{1}{2}||w||^2 + C\textstyle\sum_{i=1}^{n} \mathbf{x}i_i$$

s.t. for $i = 1$ to n

$$y_i(< w, \mathbf{x}_i > +b) \geq 1 - \mathbf{x}i_i; \quad \mathbf{x}i_i \geq 0$$

Nonstandard Criteria in Evolutionary Learning, Fig. 2 Linear support vector machines. The optimal hyperplane is the one maximizing the minimal distance to the examples

for which the constraint is active (Lagrange multiplier $\alpha_i > 0$), then it becomes

$$h(\mathbf{x}) = \sum y_i \alpha_i < \mathbf{x}_i, \mathbf{x} > +b \quad \text{with } \alpha_i > 0;$$
$$\sum \alpha_i y_i = 0$$

As will be seen in section "Evolutionary Regularization" this formulation defines a search space, which can be directly explored by EC (Mierswa 2007).

Obviously however, linear classifiers are limited. The power of SVMs comes from the so-called kernel *trick*, naturally exporting the SVM approach to nonlinear hypothesis spaces. Let us map the instance space X onto some *feature space* X' via mapping Φ. If the scalar product on X' can be computed in X (e.g., $< \Phi(\mathbf{x}), \Phi(\mathbf{x}') >=_{\text{def}} K(x, x')$) then a linear classifier in X' (nonlinear with reference to X) is given as $h(\mathbf{x}) = \sum_i y_i \alpha_i K(\mathbf{x}_i, \mathbf{x}) + b$. The only requirement is to use a positive definite kernel (ensuring that the underlying optimization problem is well posed). Again, this requirement can be relaxed in the evolutionary learning framework (Mierswa 2006).

Among the most widely used kernels are the Gaussian kernel $\left(K(x, x') = \exp\left\{-\frac{||x-x'||^2}{\sigma^2}\right\}\right)$ and the polynomial kernel $(K(x, x') = (< x, x' > +c)^d)$. The kernel parameters σ, c, d, referred to as learning hyper-parameters, have been tuned by some authors using EC, as well as the kernel itself (see among others Friedrichs and Igel 2005; Gagné et al. 2006; Mierswa 2006).

Ensemble Methods

The other mainstream approach in supervised learning, ▸ ensemble learning (EL), relies on somewhat different principles. Schapire's seminal paper, *The strength of weak learnability*, exploring the relationship between *weak learnability* (ability of building a hypothesis slightly better than random guessing, whatever the distribution of the dataset is (C)) and *strong learnability* (ability of building a hypothesis with arbitrarily high predictive accuracy), established a major and counterintuitive result: strong and weak learnability are equivalent (Schapire 1990). The idea behind the proof is that combining many weak hypotheses learned under different distributions yields an arbitrarily accurate hypothesis. As the errors of the weak hypotheses should not concentrate in any particular region of the instance space (for condition C to hold), the law of large numbers states that averaging them leads to exponentially decrease the empirical error.

Two main EL approaches have been investigated in the literature. The first one, ▸ bagging (Breiman 1998), builds a large number of independent hypotheses; the source of variations is bootstrapping (uniformly selecting the training set with replacement from the initial dataset); or varying the parameters of the learning algorithm; or subsampling the features considered at each step of the learning process (Amit et al. 1997; Breiman 2001). The final classifier is usually obtained by averaging these solutions.

The other EL approach, ▸ boosting (Freund and Shapire 1996), iteratively builds a sequence of hypotheses, where each h_i somehow is in charge of correcting the mistakes of $h_1, \ldots h_{i-1}$. Specifically, a distribution $\mathcal{W}_t$ is defined on the training set at step t, with $\mathcal{W}_0$ being the uniform distribution. At step t, the weight of every example misclassified by ht is increased (multiplied by $\exp\{-h_t(\mathbf{x}_i).\ h_i\}$; then a normalization step follows to ensure that $\mathcal{W}_{t+1}$ still sums to 1); hypothesis h_{t+1} will thus focus on the examples misclassified by h_t. Finally, the classifier is defined as the weighted vote of all h_t.

The intuition behind boosting is that not all examples are equal: some examples are more difficult than others (more hypotheses misclassify them) and the learning process should thus focus on these examples (with the caveat that a difficult example might be so because it is noisy). Interestingly, the intuition that examples are not equal has been formalized in terms of coevolution (When designing a program, the fitness of the candidate solutions is computed after some test cases; for the sake of accuracy and feasability, the difficulty and number of test cases must be commensurate with the competence of the current candidate solutions. Hillis defined a competitive coevolution setting between the program species and the test case species: while programs aim at solving test cases, test cases aim at defeating candidate programs. This major line of research however is outside the scope of evolutionary learning as it assumes that the whole distribution PXY is known.) by D. Hillis in the early 1990s (Hillis 1990).

Many empirical studies suggest that boosting is more effective than bagging (with some caveat in the case of noisy domains), thanks to the higher diversity of the boosting ensemble (Dietterich 2000; Margineantu and Dietterich 1997).

In the ensemble learning framework, the *margin* of an example $\mathbf{x}$ is defined as the difference between the (cumulated weight or number) of hypotheses labeling $\mathbf{x}$ as positive, and those labeling $\mathbf{x}$ as negative. Like in the SVM framework, the margin of an example reflects the confidence of its classification (how much this example should be perturbed for its label to be modified).

Learning Criteria

Learning criterion and *fitness function* will be used interchangeably in the following. Since Holland's seminal papers on evolutionary learning (Holland 1975, 1986), the most used learning criterion is the predictive accuracy on the available dataset. After the early 1990s however, drawbacks related to either learning or evolutionary issues motivated the design of new fitness functions.

Evolutionary Regularization

In the ▸ genetic programming field, the early use of more sophisticated learning criteria was motivated by the so-called bloat phenomenon (Banzhaf and Langdon 2002; Poli 2008), that is, the uncontrolled growth of the solution size as evolution goes on. Two main approaches have been considered. The first one boils down to regularization (section "Formal Background"): the fitness function is composed of the predictive accuracy plus an additional term meant to penalize large-sized solutions (Blickle 1996). The tricky issue of course is how to adjust the weight of the penalization term; the statistical ML theory offers no principled solution to this issue (except in an asymptotic perspective, when the number of training examples goes to infinity (Gelly et al. 2006)); thus, the weight is adjusted empirically using cross-validation (section "Formal Background").

Another approach (Blickle 1996) is based on the use of two fitness functions during the same evolution run, after the so-called behavioral memory paradigm (Schoenauer and Xanthakis 1993). In a first phase, the population is evolved to maximize the predictive accuracy. In a second phase, the optimization goal becomes to minimize the solution size *while preserving the predictive accuracy* reached in the former phase. As could have been expected, this second approach also depends upon the careful empirical adjustment of hyper-parameters (when to switch from one phase to another one).

Another approach is to consider regularized learning as a multi-objective optimization problem, avoiding the computationally heavy tuning of the regularization weight (Note however that in the case where the regularization involves the L_1 norm of the solution, the Pareto front can be analytically derived using the celebrated LASSO algorithm (Hastie et al. 2004; Tibshirani 1996).). Mierswa (2007) applies multi-objective evolutionary optimization, specifically NSGA-II ((Deb et al. 2000); see the Multi-Objective Evolutionary Optimization entry in this encyclopedia), to the simultaneous optimization of the margin and the error. The search space is nicely and elegantly derived from the dual form of SVMs (section "Support Vector Machines"): it consists of vectors $(\alpha_1, \ldots \alpha_n)$, where most α_i are zero and $\sum_i \alpha_i y_i = 0$. A customized mutation operator, similar in spirit to the sequential minimization optimization proposed by Platt (1999), enables to explore the solutions with few support vectors. The Pareto front shows the trade-off between the regularization term and the training error. At some point however, a hold-out (test set) needs be used to detect and avoid overfitting solutions, boiling down to cross-validation. Another multi-objective optimization learning is proposed by Suttorp and Igel (2006) (see section "AUC: Area Under the ROC Curve").

Ensemble Learning and Boosting

Ensemble learning and evolutionary computation share two main original features. Firstly, both rely on a population of candidate solutions; secondly, the diversity of these solutions commands the effectiveness of the approach. It is no surprise therefore that evolutionary ensemble learning, tightly coupling EC and EL, has been intensively investigated in the last decade (Another exploitation of the hypotheses built along independent evolutionary learning runs concerns feature selection (Jong et al. 2004), which is outside the scope of this entry.)

A family of diversity-oriented learning criteria has been investigated by Xin Yao and collaborators, switching the optimization goal from "learning the best hypothesis" toward "learning the best ensemble" Monirul Islam and Yao (2008). The hypothesis space is that of neural networks (NNs). Nonparametric and parametric operators are used to simultaneously optimize the neural topology and the NN weights. Among parametric operators is the gradient-based backpropagation (BP) algorithm to locally optimize the weights (Rumelhart and McClelland 1990), combined with simulated annealing to escape BP local minima.

Liu et al. (2000) enforce the diversity of the networks using a *negative correlation* learning criterion. Specifically, the BP algorithm is modified by replacing the error of the t-th NN on the i-th example with a weighted sum of this error and the error of the ensemble of the other NNs; denoting H_{-t} the ensemble made of all NNs but the tth one:

$$(h_t(x_i) - y_i)^2 \rightarrow (1-\lambda)(h_t(x_i) - y_i)^2 + \lambda(H_{-t}(x_i) - y_i)^2$$

Moreover, ensemble negative correlation–based learning exploits the fact that not all examples are equal, along the same line as boosting (section "Ensemble Methods"): to each training example is attached a weight, reflecting the number of hypotheses that misclassify it; finally the fitness associated to each network is the sum of the weights of all examples it correctly classifies. While this approach nicely suggests that ensemble learning is a multiple objective optimization (MOO) problem (minimize the error rate and maximize the diversity), it classically handles the MOO problem as a fixed weighted sum of the objectives (the value of parameter λ is fixed by the user).

The MOO perspective is further investigated by Chandra and Yao in the DIVACE system, enforcing the multilevel evolution of ensemble of classifiers (Chandra and Yao 2006a,b). In (Chandra and Yao 2006b), the top-level evolution simultaneously minimizes the error rate (accuracy) and maximizes the negative correlation (diversity). In (Chandra and Yao 2006a), the negative correlation-inspired criterion is replaced by a *pairwise failure crediting*; the difference concerns the misclassification of examples that are correctly classified by other classifiers. Several heuristics have been investigated to construct the ensemble from the last population, based on averaging the hypothesis values, using the (weighted) vote of all hypotheses, or selecting a subset of hypotheses, for example, by clustering the final hypothesis population after their phenotypic distance, and selecting a hypothesis in each cluster.

Gagné et al. (2007) tackle both the construction of a portfolio of classifiers, and the selection of a subset thereof, either from the final population only as in (Chandra and Yao 2006a,b), or from all generations. In order to do so, a reference set of classifiers is used to define a dynamic optimization problem: the fitness of a candidate hypothesis reflects whether h improves on the reference set; in the meantime, the reference set is updated every generation. Specifically, noting *wi* the fraction of reference classifiers misclassifying the i-th example, $\mathcal{F}(h)$ (h) is set to the sum of w_i^γ, taken over all examples correctly classified by h. Parameter γ is used to mitigate the influence of noisy examples.

Boosting and Large-Scale Learning

Another key motivation for designing new learning criteria is to yield scalable learning algorithms, coping with giga or terabytes of data (see Sonnenburg et al. 2008).

Song et al. (2003, 2005) presented an elegant genetic programming approach to tackle the intrusion detection challenge (Lippmann et al. 2000); this challenge offers a 500,000 pattern training set, exceeding standard available RAM capacities. The proposed approach relies on the dynamic subset selection method first presented by Gathercole and Ross (1994). The whole dataset is equally and randomly divided into subsets $\mathcal{E}_i$ with same distribution as the whole dataset, where each $\mathcal{E}_i$ fits within the available RAM. Iteratively, some subset $\mathcal{E}_i$ is selected with uniform probability, and loaded in memory; it is used for a number of generations set to $G_{\max} \times Err(i)$ where $G_{\max}$ is the user-supplied maximum number of generations, and $Err(i)$ is the minimum number of patterns in $\mathcal{E}_i$ misclassified the previous time $\mathcal{E}_i$ was considered. Within $\mathcal{E}_i$, a competition is initiated between training patterns to yield a frugal yet challenging assessment of the hypotheses. Specifically, every generation or so, a restricted subset is selected by tournament in $\mathcal{E}_i$, considering both the difficulty of the patterns (the difficulty of pattern $\mathbf{x}_j$ being the number of hypotheses misclassifying $\mathbf{x}_j$ last time $\mathbf{x}_j$ was selected) and its age (the number of generations since $\mathbf{x}_j$ was last selected). With some probability (30 % in the experiments), the tournament returns the pattern with maximum age; otherwise, it returns the pattern with maximum difficulty.

The dynamic selection subset (DSS) heuristics can thus be viewed as a mixture of uniform sampling (modeled by the age-based selection) and boosting (corresponding to the difficulty-based selection). This mixed distribution gets the best of both worlds: it speeds up learning by putting the stress on the most challenging patterns, akin boosting; in the meanwhile, it prevents noisy examples from leading learning astray as the training set always includes a sufficient proportion of uniformly selected examples. The authors report that the approach yields accurate classifiers (though outperformed by the Challenge winning entry), while one trial takes 15 min on a modest laptop computer (1 GHz Pentium, 256 MB RAM).

Gagné et al., aiming at the scalable optimization of SVM kernels, proposed another use of dynamic selection subset in a coevolutionary perspective (Gagné et al. 2006). Specifically, any kernel induces a similarity on the training set

$$s(\mathbf{x}, \mathbf{x}') = 2K(\mathbf{x}, \mathbf{x}') - K(\mathbf{x}, \mathbf{x}) - K(\mathbf{x}', \mathbf{x}')$$

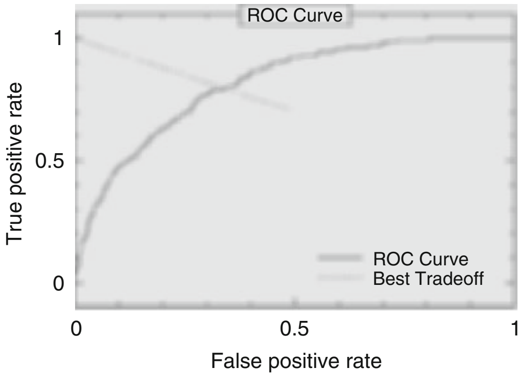
This similarity directly enables the classification of examples along the k-nearest neighbor approach (Duda et al. 2001) (see ▶ Nearest Neighbor), labeling an example after the majority of its neighbors. Inspired from (Gilad-Bachrach et al. 2004), the margin of an example is defined as the rank of its closest neighbor in the same class, minus the rank of its closest neighbor in the other class (the closer a neighbor, the higher its rank is). The larger the margin of an example, the more confident one can be it will be correctly classified; the fitness of the kernel could thus be defined as the sum of the example margins. Computed naively however, this fitness would be quadratic in the size of the training set, hindering the scalability of the approach.

A three-species coevolutionary framework was thus defined. The first species is that of kernels; the second species includes the candidate neighbor instances, referred to as prototypes; the third species includes the training instances, referred to as test cases. Kernels and prototypes undergo a cooperative co-evolution: they cooperate to yield the underlying metric (similarity) and the reference points (prototypes) enabling to classify all training instances. The test cases, in the meanwhile, undergo a competitive coevolution with the other two species: they present the learning process with more and more difficult training examples, aiming at a good coverage of the whole instance space. The approach reportedly yields accurate kernels at a moderate computational cost.

AUC: Area Under the ROC Curve

The misclassification rate criterion is notably ill-suited to problem domains with a minority class. If the goal is to discriminate a rare disease (<1 % of the training set) from a healthy state, the default hypothesis ("everyone is healthy" with 1 % misclassified examples) can hardly be outperformed in terms of predictive accuracy. Standard heuristics accommodating ill-balanced problems involve the oversampling of the minority class, undersampling of the majority class, or cost-sensitive loss function (e.g., misclassifying a healthy person for an ill one costs 1, whereas the opposite costs 100) (Domingos 1999).

Another principled approach is based on the so-called area under the receiver-operating characteristics curve (see ▶ ROC Analysis). Let us consider a continuous hypothesis h, mapping the instance space on the real-value space $\mathbb{R}$. For each threshold τ let the binary classifier h_τ be defined as instance x is positive iff $h(x) > \tau$. To each τ value can be associated the true positive (TP) rate (fraction of ill persons that are correctly classified) and the false positive (FP) rate (fraction of healty persons misclassified as ill ones). In the (FP,TP) plane, the curve drawn as τ varies defines the ROC curve (Fig. 3).



Nonstandard Criteria in Evolutionary Learning, Fig. 3 The receiver operating characteristic (ROC) Curve depicts how the true positive (TP) rate increases vs the false positive (FP) rate. Random guessing corresponds to the diagonal line. The ROC curve is insensitive to ill-balanced distributions as TP and FP rates are normalized

Noting that the ideal classifier lies in the upper left corner (0 % false positive rate, 100 % true positive rate), it comes naturally to optimize the area under the ROC curve. This criterion, also referred to as Wilcoxon rank test, has been intensively studied in both theoretical and algorithmic perspectives (see among many others Cortes and Mohri 2004; Ferri et al. 2002; Joachims 2005; Rosset 2004).

The AUC criterion has been investigated in the EC literature since the 1990s (Fogel et al. 1998), for it defines a combinatorial optimization problem. Considering the search space of real-valued functions, mapping instance space X onto R, the AUC (Wilcoxon) criterion is defined as

$$\mathcal{F}(h) = Pr(h(\mathbf{x}) > h(\mathbf{x}')|y > y')$$

$$\mathcal{F}_e(h) \infty \#\{(\mathbf{x}_i, \mathbf{x}_j) s.t. h(\mathbf{x}_i) > h(\mathbf{x}_j),$$

$$y_i = 1, y_j = 0\}$$

Specifically, hypothesis h is used to rank the instances; any ranking such that all positive instances are ranked before the negative ones gets the optimal AUC. The fitness criterion can be computed with complexity $\mathcal{O}(n \log n)$ where n stands for the number of training instances, by showing that

$$\mathcal{F}_e(h) \infty \sum_{i=1 \ldots n, y_i=1} i \times \text{rank}(i)$$

Interestingly, the optimization of the AUC criterion can be dealt with in the SVM framework, as shown by Joachims (2005), replacing class constraints by inegality constraints (Fig. 2):

$$y_i(< w, \mathbf{x}_i > +b) \geq 1 \; i = 1 \ldots n$$
$$\rightarrow \; < w, \mathbf{x}_i - \mathbf{x}_j > \geq 1 \; i, j = 1 \ldots n, s.t. y_i > y_i$$

In practice, the quadratic optimization process introduces gradually the violated constraints only, to avoid dealing with a quadratic number of constraints.

The flexibility of EC can still allow for more specific and application-driven interpretation of the AUC criterion. Typically in medical applications, the physician is most interested in the beginning of the AUC curve, trying to find a threshold τ retrieving a high fraction of ill patients for a very low false positive rate. The same situation occurs in customer relationship management, replacing positive cases by potential churners. The AUC criterion can be easily adapted to minimize the number of false positive within the top k-ranked individuals, as shown by Mozer et al. (2001).

In a statistical perspective however (and contrarily to a common practice in the ML and data mining communities), it has been argued that selecting a classifier based on its AUC was not appropriate (Hand 2009). The objection is that the AUC maximization yields the best hypothesis *under a uniform distribution of the misclassification costs*, whereas hypothesis h is used with a specific threshold τ, corresponding to a particular point of the ROC curve (Fig. 3).

Still, ROC curves convey very clear intuitions about the trade-off between TP and FP rates; analogous to a Pareto front, they enable one to select a posteriori the best trade-off according to a one's implicit preferences. An interesting approach along these lines has been investigated by Suttorp and Igel (2006) to learn SVMs, using a multi-objective optimization setting to simultaneously minimize the FP rate, and maximize the TP rate, and maximize the number of support vectors.

The last objective actually corresponds to a regularization term: the empirical error plus the number of support vectors upper-bounds the so-called leave-one-out error (when the number of folds in cross-fold validation is set to the number of examples), since the hypothesis is not modified when removing a non-support vectors. (see Zhang (2003) for more detail).

Conclusions

Unsurprisingly, the bottom line of evolutionary learning matches that of EC: any effort to customize the fitness function is highly rewarded; a good knowledge of the domain application enables to choose appropriate, frugal yet effective, search space and variation operators.

Another message concerns the validation of the proposed approaches. In early decades, hypotheses were assessed from their training error, with poor applicative relevance due to overfitting. Better practices are now widely used (e.g., training, validation, and test sets); as advocated by Dietterich (1998), good practices are based on cross-validation. Taking into account early remarks about the University of California Irvine (UCI) repository (Holte 1993), experimental validation should consider actually challenging problems.

Due to space limitations, this entry has excluded some nice and elegant work at the crossroad of machine learning and evolutionary computation, among others, interactive optimization and modelisation of the user's preferences (Llorà et al. 2005), interactive feature construction (Krawiec and Bhanu 2007;

Venturini et al. 1997), or ML-based heuristics for noisy optimization (Heidrich-Meisner and Igel 2009).

NP-Completeness

Definition

A *decision problem* consists in identifying symbol strings, presented as inputs, that have some specified property. The output consists in a yes/no or 0/1 answer. A decision problem belongs to the class P if there exists an algorithm, that is, a deterministic procedure, for deciding any instance of the problem in a length of time bounded by a polynomial function of the length of the input.

A decision problem is in the class NP if it is possible for every yes-instance of the problem to verify in polynomial time, after having been supplied with a polynomial-length *witness*, that the instance is indeed of the desired property.

An example is the problem to answer the question for two given numbers n and m whether n has a divisor d strictly between m and n. This problem is in NP: if the answer is positive, then such a divisor d will be a witness, since it can be easily checked that d lies between the required bounds, and that n is indeed divisible by d. However, it is not known whether this decision problem is in P or not, as it may not be easy to find a suitable divisor d, even if one exists.

The class of *NP-complete* decision problems contains such problems in NP for which if some algorithm decides it, then every problem in NP can be decided in polynomial time. A theorem of Stephen Cook and Leonid Levin states that such decision problems exist. Several decision problems of this class are problems on ▶ graphs.

Observation Language

Hendrik Blockeel
Katholieke Universiteit Leuven, Heverlee, Leuven, Belgium
Leiden Institute of Advanced Computer Science, Heverlee, Belgium

Synonyms

Instance language

Definition

The *observation language* used by a machine learning system is the language in which the observations it learns from are described.

Motivation and Background

Most machine learning algorithms can be seen as a procedure for deriving one or more hypotheses from a set of observations. Both the input (the observations) and the output (the hypotheses) need to be described in some particular language and this language is called the observation language or the ▶ Hypothesis Language respectively. These terms are mostly used in the context of symbolic learning, where these languages are often more complex than in subsymbolic or statistical learning.

C. Sammut, G.I. Webb (eds.), *Encyclopedia of Machine Learning and Data Mining*,
DOI 10.1007/978-1-4899-7687-1

The following sections describe some of the key observation languages.

Attribute-Value Learning

Probably the most used setting in machine learning is the *attribute-value* setting (see ▶ Attribute-Value Learning). Here, an example (observation) is described by a fixed set of attributes, each of which is given a value from the domain of the attribute. Such an observation is often called a vector or, in relational database terminology, a tuple. The attributes are usually atomic (i.e., not decomposable in component values) and single-valued (i.e., an attribute has only one value, not a set of values). So we have an instance space (or space of observations)

$$\mathcal{O} = A_1 \times \cdots \times A_n,$$

elements of which are denoted using an observation language that typically has the same structure:

$$\mathcal{L}_O = \mathcal{L}_{A_1} \times \cdots \times \mathcal{L}_{A_n},$$

(the language contains tuples of objects that represent the attribute values).

The attribute-value framework easily allows for both supervised and unsupervised learning; in the supervised learning setting, the label of an instance is simply included as an attribute in the tuple, where as for unsupervised learning, it is excluded.

The attribute-value setting assumes that all instances can be represented using the same fixed set of attributes. When instances can be of different types or are variable-sized (e.g., when an instance is set-valued), this assumption may not hold, and more powerful languages may have to be used instead.

Learning from Graphs, Trees, or Sequences

We here consider the case in which a single instance is a graph, or a node in a graph. Note that trees and sequences are special cases of graphs.

A graph is defined as a pair (V, E), where V is a set of vertices and E a set of edges each edge being a pair of vertices. If the pair is ordered, the graph is directed; otherwise it is undirected. For simplicity, we restrict ourselves to undirected graphs.

A graph can, in practice, not be encoded in attribute-value format without the loss of information. That is, one could use a number of properties of graphs as attributes in the encoding, but several graphs may then still map onto the same representation, which implies loss of information. In theory, one could imagine defining a total order on (certain classes of) graphs and representing each graph by its rank in that order (which is a single numerical attribute), thus representing graphs as numbers without loss of information; but then it is not obvious how to map patterns in this numerical representation to patterns in the original representation. No such approaches have been proposed till now.

Describing the instance space is more difficult here than in the attribute value case. Consider a task of graph classification, where in observations are of the form (G, y) with G a graph and y a value for a target attribute Y. Then we can define the instance space as

$$\mathcal{O} = \{(V, E) | V \subseteq \mathbf{N} \wedge E \subseteq V^2\} \times Y,$$

where $\mathbf{N}$ is the set of all natural numbers. (For each graph, there exists a graph defined over $\mathbf{N}$ that is isomorphic with it, so $\mathcal{O}$ contains all possible graphs up to isomorphism.)

A straightforward observation language in the case of graph classification is then

$$\begin{aligned}&\{(G, y) | G\\ &\quad = (V, E) \wedge V \subseteq \mathcal{L}_V \wedge E \subseteq V^2 \wedge y \in Y\},\end{aligned}$$

where $\mathcal{L}_V$ is some alphabet for representing nodes.

In learning from graphs, there are essentially two settings: those where a prediction is made for entire graphs, and those where a prediction is made for single nodes in a graph. In the first case, observations are of the form (G, y), where

Observation Language, Fig. 1 A small database of students

as, in the second case, they are of the form (G, v, y), where $G = (V, E)$ and $v \in V$. That is, a node is given together with the graph in which it occurs (its "environment"), and a prediction is to be made for this specific node, using the information about its environment.

In many cases, the set of observations one learns from is of the form (G, v_i, y_i), where each instance is a different node of exactly the same graph G. This is the case when, for instance, classifying web pages, we take the whole web as their environment.

In a labeled graph, labels are associated with each node or edge. Often these are assumed atomic, being elements of a finite alphabet or real numbers, but they can also be vectors of reals.

Relational Learning

In ▸ relational learning, it is assumed that relationships may exist between different instances of the instance space, or an instance may internally consist of multiple objects among which relationships exist.

This essentially corresponds to learning from graphs, except that in a graph only one binary relation exists (the edges E), whereas here there may be multiple relations and they may be non binary. The expressiveness of the two settings is the same, however, as any relation can be represented using only binary relations.

In the attribute-value setting, one typically uses one table where each tuple represents all the relevant information for one observation. In the relational setting, there may be multiple tables, and information on a single instance is contained in multiple tuples, possibly belonging to multiple relations.

Example 1 Assume we have a database about students, courses, and professors (see Fig. 1). We can define a single observation as all the information relevant to one student, that is: the name, year of entrance, etc. of the student and also the courses they take and the professors teaching these courses.

The most obvious link to the graph representation is as follows: create one node for each tuple, labeled with that tuple, and create a link between two nodes if the corresponding tuples are connected by a foreign key relationship.

Defining a single observation as a set of tuples that are connected through foreign keys in the database corresponds to representing each observation (G, v, y) as (G', v, y), where G' is the connected component of G that contains v. The actual links are usually not explicitly written in this representation, as they are implicit: there is an edge between two tuples if they have the same value for a foreign key attribute.

Inductive Logic Programming

In ▸ inductive logic programming, a language based on first order logic is used to represent the observations. Typically, an observation is then represented by a *ground fact*, which basically corresponds to a single tuple in a relational database. In some settings an observation is represented by an *interpretation*, a set of ground facts, which corresponds to the set of tuples mentioned in the previous subsection.

While the target variable can always be represented as an additional attribute, ILP systems often learn from examples and counterexamples of a concept. The target variable is then implicit: it is true or false depending on whether the example is in the positive or negative set, but it is not explicitly included in the fact.

Typical for the inductive logic programming setting is that the input of a system may contain, besides the observations, background knowledge about the application domain. The advantage of the ILP setting is that no separate language is needed for such background knowledge: the same first order logic-based language can be used for representing the observations as well as the background knowledge.

Example 2 *Take the following small dataset*:

```
sibling(bart,lisa).
sibling(lisa,bart).
:- sibling(bart, bart).
:- sibling(lisa, lisa).
father(homer, bart).
mother(marge, bart).
father(homer, lisa).
mother(marge, lisa).
```

There are positive and negative (preceded by :-) examples of the Sibling relation. The following hypothesis might be learned:

```
sibling(X,Y) :- father(Z,X),
father(Z,Y), X ≠ Y.
sibling(X,Y) :- mother(Z,X),
mother(Z,Y), X ≠ Y.
```

If the following clauses as included as background knowledge:

```
parent(X,Y) :- father(X,Y).
parent(X,Y) :- mother(X,Y).
```

then the same ILP system might learn the following more compact definition:

```
sibling(X,Y) :- parent(Z,X),
parent(Z,Y), X ≠ Y.
```

Further Reading

Most of the literature on hypothesis and observation languages is found in the area of inductive logic programming. Excellent starting points to become familiar with this field are *Relational Data Mining* by Džeroski and Lavraè (2001) and *Logical and Relational Learning* by De Raedt (2008).

De Raedt (1998) compares a number of different observation and hypothesis languages with respect to their expressiveness, and indicates relationships between them.

Occam's Razor

Geoffrey I. Webb
Faculty of Information Technology, Monash University, Victoria, Australia

Synonyms

Ockham's Razor

Definition

Occam's Razor is the maxim that "entities are not to be multiplied beyond necessity," or as it is often interpreted in the modern context "of two hypotheses H and H', both of which explain E, the simpler is to be preferred" (Good 1977)

Motivation and Background

Most attempts to learn a model from data confront the problem that there will be many models that are consistent with the data. In order to learn a single model, a choice must be made between the available models. The factors taken into account by a learner in choosing between models are called its learning biases (Mitchell 1980). A preference for simple models is a common learning bias and is embodied in many learning techniques including pruning, minimum message length, and minimum description length. Regularization is also sometimes viewed as an application of Occam's razor.

Occam's razor is an imperative, rather than a proposition. That is, it is neither true nor false. Rather, it is a call to act in a particular way without making any claim about the consequences of doing so. In machine learning the so-called *Occam thesis* is sometimes assumed that: given a choice between two plausible classifiers that perform identically on the training set, the simpler classifier is expected to classify correctly more objects outside the training set. (Webb 1996)

While there are many practical advantages in having a learning bias toward simple models, there remains controversy as to whether the Occam thesis is true (Webb 1996; Domingos 1999; Blumer et al. 1987).

Online Controlled Experiments and A/B Testing

Ron Kohavi[1] and Roger Longbotham[2]
[1]Application Services Group, Microsoft, Bellevue, WA, USA
[2]Data and Decision Sciences Group, Microsoft, Redmond, WA, USA

Abstract

The Internet connectivity of client software (e.g., apps running on phones and PCs), websites, and online services provide an unprecedented opportunity to evaluate ideas quickly using controlled experiments, also called A/B tests, split tests, randomized experiments, control/treatment tests, and online field experiments. Unlike most data mining techniques for finding correlational patterns, controlled experiments allow establishing a causal relationship with high probability. Experimenters can utilize the scientific method to form a hypothesis of the form "If a specific change is introduced, will it improve key metrics?" and evaluate it with real users.

The theory of a controlled experiment dates back to Sir Ronald A. Fisher's experiments at the Rothamsted Agricultural Experimental Station in England in the 1920s, and the topic of offline experiments is well developed in Statistics (Box et al., Statistics for experimenters: design, innovation, and discovery. Wiley, Hoboken, 2005). Online-controlled experiments started to be used in the late 1990s with the growth of the Internet. Today, many large sites, including Amazon, Bing, Facebook, Google, LinkedIn, and Yahoo!, run thousands to tens of thousands of experiments each year testing user interface (UI) changes, enhancements to algorithms (search, ads, personalization, recommendation, etc.), changes to apps, content management system, etc. Online-controlled experiments are now considered an indispensable tool, and their use is growing for startups and smaller websites. Controlled experiments are especially useful in combination with Agile software development (Martin, Clean code: a handbook of Agile software craftsmanship. Prentice Hall, Upper Saddle River, 2008; Rubin, Essential scrum: a practical guide to the most popular Agile process. Addison-Wesley Professional, Upper Saddle River, 2012), Steve Blank's Customer Development process (Blank, The four steps to the epiphany: successful strategies for products that win. Cafepress.com., 2005), and MVPs (minimum viable products) popularized by Eric Ries's Lean Startup (Ries, The lean startup: how today's entrepreneurs use continuous innovation to create radically successful businesses. Crown Business, New York, 2011).

A/B Testing; Randomized Experiments; Split Tests

Motivation and Background

Many good resources are available with motivation and explanations about online-controlled experiments (Siroker and Koomen 2013; Goward 2012; McFarland 2012b; Schrage 2014; Kohavi et al. 2009, 2014, 2013).

We provide a motivating visual example of a controlled experiment that ran at Microsoft's Bing. The team wanted to add a feature allowing advertisers to provide links to the target site. The rationale is that this will improve ads' quality by giving users more information about what the advertiser's site provides and allows users to directly navigate to the subcategory matching their intent. Visuals of the existing ads layout (control) and the new ads layout (treatment) with site links added are shown in Fig. 1.

In a controlled experiment, users are randomly split between the variants (e.g., the two different ads layouts) in a persistent manner (a user receives the same experience in multiple visits). Their interactions with the site are instrumented

Online Controlled Experiments and A/B Testing, Fig. 1 Ads with site link experiment. Treatment (*bottom*) has site links. The difference might not be obvious at first but it is worth tens of millions of dollars

and key metrics computed. In this experiment, the Overall Evaluation Criterion (OEC) was simple: increasing average revenue per user to Bing without degrading key user engagement metrics. Results showed that the newly added site links increased revenue, but also degraded user metrics and page load time, likely because of increased vertical space usage. Even offsetting the space by lowering the average number of mainline ads shown per query, this feature improved revenue by tens of millions of dollars per year with neutral user impact, resulting in extremely high ROI (return on investment).

Running online-controlled experiments is not applicable for every organization. We begin with key tenets, or assumptions, an organization needs to adopt (Kohavi et al. 2013).

Tenet 1: The Organization Wants to Make Data-Driven Decisions and Has Formalized the Overall Evaluation Criterion (OEC)

You will rarely hear someone at the head of an organization say that they don't want to be data-driven, but measuring the incremental benefit to users from new features has costs, and objective measurements typically show that progress is not as rosy as initially envisioned. In any organization, there are many important metrics reflecting revenue, costs, customer satisfaction, loyalty, etc., and very frequently an experiment will improve one but hurt another of these metrics. Having a single metric, which we call the Overall Evaluation Criterion, or OEC, that is at a higher level than these and incorporates the tradeoff among them is essential for organizational decision-making.

An OEC has to be defined, and it should be measurable over relatively short durations (e.g., 2 weeks). The hard part is finding metrics that are measurable in the short-term that are predictive of long term goals. For example, "profit" is not a good OEC, as short-term theatrics (e.g., raising prices) can increase short-term profit, but hurt it in the long run. As shown in *Trustworthy Online Controlled Experiments: Five Puzzling Outcomes Explained* (Kohavi et al. 2012), market share can be a long-term goal, but it is a terrible short-term criterion: making a search engine worse forces people to issue more queries to find an answer, but, like hiking prices, users will find better alternatives long-term. Sessions per user, or repeat visits, is a much better OEC for a search engine. Thinking of the drivers of lifetime value can lead to a strategically powerful OEC (Kohavi et al. 2009). We cannot overemphasize the importance of coming up with a good OEC that the organization can align behind.

Tenet 2: Controlled Experiments Can Be Run and Their Results Are Trustworthy

Not every decision can be made with the scientific rigor of a controlled experiment. For example, you cannot run a controlled experiment on the possible acquisition of one company by another. Hardware devices may have long lead times for manufacturing, and modifications are hard, so controlled experiments with actual users are hard to run on a new phone or tablet. For customer-facing websites and services, changes are easy to make through software, and running controlled experiments is relatively easy.

Assuming you can run controlled experiments, it is important to ensure their trustworthiness. When running online experiments, getting numbers is easy; getting numbers you can trust is hard, and we have had our share of pitfalls and puzzling results (Kohavi et al. 2012, 2010; Kohavi and Longbotham 2010).

Tenet 3: We Are Poor at Assessing the Value of Ideas

Features are built because teams believe they are useful, yet in many domains, most ideas fail to improve key metrics. Only one third of the ideas tested on the Experimentation Platform at Microsoft improved the metric(s) they were designed to improve (Kohavi et al. 2009). Success is even harder to find in well-optimized domains like Bing. Jim Manzi (2012) wrote that at Google, only "about 10 percent of these [controlled experiments, were] leading to business changes." Avinash Kaushik wrote in his Experimentation and Testing primer (Kaushik 2006) that "80 % of the time you/we are wrong about what a customer wants." Mike Moran (2007, 240) wrote that Netflix considers 90 % of what they try to be wrong. Regis Hadiaris from Quicken Loans wrote that "in the five years I've been running tests, I'm only about as correct in guessing the results as a major league baseball player is in hitting the ball. That's right - I've been doing this for 5 years, and I can only "guess" the outcome of a test about 33 % of the time!" (Moran 2008). Dan McKinley at Etsy wrote (McKinley 2013) "nearly everything fails" and "it's been humbling to realize how rare it is for them [features] to succeed on the first attempt. I strongly suspect that this experience is universal, but it is not universally recognized or acknowledged." Finally, Colin McFarland wrote in the book *Experiment!* (McFarland 2012b, 20) "No matter how much you think it's a no-brainer, how much research you've done, or how many competitors are doing it, sometimes, more often than you might think, experiment ideas simply fail."

Not every domain has such poor statistics, but most who have run controlled experiments in customer-facing websites and applications have experienced this humbling reality: we are poor at assessing the value of ideas, and that is the greatest motivation for getting an objective assessment of features using controlled experiments.

Structure of an Experimentation System

Elements of an Experimentation System

The simplest experimental setup is to evaluate a factor with two levels, a control (version A) and a treatment (version B). The control is normally the default version, and the treatment is the change that is tested. Such a setup is commonly called an A/B test. It is commonly extended by having several levels, often referred to as A/B/n split tests. An experiment with multiple factors is referred to as multivariable (or multivariate).

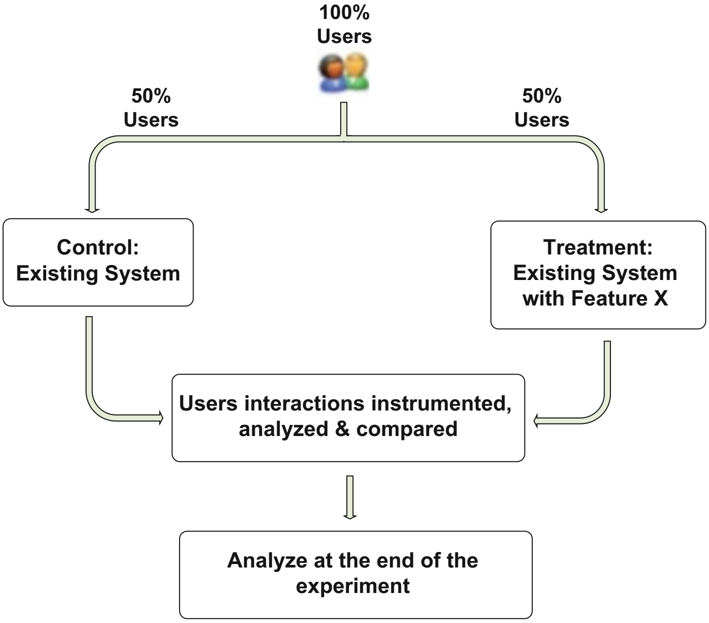
Figure 2 shows the high-level structure of an A/B experiment. In practice, one can assign any percentages to the treatment and control, but 50 % provides the experiment the maximum statistical power, and we recommend maximally powering the experiments after a ramp-up period at smaller percentages to check for egregious errors.

In a general sense, the analysis will test if the statistical distribution of the treatment is different from that of the control. In practice, the most common test is whether the two means are equal or not. For this case, the effect of version B (or treatment effect) is defined to be

$$E(B) = \bar{X}_B - \bar{X}_A \qquad (1)$$

where X is a metric of interest and $\bar{X}_B$ is the mean for variant B. However, for interpretability, the percent change is normally reported with a suitable (e.g., 95 %) confidence interval. See, for example, Kohavi et al. (2009).

Control of extraneous factors and randomization are two essential elements of any experimentation system. Any factor that may affect



Online Controlled Experiments and A/B Testing, Fig. 2 High-level structure of an online experiment

an online metric is either a test factor (one you intentionally vary to determine its effect) or a non-test factor. Non-test factors could either be held fixed, blocked, or randomized. Holding a factor fixed can impact external validity and is thus not recommended. For example, if weekend days are known to be different from week days, you could run the experiment only on weekdays (or weekends), but it would be better to have complete weeks in the experiment for better external validity. Blocking (e.g., pairing) can reduce the variance relative to randomization and is recommended when experimentation units in each block are more homogenous than between blocks. For example, if the randomization unit is a user page view, then blocking by weekend/weekday can reduce the variance of the effect size, leading to higher sensitivity. Time is a critical non-test factor, and because many external factors vary with time, it is important to randomize over time by running the control and treatment(s) concurrently with a fixed percentage to each throughout the experiment. (If the relative percentage changes, you will be subject to Simpson's paradox (Malinas and Bigelow 2009; Kohavi and Longbotham 2010).) Controlling a non-test factor assures it will have equal influence on the control and treatment, hence not affecting the estimate of the treatment effect.

Experimentation Architecture Alternatives

Controlled experiments on the web: survey and practical guide (Kohavi et al. 2009) provides a review of many architecture alternatives. The main three components of an experimentation capability involve the randomization algorithm, the assignment method (i.e., how the randomly assigned experimental units are given the variants), and the data path (which captures raw observation data and processes it). Tang et al. (2010) give a detailed view of the infrastructure for experiments as carried out by Google.

To validate an experimentation system, we recommend that A/A tests be run regularly to test that the experimental setup and randomization mechanism is working properly. An A/A test, sometimes called a null test (Peterson 2004), exercises the experimentation system, assigning users to one of two groups, but exposes them to exactly the same experience. An A/A test can be used to (i) collect data and assess its variability for power calculations and (ii) test the experimentation system (the null hypothesis should be rejected about 5 % of the time when a 95 % confidence level is used) (Kohavi et al. 2009; Martin 2008).

Planning Experiments

Several aspects of planning an experiment are important: estimating adequate sample size, gathering the right metrics, tracking the right users, and randomization unit.

Sample size. Sample size is determined by the percent of users admitted into the experiment variants (control and treatments) and how long the experiment runs. As an experiment runs longer, more visitors are admitted into the variants, so sample sizes increase. Experimenters can choose the relative percent of visitors that are in the control and treatment which affects how long you will need to run the experiment. Several authors (Deng et al. 2013; Kohavi et al. 2009) have addressed the issue of sample size and length of experiment in order to achieve adequate statistical power for an experiment, where statistical power of an experiment is the probability of detecting a given effect when it exists (technically, the probability of correctly rejecting the null hypothesis when it is false). In addition to planning an experiment for adequate power, a best practice is to run the experiment for at least one week (to capture a full weekly cycle) and then multiple weeks beyond that. When "novelty" or "primacy" effects are suspected (i.e., the initial effect of the treatment is not the same as the long-term effect), the experiment should be run long enough to estimate the asymptotic effect of the treatment. Finally, measuring the effect on high-variance metric, such as loyalty (sessions/user), will generally require more users than for other metrics (Kohavi et al. 2012).

Observations, Metrics, and the OEC. Gathering observations (i.e., logging events) so that the right metrics can be computed is critical to successful experimentation. Whenever possible and economically feasible, one should gather as many observations as possible that relate to answering potential questions of interest, whether user related or performance related (e.g., latency, utilization, crashes). We recommend computing many metrics from the observations (e.g., hundreds) because they can give rise to surprising insights, although care must be taken to correctly understand and control for the false-positive rate (Kohavi et al. 2013; Hochberg and Benjamini 1995). While having many metrics is great for insights, decisions should be made using the Overall Evaluation Criterion (OEC). See Tenet 1 earlier for a description of the OEC.

Triggering. Some treatments may be relevant to all users who come to a website. However, for many experiments, the difference introduced is relevant for a subset of visitors (e.g., a change to the checkout process, which only 10 % of visitors start). In these cases, it is best to include only those visitors who would have experienced a difference in one of the variants (this commonly requires counterfactual triggering for the control). Some architectures (Kohavi et al. 2009) trigger users into an experiment either explicitly or using lazy (or late-bound) assignment. In either case, the key is to analyze only the subset of the population that was potentially impacted. Triggering reduces the variability in the estimate of treatment effect, leading to more precise estimates. Because the diluted effect is often of interest, the effect can then be diluted (Deng and Hu 2015).

Randomization Unit. Most experiments use the visitor as the randomization unit for several reasons. First, for many changes being tested, it is important to give the user a consistent online experience. Second, most experimenters evaluate metrics at the user level, such as sessions per user and clicks per user. Ideally, the randomization by the experimenter is by a true user, but in many unauthenticated sites, a cookie stored by the user's browser is used, so in effect, the randomization unit is the cookie. In this case, the same user will appear to be different users if she comes to the site using a different browser, different device, or having deleted her cookie during the experiment. The next section will discuss how the choice of randomization unit affects how the analysis of different metrics should be carried out. The randomization unit can also affect the power of the test for some metrics.

For example, Deng et al. (2011) showed that the variance of page level metrics can be greatly reduced if randomization is done at the page level, but user metrics cannot be computed in such cases. In social-network settings, spillover effects violate the standard no-interference assumption, requiring unique approaches, such as clustering (Ugander et al. 2013).

Analysis of Experiments

If an experiment is carried out correctly, the analysis should be a straightforward application of well-known statistical methods. Of course, this is much preferred than trying to recover from a poor experimental design or implementation.

Confidence Intervals. Most reporting systems will display the treatment effect (actual and percent change) along with suitable confidence intervals. For reasonably large sample sizes, generally considered to be thousands of users in each variant, the means may be considered to have normal distributions (see Kohavi et al. (2014) for detailed guidance), making the formation of confidence intervals routine. However, care must be taken to use the Fieller theorem formula (Fieller 1954) for percent effect since there is a random quantity in the denominator.

Decision-making. A common approach to deciding if the treatment is better than the control is the usual hypothesis-testing procedure, assuming the normal distribution if the sample size is sufficient (Kohavi et al. 2009). Alternatives to this when normality cannot be assumed are transformations of the data (Bickel and Doksum 1981) and nonparametric or resampling/permutation methods to determine how unusual the observed sample is under the null hypothesis (Good 2005). When conducting a test of whether the treatment had an effect or not (e.g., a test of whether the treatment and control means are equal), a p value of the statistical test is often produced as evidence. More precisely, the p value is the probability to obtain an effect equal to or more extreme than the one observed, presuming the null hypothesis of no effect is true (Biau et al. 2010).

Another alternative is to use Bayes' theorem to calculate the posterior odds that the treatment had a positive impact versus the odds it had no impact (Stone 2013).

Analysis Units. Metrics may be defined with different analysis units, such as user, session, or other appropriate bases. For example, an ecommerce site may be interested in metrics such as revenue per user, revenue per session, or revenue per purchaser. Straightforward statistical methods (e.g., the usual t-test and variants) apply to any metric that has user as its analysis unit if users are the unit of randomization since users may be considered independent. However, if the analysis unit is not the same as the randomization unit, the analysis units may not be considered independent, and other methods need to be used to calculate standard deviation or to compare treatment to control. Bootstrapping (Efron and Tibshirani 1993) and the delta method (Casella and Berger 2001) are two commonly used methods when the analysis unit is not the same as the randomization unit.

Variance Reduction. Increasing the sample size is one way to increase power. However, online researchers are continually looking for ways to increase the power of their experiments while shortening, or at least not extending, the length of the tests. One way to do this is to use covariates such as pre-experiment user metrics, user demographics, location, equipment, software, connection speed, etc. (Deng et al. 2013) gave an example where a 50 % reduction in variance for a metric could be achieved by using only the pre-experiment metric values for the users.

Diagnostics. In order to assure the experimental results are trustworthy, every experimentation system should have some diagnostic tools built in. Graphs of the number of users in each variant, metric means, and treatment effects over time will help the researcher see unexpected problems or upsets to the experiment. In addition, diagnostic tests that trigger an alarm when an expected condition is not met should be built in. One critical diagnostic test is the "sample ratio mismatch" or SRM. A simple statistical test checks if the actual percentage for each variant is close enough to the planned percentages. We have found this one diagnostic is frequently the "canary in the coal mine" for online experiments. There are many possible ways an experiment can skew the number of visitors to one variant or another, and many of them will cause a large bias in the treatment effect. Another common useful test is that the performance, or latency, of the two versions is similar when expected to be so. It some cases, the treatment may be slower due to caching issues (e.g., cold start), or if the variant are unbalanced (e.g., 90/10 %), a shared resource like an LRU cache (Least Recently Used) will give an advantage to the larger variant (Kohavi and Longbotham 2010). When an experimentation platform allows overlapping experiments, a diagnostic to check for interactions between overlapping experiments is also helpful. Anytime an alarm or graph indicates a potential problem, the researcher should investigate to determine the source.

Robot Removal. Robots must be removed from any analysis of web data since their activity can severely bias experiment results; see Kohavi et al. (2009). Some robots may slip through robot-filtering techniques and should be considered when diagnostics suggest there may be a problem with the experiment.

Summary

The Internet and online connectivity of client software, websites, and online services provide a fertile ground for scientific testing methodology. Online experimentation is now recognized as a critical tool to determine whether a software or design change should be made. The benefit of experimenting online is the ability to set up a software platform for conducting the tests, which makes experimentation much more scalable and efficient and allows evaluating ideas quickly.

Online Learning

Peter Auer
Department of Information Technology,
University of Leoben, Leoben, Austria

Abstract

Online learning and its variants are one of the main models of computational learning theory, complementing statistical PAC learning and related models. An online learner needs to make predictions about a sequence of instances, one after the other, and receives feedback after each prediction. The performance of the online learner is typically compared to the best predictor from a given class, often in terms of its excess loss (the regret) over the best predictor. Some of the fundamental online learning algorithms and their

variants are discussed: weighted majority, follow the perturbed leader, follow the regularized leader, the perceptron algorithm, the doubling trick, bandit algorithms, and the issue of adaptive versus oblivious instance sequences. A typical performance proof of an online learning algorithm is exemplified for the perceptron algorithm.

Synonyms

Mistake-bounded learning; Prediction with expert advice; Sequential learning

Definition

In the online learning model, the learner needs to make predictions or choices about a sequence of instances, one after the other, and receives a loss or reward after each prediction or choice. Typically, the learner receives a description of the current instance before making a prediction. The goal of the learner is to minimize its accumulated losses (or equivalently maximize the accumulated rewards).

The performance of the online learner is usually compared to the best predictor in hindsight from a given class of predictors. This comparison with a predictor in hindsight allows for meaningful performance bounds even without any assumptions on how the sequence of instances is generated. In particular, this sequence of instances may not be generated by a random process but by an adversary that tries to prevent learning.

In this sense performance bounds for online learning are typically worst-case bounds that hold for any sequence of instances. This is possible since the performance bounds are relative to the best predictor from a given class. Often these performance guarantees are quite strong, showing that the learner can do nearly as well as the best predictor from a large class of predictors.

Motivation and Background

Online learning is one of the main models of learning theory, complementing the statistical approach of the PAC learning model by allowing a more general process for generating learning instances. The distinctive properties of the online learning model are:

- Learning proceeds in trials,
- There is no designated learning phase, the performance of the learner is evaluated continuously from the start,
- No assumptions on the generation of the inputs to the learner are necessary; they may depend even adversarially on previous predictions of the learner,
- Sequential predictions model an interaction between the learner and its environment,
- Performance guarantees for learning algorithms are typically relative to the performance of the best predictor in hindsight from some given class.

The first explicit models of online learning were proposed by Angluin (1988) and Littlestone (1988), but related work on repeated games by Hannan (1957) dates back to 1957. Littlestone proposed online learning as a sequence of trials, where in each the learner receives some input, makes a prediction of the associated output, and receives the correct output. It was assumed that some function from a known class maps the inputs to correct outputs. The performance of the learner is measured by the number of mistakes made by a learner, before it converges to the correct predictor. Angluin's equivalence query model of learning is formulated differently but is essentially equivalent to Littlestone's model.

The restriction that some function from the class must predict all outputs correctly was then removed, e.g., Vovk (1990) and Littlestone and Warmuth (1994). In their setting the learner competes with the best predictor from the given class. As the class of predictors can be seen as a set of experts advising the learner about the correct predictions, this led to the term “prediction with expert advice." A comprehensive treatment of binary predictions with expert advice can be found in Cesa-Bianchi et al. (1997). Relations of online learning to several other fields (e.g., compression, competitive analysis, game theory, and portfolio selection) are discussed in the excellent book on sequential prediction by Cesa-Bianchi and Lugosi (2006).

Structure of Learning System

The online learning model is formalized as follows. In each trial $t = 1, 2, \ldots$, the learner

1. Receives input $x_t \in X$,
2. Chooses a prediction or output $y_t \in Y$,
3. Receives response $z_t \in Z$,
4. Incurs loss $\ell_t = \ell(y_t, z_t)$,

where $\ell : Y \times Z \mapsto \mathbb{R}$ is some loss function. The performance of a learner up to trial T is measured by its accumulated loss $L_T = \sum_{t=1}^{T} \ell_t$. For now it is assumed that inputs x_t and responses z_t are independent from the learner's predictions y_t. Such sequences of instances are called *oblivious* to the learner. *Adaptive* sequences of instances will be discussed later.

Performance bounds for online learning algorithms are typically in respect to the performance of an optimal predictor (or expert) E^* in hindsight from some class $\mathcal{E}$, $E^* \in \mathcal{E}$. A predictor E maps the past given by $(x_1, y_1, z_1), \ldots, (x_{t-1}, y_{t-1}, z_{t-1})$ and the current input x_t to a prediction y_t^E. As for the learner, the performance of a predictor is measured by its accumulated loss $L_T^E = \sum_{t=1}^{T} \ell_t^E$, where $\ell_t^E = \ell(y_t^E, z_t)$. Most bounds for the loss of online algorithms are of the form

$$L_T \leq a \min_{E \in \mathcal{E}} L_T^E + b\mathcal{C}(\mathcal{E}),$$

where the constants a and b depend on the loss function and $\mathcal{C}(\mathcal{E})$ measures the complexity of the class of predictors (e.g., the complexity $\mathcal{C}(\mathcal{E})$ could be $\log |\mathcal{E}|$ for a finite class $\mathcal{E}$.) Often it is possible to trade the constant a against the constant b such that bounds

$$L_T \leq L_T^* + o(L_T^*)$$

can be achieved, where $L_T^* = \min_{E \in \mathcal{E}} L_T^E$ is the loss of the best predictor in hindsight up to time T. These bounds are of particular interest as they show that the loss of the learning algorithm is only little larger than the loss of the best predictor. For such bounds the regret R_T of the learning algorithm,

$$R_T = L_T - L_T^*,$$

is the relevant quantity that measures the cost of not knowing the best predictor in advance.

The next section makes this general definition of online learning more concrete by presenting some important online learning algorithms.

Theory/Solution

The Weighted Majority Algorithm

The weighted majority algorithm developed by Littlestone and Warmuth (1994) is one of the fundamental online learning algorithms, with many relatives using similar ideas. We will present it for the basic scenario with a finite set of experts $\mathcal{E}$, binary predictions $y_t \in \{0, 1\}$, binary responses $z_t \in \{0, 1\}$, and the discrete loss which just counts mistakes, $\ell(y, z) = |y - z|$, such that $\ell(y, z) = 0$ if $y = z$ and $\ell(y, z) = 1$ if $y \neq z$. (We will use the terms experts and predictors interchangeably. In the literature finite sets of predictors are often called experts.)

The weighted majority algorithm maintains a weight w_t^E for each expert $E \in \mathcal{E}$ that is initialized as $w_1^E = 1$. The weights are used to combine the predictions y_t^E of the experts by a weighted majority vote: $y_t = 1$ if $\sum_E w_t^E y_t^E \geq \frac{1}{2} \sum_E w_t^E$, and $y_t = 0$ otherwise. After receiving the response z_t, the weights of experts that made incorrect predictions are reduced by multiplying with some constant $\beta < 1$, $w_{t+1}^E = \beta w_t^E$ if $y_t^E \neq z_t$, and $w_{t+1}^E = w_t^E$ if $y_t^E = z_t$. As a performance bound for the weighted majority algorithm one can achieve

$$L_T \leq 2L_T^* + 2\sqrt{2L_T^* \log |\mathcal{E}|} + 4 \log |\mathcal{E}|$$

with $L_T^* = \min_{E \in \mathcal{E}} L_T^E$ and an appropriate β. (Better constants on the square root and the logarithmic term are possible.)

While in this bound the loss of the deterministic weighted majority algorithm is twice the loss of the best expert, the randomized version of the weighted majority algorithm almost achieves the loss of the best expert. Instead of using a deterministic prediction, the randomized weighted majority algorithm tosses a coin and predicts $y_t = 1$ with probability $\sum_E w_t^E y_t^E / \sum_E w_t^E$. Below we prove the following bound on the expected loss of the randomized algorithm:

$$\mathbb{E}\left[L_T\right] \le \frac{\log(1/\beta)}{1-\beta} L_T^* + \frac{1}{1-\beta} \log|\mathcal{E}|. \quad (1)$$

Approximately optimizing for β yields $\beta = 1 - \varepsilon$, where $\varepsilon = \min\{1/2, \sqrt{2(\log|\mathcal{E}|)/L_T^*}\}$, and

$$\mathbb{E}\left[L_T\right] \le L_T^* + \sqrt{2L_T^* \log|\mathcal{E}|} + 2\log|\mathcal{E}|. \quad (2)$$

The expectation in these bounds is only in respect to the randomization of the algorithm, no probabilistic assumptions on the experts or the sequence of responses are made. These bounds hold for any set of experts and any oblivious sequence of responses that does not depend on the randomization of the algorithm. It can be even shown that the following similar bound holds with probability $1 - \delta$ (in respect to the randomization of the algorithm):

$$L_T \le L_T^* + \sqrt{T \log(|\mathcal{E}|/\delta)}. \quad (3)$$

The proof of bound (1) shows many of the ideas used in the proofs for online learning algorithms. Key ingredients are a potential function and how the changes of the potential function relate to losses incurred by the learning algorithm. For the weighted majority algorithm, a suitable potential function is the sum of the weights, $W_t = \sum_E w_t^E$. Then, since the losses are 0 or 1,

$$\begin{aligned} \frac{W_{t+1}}{W_t} &= \frac{\sum_E w_{t+1}^E}{\sum_E w_t^E} = \frac{\sum_E \beta^{\ell_t^E} w_t^E}{\sum_E w_t^E} \\ &= \frac{\sum_E [1 - (1-\beta)\ell_t^E] w_t^E}{\sum_E w_t^E} \\ &= 1 - (1-\beta) \frac{\sum_E \ell_t^E w_t^E}{\sum_E w_t^E}. \end{aligned} \quad (4)$$

Since the probability that the randomized weighted majority algorithm makes a mistake is given by $\mathbb{E}\left[\ell_t\right] = \sum_E \ell_t^E w_t^E / \sum_E w_t^E$, we get by taking logarithms that

$$\begin{aligned} \log W_{t+1} - \log W_t &= \log(1 - (1-\beta)\mathbb{E}\left[\ell_t\right]) \\ &\le -(1-\beta)\mathbb{E}\left[\ell_t\right] \end{aligned} \quad (5)$$

(since $\log(1-x) \le -x$ for $x \in (0,1)$). Summing over all trials $t = 1, \ldots, T$, we find

$$\log W_{T+1} - \log W_1 \le -(1-\beta)\mathbb{E}\left[L_t\right].$$

Since $W_1 = |\mathcal{E}|$ and $W_{T+1} = \sum_E w_{T+1}^E = \sum_E \beta^{L_T^E} \ge \beta^{L_T^*}$, rearranging the terms gives (1).

Extensions and Modifications of the Weighted Majority Algorithm

Variants and improved versions of the weighed majority algorithm have been analyzed for various learning scenarios. An excellent coverage of the material can be found in Cesa-Bianchi and Lugosi (2006). In this section we mention a few of them.

General loss functions. The analysis of the weighted majority algorithm can be generalized to any convex set of predictions Y and any set of outcomes Z, as long as the loss function $\ell(y, z)$ is bounded and convex in the first argument. Typically it is possibly to derive a learning algorithm with loss bound

$$L_T \le aL_T^* + b \log|\mathcal{E}|$$

for suitable values a and b. Of particular interest is the smallest b for which a loss bound with $a =$

1 can be achieved. Some algorithms for convex prediction sets Y will be discussed later.

Tracking the best expert and other structured experts. For a large number of experts, the loss bound of the weighted majority algorithm is still interesting since it scales only logarithmically with the number of experts. Nevertheless, the weighted majority algorithm and other online learning algorithms become computationally demanding as they need to keep track of the performance of all experts (computation time scales linearly with the number of experts). If the experts exhibit a suitable structure, then this computational burden can be avoided.

As an example we consider the problem of tracking the best expert. Let $\mathcal{E}_0$ be a small set of base experts. The learning algorithm is required to compete with the best sequence of at most S experts from $\mathcal{E}_0$: the trials are divided into S periods, and in each period another expert might predict optimally. Thus the minimal loss of a sequence of S experts is given by

$$L^*_{T,S} = \min_{0=T_0\le T_1\le T_2\le\cdots\le T_S=T} \sum_{i=1}^{S} \min_{E\in\mathcal{E}_0} \sum_{t=T_{i-1}+1}^{T_i} \ell_t^E,$$

where the trials are optimally divided into S periods $[T_{i-1}+1, T_i]$, and the best base expert is chosen for each period. Such sequences of base experts can be seen as experts themselves, but the number of such compound experts is $\binom{T-1}{S-1}|\mathcal{E}_0|^S$ and thus computationally prohibitive. Fortunately, a slightly modified weighted majority algorithm applied to the base experts achieves almost the same performance as the weighted majority algorithm applied to the compound experts. The modification of the weighted majority algorithm just lower bounds the relative weight of each base expert. This allows the relative weight of a base expert to grow large quickly if this expert predicts best in the current period. Hence, also the learning algorithm will predict almost optimally in each period. A recent and improved version of the weighted majority algorithm with many related references is given in Luo and Schapire (2015).

Other examples of structured experts include tree experts and shortest path problems (see Cesa-Bianchi and Lugosi (2006) for further references). For the shortest path problem in a graph, the learner has to compete with the single best path in hindsight, while edge costs may change at each time t. In principle the weighted majority algorithm could be employed with one expert for each path, but since the number of paths is usually exponential in the size of the graph, this might be computationally infeasible. Instead, the *follow the perturbed leader* strategy can be used as an alternative to the weighted majority algorithm.

Follow the perturbed leader. This is a simple prediction strategy that was originally proposed by Hannan (1957). In each trial t, it generates identically distributed random values ψ_t^E for every expert E, adds these random values to the losses of the experts so far, and predicts with the expert that achieves the minimum sum,

$$\hat{E}_t = \arg\min_{E\in\mathcal{E}} L_{t-1}^E + \psi_t^E,$$

$$y_t = y_t^{\hat{E}_t}.$$

For carefully chosen distributions of the ψ_t^E, this prediction strategy achieves loss bounds similar to the weighted majority like algorithms.

To apply this strategy to the shortest path problem described above, it is assumed that all paths have an equal number of edges (by possibly adding dummy edges). Then instead of generating random values ψ_t^E for each path E, a random value for each edge is generated, and the value ψ_t^E for a path is given by the sum of the random values for its edges. This allows to find the best path $\hat{E}_t$ efficiently by a shortest path calculation according to the accumulated and randomly modified edge costs.

The doubling trick. The optimal choice of β in the performance bound (1) requires knowledge about the loss of the best expert L_T^*. If such knowledge is not available, the doubling trick can be used. The idea is to start with an initial guess $\hat{L}^*$ and choose β according to this guess. When the loss of the best expert exceeds this guess, the guess is doubled, β is modified, and the learning algorithm is restarted. The bound (2) increases only slightly when L_T^* is not known and the doubling trick is used. It can be shown that still

$$\mathbb{E}[L_T] \leq L_T^* + c_1\sqrt{L_T^* \log|\mathcal{E}|} + c_2 \log|\mathcal{E}|$$

for suitable constants c_1 and c_2. A thorough analysis of the doubling trick can be found in Cesa-Bianchi et al. (1997). Variations of the doubling trick can be used for many online learning algorithms to "guess" unknown quantities. A drawback of the doubling trick is that it restarts the learning algorithm and forgets about all previous trials. An alternative approach is an iterative adaptation of the parameter β, which can be shown to give better bounds than the doubling trick. The advantage of the doubling trick is that its analysis is quite simple.

Prediction with limited feedback and the multiarmed bandit problem. In the setting considered so far, the learner has full information of the past, as all past outcomes $z_1, \ldots, z_{t-1} \in \{0, 1\}$ and all predictions of the experts $y_1^E, \ldots, y_t^E$, $E \in \mathcal{E}$, are available, before prediction y_t is made. In some learning scenarios, the learner might not have such full information. One example is the multiarmed bandit problem, and a more general case is *prediction with partial monitoring*.

In the multiarmed bandit problem the learner chooses to follow one of K experts, observes the loss of this expert, and also incurs the loss of this expert. Formally, the learner chooses an expert $y_t = E_t \in \mathcal{E} = \{1, \ldots, K\}$, receives the loss of the chosen prediction $z_t = \ell_t(E_t)$, and incurs loss $\ell(y_t, z_t) = z_t = \ell_t(E_t)$. (Here $\ell_t(E)$ denotes the loss of expert E at time t.) The losses of the other experts, $\ell_t(E)$, $E \neq E_t$, are not revealed to the learner. The goal of the learner is to compete with the loss of the single best expert, $L_T^* = \min_{E \in \mathcal{E}} L_T^E$, $L_T^E = \sum_{t=1}^T \ell_t(E)$. The multiarmed bandit problem looks very much like the original online learning problem with the predictions $y \in Y$ as experts.

Since at each time t the learner observes only the loss of the chosen expert, it needs to estimate the unseen losses of the other experts and use these estimates when choosing an expert. Since accurate estimates need a sufficient amount of data, this leads to a trade-off between choosing the (apparently) best expert to minimize losses and choosing a different expert for which more data are needed. This exploration-exploitation trade-off also appears elsewhere in online learning, but it is most clearly displayed in the bandit problem. An algorithm that deals well with this trade-off is again a simple variant of the weighted majority algorithm. This algorithm does exploration trials with some small probability, and in such exploration trials, it chooses an expert uniformly at random. This algorithm has been analyzed in Auer et al. (2002) for gains instead of losses. For losses $\ell \in [-1, 0]$ the accumulated loss of the algorithm can be bounded as

$$\mathbb{E}[L_T] \leq L_T^* + 3\sqrt{K|L_T^*| \log K}.$$

Compared with (2), the regret increases only by a factor of $\sqrt{K}$. Further results, including lower bounds and results for stochastic bandit problems, are summarized in Bubeck and Cesa-Bianchi (2012). For the stochastic multiarmed bandit problem, it is assumed that the losses of the experts are generated independently at random by some distribution for each expert. This allows for specialized algorithms with substantially improved regret bounds.

A generalization of bandit problems are partial monitoring games (Bartók 2014), where the learner receives only indirect feedback about the losses of the experts. Depending on how much the feedback reveals about the incurred losses, partial monitoring games can be classified as games with either 0, $\Theta(T^{1/2})$, $\Theta(T^{2/3})$, or $\Theta(T)$ regret.

The Perceptron Algorithm

In this section we consider an example for an online learning algorithm that competes with a *continuous* set of experts, in contrast to the *finite* sets of experts we have considered so far. This algorithm—the perceptron algorithm (Rosenblatt 1958)—was among the first online learning algorithms developed. Another of this early online learning algorithms with a continuous set of experts is the Winnow algorithm by Littlestone (1988). A unified analysis of these algorithms can be found in Cesa-Bianchi and Lugosi (2006). This analysis covers a large class of algorithms, in particular the p-norm perceptrons, which smoothly interpolate between the perceptron algorithm and Winnow.

The perceptron algorithm aims at learning a linear classification function. Thus inputs are from a Euclidean space, $X = \mathbb{R}^d$, the predictions and responses are binary, $Y = Z = \{0, 1\}$, and the discrete misclassification loss is used. Each expert is a linear classifier, represented by its weight vector $v \in \mathbb{R}^d$, whose linear classification is given by $\Phi_v : X \to \{0, 1\}$, $\Phi_v(x) = 1$ if $v \cdot x \geq 0$ and $\Phi_{v,\theta}(x) = 0$ if $v \cdot x < 0$.

The perceptron algorithm maintains a weight vector $w_t \in \mathbb{R}^d$ that is initialized as $w_1 = (0, \ldots, 0)$. After receiving input x_t, the perceptron's prediction is calculated using this weight,

$$y_t = \Phi_{w_t}(x_t),$$

and the weight vector is updated,

$$w_{t+1} = w_t + \eta(z_t - y_t)x_t,$$

where $\eta > 0$ is a learning rate parameter. Thus, if the prediction is correct, $y_t = z_t$, then the weights are not changed. Otherwise, the product $w_{t+1} \cdot x_t$ is moved into the correct direction: since $w_{t+1} \cdot x_t = w_t \cdot x_t + \eta(z_t - y_t)||x_t||^2$, $w_{t+1} \cdot x_t > w_t \cdot x_t$ if $y_t = 0$ but $z_t = 1$, and $w_{t+1} \cdot x_t < w_t \cdot x_t$ if $y_t = 1$ but $z_t = 0$.

We may assume that the inputs are normalized, $||x_t|| = 1$, otherwise a normalized x_t can be used in the update of the weight vector. Furthermore, we note that the learning rate η is irrelevant for the performance of the perceptron algorithm, since it scales only the size of the weights but does not change the predictions. Nevertheless, we keep the learning rate since it will simplify the analysis.

Analysis of the perceptron algorithm. To compare the perceptron algorithm with a fixed (and optimal) linear classifier v, we again use a potential function, $||w_t - v||^2$. For the change of the potential function when $y_t \neq z_t$, we find

$$\begin{aligned} &||w_{t+1} - v||^2 - ||w_t - v||^2 \\ &= ||w_t + \eta(z_t - y_t)x_t - v||^2 - ||w_t - v||^2 \\ &= ||w_t - v||^2 + 2\eta(z_t - y_t)(w_t - v) \cdot x_t \\ &+ \eta^2(z_t - y_t)^2\, ||x_t||^2 - ||w_t - v||^2 \\ &= 2\eta(z_t - y_t)(w_t \cdot x_t - v \cdot x_t) + \eta^2. \end{aligned}$$

Since $w_t \cdot x_t < 0$ if $y_t = 0$ and $w_t \cdot x_t \geq 0$ if $y_t = 1$, we get $(z_t - y_t)(w_t \cdot x_t) \leq 0$ and

$$||w_{t+1} - v||^2 - ||w_t - v||^2 \leq -2\eta(z_t - y_t)(v \cdot x_t) + \eta^2.$$

Analogously, the linear classifier v makes a mistake in trial t if $(z_t - y_t)(v \cdot x_t) < 0$, and in this case $-(z_t - y_t)(v \cdot x_t) \leq ||v||$. Hence, summing over all trials (where $y_t \neq z_t$) gives

$$\begin{aligned} &||w_{T+1} - v||^2 - ||w_1 - v||^2 \leq -2\eta \\ &\sum_{t:\ell_t = 1, \ell_t^v = 0} |v \cdot x_t| + 2\eta||v||L_T^v + \eta^2 L_T, \qquad (6) \end{aligned}$$

where the sum is over all trials where the perceptron algorithm makes a mistake but the linear classifier v makes no mistake. To proceed, we assume that for the correct classifications of the linear classifier v, the product $v \cdot x_t$ is bounded away from 0 (which describes the decision boundary). We assume $|v \cdot x_t| \geq \gamma_v > 0$. Then

$$\begin{aligned} ||w_{T+1} - v||^2 - ||w_1 - v||^2 &\leq -2\eta\gamma_v(L_T - L_T^v) \\ &+ 2\eta||v||L_T^v + \eta^2 L_T, \qquad (7) \end{aligned}$$

and

$$L_T(2\eta\gamma_v - \eta^2) \leq ||v||^2 + L_T^v(2\eta\gamma_v + 2\eta||v||),$$

since $||w_{T+1} - v||^2 \geq 0$ and $w_1 = (0, \ldots, 0)$. For $\eta = \gamma_v$ the following loss bound for the perceptron algorithm is achieved:

$$L_T \leq ||v||^2/\gamma_v^2 + 2L_T^v(1 + ||v||/\gamma_v).$$

Thus the loss of the perceptron algorithm does not only depend on the loss of an (optimal) linear classifier v but also on the gap by which the classifier can separate the inputs with $z_t = 0$ from the inputs with $z_t = 1$. The size of this gap is essentially given by $\gamma_v/||v||$.

Relation between the perceptron algorithm and support vector machines. The gap $\gamma_v/||v||$ is the quantity maximized by support vector machines, and it is the main factor determining the prediction accuracy (in a probabilistic sense) of a support vector machine. It is not coincidental that the same quantity appears in the performance bound of the perceptron algorithm, since it measures the difficulty of the classification problem.

As for support vector machines, kernels $K(\cdot,\cdot)$ can be used in the perceptron algorithm. For that, the dot product $w_t \cdot x_t$ is replaced by the kernel representation $\sum_{\tau=1}^{t-1}(z_\tau - y_\tau)K(x_\tau, x)$. Obviously this has the disadvantage that all previous inputs for which mistakes were made must be kept available.

Online Convex Optimization

For online convex optimization, the learner has to choose a prediction y_t from some convex set Y, receives as feedback a convex loss function $L_t : Y \to \mathbb{R}$, and suffers loss $\ell_t = L_t(y_t)$. An excellent exposition of online convex optimization is given in Shalev-Shwartz (2011).

Many online learning problems and algorithms can be cast in the framework of online convex optimization, in particular also the weighted majority algorithm and the perceptron algorithm. While both algorithms make binary predictions $y_t \in \{0, 1\}$ and suffer a discrete loss, they both can be *convexified*: For the weighted majority algorithm we can consider the probability p_t for $y_t = 1$ as the prediction of the algorithm, such that the expected loss is $\mathbb{E}\ell(y_t, z_t) = |z_t - p_t|$ which is a convex function in p_t. For the perceptron algorithm, the discrete loss can be upper bounded by a convex *surrogate loss function*, and the loss analysis can be done in respect to these surrogate loss functions.

Two simple but often effective strategies for online convex optimization are *follow the leader* and *follow the regularized leader*. The *follow the leader* strategy chooses the prediction that would minimize the accumulated loss so far,

$$y_t = \arg\min_{y \in Y} \sum_{i=1}^{t-1} L_i(y).$$

For some online convex optimization problems, this gives very good regret bounds, in particular for online quadratic optimization, where $Y = \mathbb{R}^d$ and $L_t(y) = ||y - z_t||^2$ is the squared Euclidean distance to some $z_t \in \mathbb{R}^d$. It can be shown that in this case, the regret is bounded by

$$\min_y \sum_{t=1}^T ||y - z_t||^2 - \sum_{t=1}^T ||y_t - z_t||^2 \leq 4Z^2(1 + \log T), \quad (8)$$

where $Z = \max_{1 \leq t \leq T} ||z_t||$. This strategy fails, though, for other loss functions, for example, for online linear optimization with losses $L_t(y) = y \cdot z_t$, when the regret might be as large as $\Omega(T)$. This problem can be avoided by the *follow the regularized leader* strategy which chooses predictions

$$y_t = \arg\min_{y \in Y} \left[\sum_{i=1}^{t-1} L_i(y) + R(y) \right]$$

for some regularization function $R : Y \to \mathbb{R}$. For online linear optimization with quadratic regularization $R(y) = \frac{Z}{B}\sqrt{\frac{T}{2}}||y||^2$, *follow the regularized leader* achieves regret

$$\min_{y:||y|| \leq B} \sum_{t=1}^T (y \cdot z_t) - \sum_{t=1}^T (y_t \cdot z_t) \leq ZB\sqrt{2T},$$

if all $||z_t|| \leq Z$. Online convex optimization is a very active field of research, and a good starting point is the exposition (Shalev-Shwartz 2011).

Oblivious Versus Adaptive Instance Sequences

So far we have assumed that the sequence of instances is not influenced by the predictions of the learner. If the sequence of instances is adaptive and depends on the predictions of the learner, additional care is necessary. In particular the definition of regret is subtle: since the instances depend on the predictions, the instances encountered by the learner may be very different from the instances encountered when following the prediction of a single expert. Therefore, it is in general not possible to bound the loss of a learner by the losses the experts would have incurred when making their predictions. This notion of regret is called *policy regret* (Dekel 2012), and it is easy to construct examples where any learning algorithm suffers $\Omega(T)$ loss while the predictions of the best expert suffer zero loss. To obtain nontrivial bounds on the policy regret, the adaptiveness of the instance sequence needs to be restricted, for example, by a bounded memory assumption: the instance at time t may depend only on the last m predictions of the learner.

In contrast, the loss of the learner can often be bounded by the loss of the best expert *on the sequence generated in response to the predictions of the learner.* The difference between the loss of the learner and the loss of the best expert on the same sequence of instances is called the *external regret*. As explained above, the notion of external regret is not fully satisfactory for adaptive sequences, but it allows to carry over many result for oblivious sequences to adaptive sequences. For an example, the high probability bound (3) for the weighted majority algorithm,

$$L_T \leq L_T^* + \sqrt{T \log(|\mathcal{E}|/\delta)},$$

holds also for any adaptive instance sequence that depends on the past predictions of the *learner*.

Ontology Learning

Different approaches have been used for building ontologies, most of them to date mainly using manual methods (▶ Text Mining for the Semantic Web). An approach to building ontologies was set up in the CYC project, where the main step involved manual extraction of common sense knowledge from different sources. Ontology construction methodologies usually involve several phases including *identifying the purpose of the ontology* (why to build it, how will it be used, the range of the users), *building the ontology*, *evalu-*

ation and documentation. Ontology learning relates to the phase of building the ontology using semiautomatic methods based on text mining or machine learning.

Abstract

Opinion stream mining aims at learning and adaptation of a polarity model over a stream of opinionated documents, i.e., documents associated with a polarity. They comprise a valuable tool to analyze the huge amounts of opinions generated nowadays through the social media and the Web. In this chapter, we overview methods for polarity learning in a stream environment focusing especially on how these methods deal with the challenges imposed by the stream nature of the data, namely the nonstationary data distribution and the single pass constraint.

Synonyms

Mining a Stream of Opinionated Documents; Polarity Learning on a Stream

Definition

Opinion stream mining is a variant of stream mining, of text mining and of opinion mining. Its goal is learning and adaptation of a polarity model over a stream of opinionated documents. An "opinionated document" is a text associated with a "polarity." Polarity is a value that represents the "strength" and the "direction" of an opinion. The strength can be a categorical value (e.g., $+$, $-$) or a ranking value (e.g., zero to five stars) or a continuous value (e.g., in the interval $[0, 1]$). The direction refers to whether the opinion is positive, negative, or neutral. Strength and direction are often mixed. For example, in a ranking using stars, five stars may stand for a very positive opinion, zero stars for a very negative one, and three stars for a neutral one.

As a variant of stream mining, opinion stream mining is subject to challenges of learning on a stream: adapting to changes in the data generating distribution – a phenomenon often called *concept drift* and processing the data as they arrive (in a single pass), since they cannot be retained permanently.

As a variant of text mining, opinion stream mining is subject to challenges of learning from texts: identifying the parts of speech that are in the text (e.g., verbs, adjectives, etc.); bringing the individual words into stem form (e.g., "opinions"→"opinion"); deciding which words will constitute the feature space and which are not informative and should be ignored; modeling the similarity between texts, taking (among other issues) differences in the length of texts into account; extracting the "entities" from

Work partially done while with the Ludwig-Maximilians University, Munich.

the text (e.g., persons, products); and detecting the "topics" of discourse in the texts.

As a variant of opinion mining, opinion stream mining faces further challenges: distinguishing between words that bear sentiment (e.g., "nice," "ugly") and those referring to facts (e.g., "sauna," "phone") and discerning different forms of sentiment (e.g., anger, joy). For static data, these challenges are addressed with techniques of natural language processing (NLP), text mining, and **Sentiment Analysis and Opinion Mining** (cf. lemma).

The aforementioned challenges are exacerbated in the stream context. Opinion stream mining provides solutions for learning and adapting a polarity model in a volatile setting: the topics in the opinionated documents may change; the attitude of people toward an entity (e.g., person, product, event) may change; the words used by people to express polarity may change; and even the words used by people, i.e., the vocabulary, may also evolve over time.

Motivation, Main Tasks, and Challenges

With the rise of WEB 2.0, more and more people use social media to upload opinions on essentially every subject – on products, persons, institutions, events, and topics of discourse. These accumulating opinionated data are valuable sources of information that can deliver valuable insights on the popularity of events; on the properties of products that are deemed important; on the positive or negative perception people have toward a product, person, or institution; on their attitude toward a specific subject of discourse; etc.

Background: The analysis of opinionated data is investigated in the research areas of *sentiment analysis* and *opinion mining*. These two areas overlap, whereby research on sentiment analysis puts more emphasis in understanding different types of "sentiment" (e.g., irony, anger, sadness, etc.), while opinion mining focuses more on learning models and discerning trends from data that simply have positive or negative "polarity" (or are neutral). For an extensive discussion of the subject, the reader is referred to the lemma **Sentiment Analysis and Opinion Mining**.

In Liu (2012), Bing Liu defines four opinion mining tasks as follows:

1. *Entity extraction:* "Extract all entity expressions in a document, and categorize or group synonymous entity expressions into entity clusters. Each entity expression cluster indicates a unique entity e_i."
2. *Property extraction:* "Extract all property expressions of the entities, and categorize these property expressions into clusters. Each property expression cluster of entity e_i represents a unique property a_{ij}."
3. *Opinion holder extraction:* "Extract opinion holders for opinions from text or structured data and categorize them. The task is analogous to the above two tasks."
4. *Sentiment classification:* "Determine whether an opinion on a property a_{ij} is positive, negative, or neutral, or assign a numeric sentiment rating to the property."

Among these tasks, the first one is not peculiar to opinion mining: *entity extraction* (EEX) is a subtask of document analysis. A widespread special case of EEX is named-entity recognition (NER); a minister is an entity, and a specific minister is a named entity. The goal of EEX and NER is to identify and annotate all entities in a document. To this purpose, NLP techniques are used, as well as collections of "named entities"; a list of the towns in a country is an example of such a collection.

The second task can be generalized in two ways. First, the properties need not be associated to an explicitly defined entity (e.g., a person or city); they may also be topics or subtopics under a subject of discourse (e.g., air pollution as a subtopic of environment pollution). Further, clustering is not the only way of identifying properties/topics: aspect-based opinion mining is a subdomain of topic modeling (cf. lemma **Topic Models for NLP Applications** for the general domain). In this subdomain, a document is perceived as a mixture of topics and sentiments.

In opinion *stream* mining, the collection of opinionated documents is not perceived as a static set but as an ongoing stream. While the first and third of the aforementioned tasks remain largely unchanged, the second and forth task must be redefined in the stream context. The task of property extraction on the stream is addressed with methods of *dynamic topic modeling* (see Blei and Lafferty (2006) for the core concepts) and with methods of text stream clustering (Aggarwal and Yu 2006).

The task of sentiment classification becomes a stream classification problem for an evolving text stream. Hereafter, we denote this task as "learning a polarity model" or simpler "polarity model learning," without referring explicitly to the fact that the model is learned on a stream.

Challenges of opinion stream mining: The challenges faced in opinion stream mining for property extraction and polarity learning emanate from the different aspects of volatility in the opinionated stream:

(a) *The data evolve with respect to the target variable:* The attitude of people toward a subject of discourse, a person, a product, or some property of this product may change over time. This corresponds to a change in the priors of the polarity class.
(b) *The topics evolve:* New subjects of discourse emerge, some product properties become uninteresting while others gain momentum. The learning algorithm must recognize that people discuss different topics.
(c) *The vocabulary evolves:* New words show up, some words fall out of use, and the polarity of some words may change. This means that the high-dimensional feature space used by the learning algorithm changes during the process of learning and adaption.
(d) *Labels are scarce:* In conventional stream classification, it is assumed that fresh labels are timely available for classifier adaption. Opinionated streams are fast and the inspection of opinions is a tedious task. So, the demand for human intervention/supervision for document labeling must be limited.

Main tasks of opinion stream mining: In response to challenges (a) and (c), opinion stream mining encompasses solutions for polarity model learning and adaption and also when the class priors change and when the vocabulary evolves. Next to fully supervised solutions, there are also semi-supervised learning methods and active learning methods, in response to challenge (d). In the following, we elaborate on supervised, semi-supervised, and active stream mining approaches for the classification of opinionated streams.

For challenge (b), we refer the reader to literature on text stream clustering, starting, e.g., with Aggarwal and Yu (2006), and to literature on dynamic topic modeling, starting with Blei and Lafferty (2006) and Wang and McCallum (2006). Dynamic topic modeling for opinionated document streams gained momentum in the last years, resulting in several works on dynamic topic mixture models that capture both aspects (properties) and sentiment. An example is Fu et al. (2015) on dynamic nonparametric hierarchical Dirichlet process topic modeling. An important characteristic of this work is that the number of topics can be determined automatically and adjusted over time. Further, an aging (time-decay) component is incorporated into the learning process; this allows for forgetting old topics (Fu et al. 2015). As we discuss in the next section, the issue of forgetting is also essential in supervised learning over the stream, as means of adaptation to concept drift.

Polarity Learning in an Opinionated Stream

Polarity learning is a supervised task that involves model learning and model adaption over an opinionated stream, i.e., an infinite sequence D of arriving *instances* $d_1, \cdots, d_i, \cdots$. An instance/opinionated document is a vector over a *word vocabulary* V, which is built up and changes over time.

An instance has a polarity label c. We denote the class attribute by C. Much of the research on opinion stream mining considers streams where documents have positive or negative polarity and are mixed with neutral documents. We use this convention in the following, i.e., we assume that the polarity label is one of positive (+), negative (−), or neutral (∅).

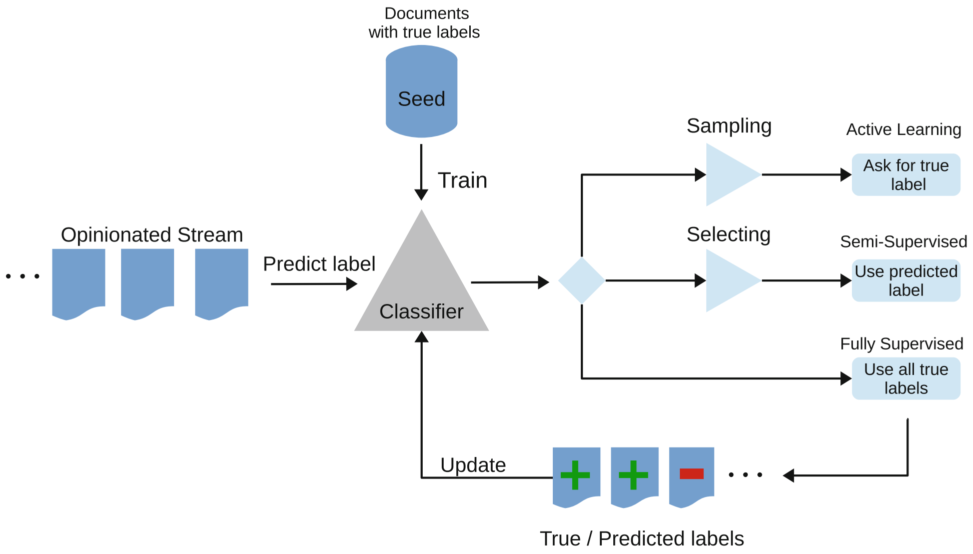
Workflow

The fully supervised stream learning scenario implies that the model is continuously learned on arriving, labeled instances. To deal with the label scarcity challenge, opinion stream mining research also contributes semi-supervised methods that learn with only an initial seed of labeled instances and active learning methods that request a label for only some of the arriving instances. An abstract workflow of the learning tasks is depicted in Fig. 1, distinguishing among supervised, semi-supervised, and active learning.

As can be seen in the figure, an initial classifier is trained on a starting set of manually labeled instances *Seed*. This set can be a small corpus of carefully selected opinionated documents that are representative of the stream, at least at the beginning, or the *Seed* can consist solely of the first arriving documents in the stream. Labels delivered by a human expert are denoted in the figure as "true labels," as opposed to the "predicted labels" that are assessed by the classifier.

In each subsequent step, the classifier predicts the labels of the arriving documents. For supervised learning, a human expert immediately delivers the true labels, which are then used for model adaption. In semi-supervised learning, the classifier adapts by using (a selection of) instances with predicted labels. In active learning, the expert is asked to deliver true labels only for some of the arriving documents which are then used for model adaption. These three ways of polarity learning are discussed hereafter.

The instances of the stream may be processed one by one as they arrive, or they may be stored into "chunks" (also called "blocks" or "batches"). In the first case, i.e., in "instance-based" processing, the classifier is adapted after seeing each new instance. In "chunk-based" processing, the classifier adapts after each chunk. A chunk may be a fixed-sized



Opinion Stream Mining, Fig. 1 Polarity learning on a stream of opinionated documents – fully supervised, semi-supervised, and active learning options block of documents or it may be defined at different levels of temporal granularity, e.g., hourly, daily, or weekly. Instance-based processing allows for fast adaption; however, the processing cost is higher as the model is updated after each instance. Chunk-based processing is more appropriate for streams where changes in the topics and/or vocabulary are manifested gradually. A detailed discussion of instance- vs chunk-based methods can be found in the lemma **Stream Classification**.

Fully Supervised Opinion Stream Classification

Fully supervised polarity learning on an opinionated stream is performed in the same way as stream classification in a conventional stream. The reader is referred to the lemma **Stream Classification** for a detailed elaboration on the interaction between the classifier and the stream, the detection of drift, and the adaption of the model. For opinionated streams, two aspects are of particular interest: how to choose a classification algorithm for polarity learning and how to deal with changes in the vocabulary.

Stream classification algorithms for polarity learning. Since there are many stream classification algorithms, it is reasonable to investigate how appropriate they are for learning on an opinionated stream. Several comparative studies have emerged at the beginning of the decade, including Bifet and Frank (2010) and Gokulakrishnan et al. (2012). In Gokulakrishnan et al. (2012), Gokulakrishnan et al. study a Twitter stream (i.e., a stream of short texts) and evaluate multinomial Naive Bayes (MNB), support vector machines (SVM), Bayesian logistic regression, sequential minimal optimization (SMO), and random forests (RF); they show that Bayesian classifiers, RF, and SMO outperform the other methods. In Bifet and Frank (2010), Bifet et al. compare MNB, stochastic gradient descend (SGD), and a Hoeffding tree (HT) algorithm; they report that MNB and SGD perform comparably when the stream is stable, but MNB has difficulties in adapting to drifts. In terms of efficiency, MNB is the fastest and HT is the slowest.

In their survey on concept drift adaption (Gama et al. 2014), Gama et al. elaborate on how *forgetting* of old data can be used to adjust a model to drift, and they discuss different forgetting strategies. The Hoeffding tree variant AdaHT (Bifet and Gavaldà 2009) forgets subtrees if performance degrades. In an opinionated stream, it is reasonable to also forget *words*, i.e., parts of the feature space, since the choice of words used in the data (here: documents!) may also change. The MNB variant proposed in Wagner et al. (2015) quantifies the contribution of a word to the polarity model by considering the number of documents containing this word and the recency of these documents; this variant is shown to adapt well to changes in the stream.

Stream classification algorithms for an evolving vocabulary. The problem of vocabulary evolution is rarely investigated in the context of stream mining. There are studies on online topic modeling and clustering on text streams, in which the model is adapted when the vocabulary – the feature space – changes (AlSumait et al. 2008; Gohr et al. 2009; Zimmermann et al. 2016), but most studies assume that all words are known in advance, and only their contribution to the model may change over time.

Among the stream classification algorithms, adaption to an evolving vocabulary is possible for some algorithms. The Hoeffding tree variant AdaHT (Bifet and Gavaldà 2009) can forget deprecated words when it forgets parts of the model (subtrees) and may be able to include new words when it builds new subtrees. The multinomial Naive Bayes variant proposed in Wagner et al. (2015) does modify the vocabulary, by considering at each timepoint only words that appear often in recent documents.

Adaption to an evolving vocabulary is an open problem. Currently, only few stream classification algorithms can deal with changes in the feature space. How to employ other classification algorithms over the opinionated stream? The fallback solution is to extend the workflow by a task that regularly recomputes the vocabulary/feature space from the most recent documents and then re-initializes the polarity model. This solution has the disadvantage that the old model is completely forgotten, but the advantage that any stream classification algorithm can be used for learning.

Semi-supervised Opinion Stream Classification

Goal of semi-supervised stream learning is to learn a model on an initial set of manually labeled documents, sometimes called the "seed set" or "initial seed," and then adapt the model by using the arriving unlabeled instances. Semi-supervised methods have the inherent advantage of not demanding human intervention after the initialization of the model.

For this family of methods, the initial seed is the only available ground truth. Hence, it is essential that the instances comprising the seed set are a representative sample. Evidently, this sample ceases being representative, as soon as concept drift occurs. Semi-supervised learning algorithms adapt to drift by building a training set that consists of the initial seed and arriving unlabeled instances, to which they themselves assign the labels. There are two strategies for the selection of unlabeled instances to be labeled by the classifier and added to the training set. The first strategy chooses instances on the grounds of the classifier's confidence to the predicted labels. The second strategy chooses instances by considering their similarity to previously labeled instances.

First strategy. Chapelle et al. point out that "Probably the earliest idea about using unlabeled data in classification is self-learning, which is also known as self-training, self-labeling, or decision-directed learning. This is a wrapper-algorithm that repeatedly uses a supervised learning method. It starts by training on the labeled data only. In each step a part of the unlabeled points is labeled according to the current decision function; then the supervised method is retrained using its own predictions as additional labeled points . . . " (Chapelle et al. 2006). However, self-training may lead to performance deterioration, because erroneous predictions of the classifier lead to erroneous labels in the training set.

Another approach is the "co-training" of several independent classifiers (Blum and Mitchell 1998). In the context of text classification, Aggarwal and Zhai propose to split the feature space into subsets and train an independent classifier on each subset (Aggarwal and Zhai 2014); then, high-confidence predictions of each single classifier are used to feed the other classifiers with new labels, so that no classifier is trained on its own predictions.

An example of co-training on a stream of tweets is in Liu et al. (2013): the complete feature space encompasses both text features (such as adjectives) and non-text features (e.g., emoticons). Views are built over this feature space, and a classifier (multiclass SVM) is trained on each view, using a small set of labeled instances only.

Second strategy. As an alternative to self-training and co-training, the second semi-supervised strategy adds to the training set those instances that are most similar to already labeled instances. One way to capitalize on labeled instances under this strategy is to cluster labeled and unlabeled instances together, then determine the label of each cluster from the labeled instances in it, and finally select for training some unlabeled instances per cluster (e.g., those closest to the cluster center).

In the context of opinionated semi-supervised stream learning, a clustering-based strategy brings two advantages. First, text stream clustering algorithms can be used, whereupon the clusters are updated gradually, as new unlabeled instances arrive. Further, these clusters reflect the properties/topics in the opinionated stream, thus addressing challenge (b) of task 2 on opinionated streams (cf. section on "Motivation, Main Tasks, and Challenges"). Example methods have been proposed by Gan et al. (2013) and by Zimmermann et al. (2015a).

In the previous section on fully supervised learning, we point out that forgetting (old data, part of the model, part of the feature space) may be beneficial for model adaption (cf. Gama et al. 2014). When learning in a semi-supervised way, though, forgetting may have negative side effects: since the seed set is the only ground truth provided by the human expert, forgetting those “precious” data labels is likely to lead to performance deterioration.

Active Learning for Opinion Stream Classification

Similarly to semi-supervised approaches, active learning methods attempt to learn and adapt to the ongoing stream without demanding a label for each arriving instance. Instead of re-acting to the labels that become available, active methods *proactively* (thereof the name “active”) request labels for the instances expected to be most informative for learning.

In active stream learning, there are two ways of requesting labels for some of the arriving instances. In the pool-based scenario, unlabeled instances are collected into a pool; the active learning algorithm chooses a subset of them and asks for their labels. In the sequential scenario, the algorithm decides for each arriving instance whether it will request a label for it. An overview of active learning methods for conventional streams is in Zliobaite et al. (2011).

Active learning is often used for various text mining tasks, including sentiment classification (Zhou et al. 2013). Active algorithms for opinionated streams also gain momentum. CloudFlows is a cloud-based platform for opinion stream mining that adheres to the pool-based scenario (Saveski and Grcar 2011; Kranjc et al. 2015): a first model of the stream is learned from a large corpus of tweets that contain emoticons; after initialization, the stream is partitioned into chunks, and an active learning algorithm is used to select instances and store them in a pool. The instances in the pool are ranked, and the top-ranked positions are shown to human experts. This approach has the advantage that human experts (e.g., in crowdsourcing) label the opinionated documents shown to them offline, whereupon these newly labeled instances are used for classifier adaption.

The algorithm ACOSTREAM (Zimmermann et al. 2015b) adheres to the sequential scenario, in the sense that sampling is done for each instance individually at its arriving time. This algorithm uses a variant of multinomial naive Bayes for classification, which (as in Wagner et al. 2015) deals with changes in the vocabulary of the arriving documents.

The multiclass active learning algorithm of Cheng et al. (2013) combines uncertainty and likelihood sampling to choose instances that are close to the current decision boundary, as well as instances from a yet unseen part of the data space. This algorithm (which adheres to the sequential scenario) is particularly interesting for learning on text streams, where some of the most recent instances may belong to an area of the data space that did not contain any instances in the past.

Recent Developments

Opinion stream mining builds upon advances in opinion mining, stream classification, active stream learning, and semi-supervised stream learning. Traditional methods in this domain have not been designed with big data in mind. However, opinionated streams have big data characteristics: volume, variability, variety, and veracity.

Volume refers to the huge number of opinions uploaded daily in social media and to the high dimensionality of the opinionated documents.

Variability refers to changes in the data flow rate and to changes in the data distribution, i.e., to concept drift.

Variety refers to the heterogeneous data types, including plain texts, images, and videos. The graph structure of the social networks, in which opinion holders are linked to each other, also adds to the variety of the data relevant to opinion mining.

Veracity refers to the uncertainty of the polarity labels provided by the human experts: labeling an opinionated stream is an inherently difficult task, since some opinionated documents (e.g., documents containing subtle irony) may be perceived differently by different people.

Challenges associated to these four Vs are not always peculiar to opinion stream mining: while challenges associated to variability are exacerbated in the opinion stream mining context, challenges associated to, e.g., volume can benefit from general-purpose big data solutions. These include, among others, scalable machine learning and online NLP algorithms, crowdsourcing approaches for data labeling, visualization advances, and visual analytics for the monitoring and interpretation of activities on social platforms.

Open Problems

Opinion stream mining is a rather young area. Open problems include:

- How to extend the traditional notion of "concept drift" so that it also cover changes in the feature space? How to design algorithms that detect such changes and adapt to them in an efficient way?
- How to distinguish between concept drift and "virtual drift" (Gama et al. 2014), i.e., between changes that do affect the decision boundary and changes that do not?

  Especially in an opinionated stream, many changes occur at each moment, e.g., new words appear, and the number of postings changes with the hour of the day, but not all of them require model adaption. How to design algorithms that recognize virtual drift and only adapt the model when true concept drift occurs?
- How to capture changes in the semantics and polarity of words?

  If a word's semantics or polarity change, how to inform existing resources (e.g., lexica like SentiWordNet) that a word's meaning and polarity are different for old documents than for recent ones?
- How to deal with label veracity in the stream? A promising approach is crowdsourcing, s is done, e.g., in CloudFlows (Kranjc et al. 2015). *Amazon Mechanical Turk* is a popular platform, where one can upload tasks for crowdsourcing. However, crowdsourcing has not been designed for learning and adaption on a fast stream, so solutions that also deal with stream velocity are necessary.

An associated open issue that can also be found in text stream mining, e.g., in the analysis of news streams, concerns the description of *bursts*. A burst is a rapid increase in social activity and may also be associated with a rapid change in the class priors and in the words being used to express polarity and to express facts. Do these changes disappear after the burst fades out, or do people take up the new words/expressions and use them also when they express opinions on other subjects? Does a burst lead to (more) permanent changes in the way people express opinions, on their perception toward a given entity, or on the topics they discuss?

Impact

Opinions have been always important for decision making. The opinion deluge we encounter nowadays mainly due to the WWW and the widespread usage of social networks is transforming business, society, and our own decisions on, e.g., what product to buy, which movie to watch, etc. Opinion (stream) mining offers solutions for automatically exploiting such sort of data for decision making, through, e.g., prediction models. Beyond its usage as a "standalone tool" for, e.g., polarity prediction, opinion (stream) mining has an impact on other areas of research, an example of which is the area of *recommenders:* next to the ratings typically used by recommenders, it is possible to also capitalize on the user reviews as more and more users also provide reviews on the rated items. These reviews are rich in information: they typically describe the aspects of the items that the users like/dislike. Further, if there are no ratings, they may be inferred from the reviews. A recent work in this area is McAuley and Leskovec (2013).

Synonyms

Overtraining

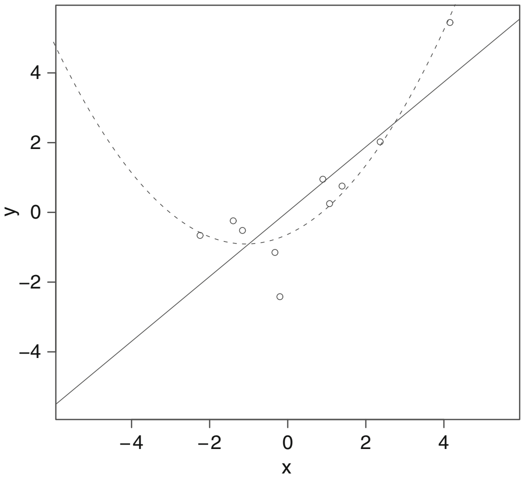
Definition

A model *overfits* the ▶ training data when it describes features that arise from noise or variance in the data, rather than the underlying distribution from which the data were drawn. Overfitting usually leads to loss of ▶ accuracy on ▶ out-of-sample data.

Discussion

In general there is a trade-off between the size of the space of distinct models that a learner can produce and the risk of overfitting. As the space of models between which the learner can select increases, the risk of overfitting will increase. However, the potential for finding a model that closely fits the true underling distribution will also increase. This can be viewed as one facet of the ▶ bias and variance trade-off.

Figure 1 illustrates overfitting. The points are drawn randomly from a distribution in which $y = x + \varepsilon$, where ε is random noise. The best single line fit to this distribution is $y = x$. ▶ Linear regression finds a model $y = 0.02044 + 0.92978 \times x$, shown as the solid line in Fig. 1. In contrast, second degree polynomial regression finds the model $-0.6311 + 0.5128 \times x + 0.2386 \times x^2$, shown as the dashed line. The space of second degree polynomial models is greater than that of linear models, and so the second degree polynomial more closely fits the example data, returning the lower ▶ squared error. However, the linear model more closely fits the true distribution and is more likely to obtain lower squared error on future samples.



Overfitting, Fig. 1 Linear and polynomial models fitted to random data drawn from a distribution for which the linear model is a better fit

While this example relates to ▶ regression, the same effect also applies to classification problems. For example, an overfitted ▶ decision tree may include splits that reflect noise rather than underlying regularities in the data.

Motivation and Background

A very important learning problem is the task of *learning a concept*. ▶ Concept learning has attracted much attention in learning theory. For having a running example, we look at humans who are able to distinguish between different "things," e.g., chair, table, car, airplane, etc. There is no doubt that humans have to learn how to distinguish "things." Thus, in this example, each concept is a thing. To model this learning task, we have to convert "real things" into *mathematical descriptions of things*. One possibility to do this is to fix some language to express a *finite* list of properties. Afterward, we decide which of these properties are relevant for the particular things we want to deal with and which of them have to be fulfilled or not to be fulfilled, respectively. The list of properties comprises qualities or traits such as "has four legs," "has wings," "is green," "has a backrest," "has a seat," etc. So these properties can be regarded as Boolean predicates, and, provided the list of properties is large enough, each thing can be described by a conjunction of these predicates. For example, a chair is described by "has four legs and has a backrest and has a seat and has no wings." Note that the color is not relevant and thus, "is green" has been omitted.

Assume that we have n properties, where n is a natural number. In the easiest case, we can denote the n properties by Boolean variables $x_1, \ldots, x_n$, where $range(x_j) \subseteq \{0, 1\}$ for $j = 1, \ldots, n$. The semantics is then obviously defined as follows. Setting $x_j = 1$ means property j is fulfilled, while $x_j = 0$ refers to property j is not fulfilled. Now, setting $\mathcal{L}_n = \{x_1, \bar{x}_1, x_2, \bar{x}_2, \ldots, x_n, \bar{x}_n\}$ (set of literals), we can express each thing as a conjunction of literals. As usual, we refer to any conjunction of literals as a *monomial*.

Therefore, formally we have as *learning domain* (also called ▶ instance space) the set of all Boolean vectors of length n, i.e., $\{0, 1\}^n$, and, in the learner's world, each thing (concept) is just a particular subset of $\{0, 1\}^n$. As far as our example is concerned, the concept chair is then the set of all Boolean vectors for which the monomial "has four legs and has a backrest and has a seat and has no wings" evaluates to 1.

Furthermore, it is usually assumed that the concept c to be learned (the target concept) is taken from a prespecified class $\mathcal{C}$ of possible

C. Sammut, G.I. Webb (eds.), *Encyclopedia of Machine Learning and Data Mining*,
DOI 10.1007/978-1-4899-7687-1

concepts called the *concept class*. In our example above, the concept class is the set of all concepts describable by a monomial. Consequently, we see that formally learning a concept is equivalent to identifying (exact or approximately) a set from a given set of possibilities by *learning* a suitable description (synonymously called representation) of it.

As in complexity theory, we usually assume that the representations are reasonable ones. Then they can be considered as strings over some fixed alphabet and the set of representations constitutes the ▸ representation language. Note that a concept may have more than one representation in a given representation language (and should have at least one) and that there may be different representation languages for one and the same concept class. For example, every Boolean function can be expressed as a ▸ conjunctive normal form (CNF) and as a ▸ disjunctive normal form (DNF), respectively. For a fixed representation language, the *size* of a concept is defined to be the length of a shortest representation for it. Since we are interested in a model of *efficient* learning, usually the following additional requirements are made: given any string over the underlying alphabet, one can decide in time polynomial in the length of the string whether or not it is a representation. Furthermore, given any element x from the underlying learning domain and a representation r for any concept, one can uniformly decide in time polynomial in the length of both inputs whether or not x belongs to the concept c described by r.

So, we always have a representation language used to define the concept class. As we shall see below, it may be advantageous to choose a possibly different representation language used by the learner. The class of all sets described by this representation language is called ▸ hypothesis space (denoted by $\mathcal{H}$), and the elements of it are said to be hypotheses (commonly denoted by h).

The *learner* is specified to be an algorithm. Further details are given below. We still have to specify the information source, the criterion of success, the hypothesis space, and the prior knowledge in order to define what PAC learning is.

The abbreviation PAC stands for *probably approximately correct* and the corresponding learning model has been introduced by Valiant (1984), while its name was dubbed by Angluin (1988). Valiant's (1984) pioneering paper triggered a huge amount of research the results of which are commonly called computational learning theory (see also the COLT and ALT conference series). Comprehensive treatises of this topic include Anthony and Biggs (1992), Kearns and Vazirani (1994), as well as Natarajan (1991).

Informally, this means that the learner has to find, on input, a randomly drawn set of labeled examples (called *sample*), with high probability a hypothesis such that the error of it is small. Here the error is measured with respect to the same probability distribution D with respect to which the examples are drawn.

Let $X \neq \emptyset$ be any learning domain and let $\mathcal{C} \subseteq \wp(X)$ be any nonempty concept class (here $\wp(X)$ denotes the power set of X). If X is infinite, we need some mild measure theoretic assumptions to ensure that the probabilities defined below exist. We refer to such concept classes as *well-behaved* concept classes. In particular, each $c \in \mathcal{C}$ has to be a Borel set. For a more detailed discussion, see Blumer et al. (1989).

Next, we formally define the *information source*. We assume any unknown probability distribution D over the learning domain X. No assumption is made concerning the nature of D and the learner has no knowledge concerning D. There is a *sampling oracle* $EX(\ )$, which has no input. Whenever $EX(\ )$ is called, it draws an element $x \in X$ according to D and returns the element x together with an indication of whether or not x belongs to the target concept c. Thus, every example returned by $EX(\ )$ may be written as $(x, c(x))$, where $c(x) = 1$ if $x \in c$ (positive examples) and $c(x) = 0$ otherwise (negative examples). If we make s calls to the example $EX(\ )$, then the elements $x_1, \dots, x_s$ are drawn independently from one another. Thus, the resulting probability distribution over all s-tuples of elements from X is the s-fold product distribution of D, i.e.,

$$\Pr(x_1, \ldots, x_s) = \prod_{i=1}^{s} D(x_i)\ , \qquad (1)$$

where $\Pr(A)$ denotes the probability of event A. Hence, the information source for a target concept c is any randomly drawn s-sample $S(c, \bar{x}) = (x_1, c(x_1), \ldots, x_s, c(x_s))$ returned by $EX(\ )$.

The *criterion of success*, i.e., *probably approximately correct* learning, is parameterized with respect to two quantities, the *accuracy parameter* ε, and the *confidence parameter* δ, where $\varepsilon, \delta \in (0, 1)$. Next, we define the *difference* between two sets $c,\ c' \subseteq X$ with respect to the probability distribution D as

$$d(c, c') = \sum_{x \in c \triangle c'} D(x),$$

where $c \triangle c'$ denotes the symmetric difference, i.e., $c \triangle c' = c \setminus c' \cup c' \setminus c$. We say that hypothesis h is an *ε-approximation* of a concept c, if $d(c, h) \leq \varepsilon$. A learner is *successful*, if it computes an ε-approximation of the target concept, and it should do so with probability at least $1 - \delta$.

The *hypothesis space* $\mathcal{H}$ is any set such that $\mathcal{C} \subseteq \mathcal{H}$, and the only *prior knowledge* is that the target concept is from the concept class.

A further important feature of the PAC learning model is the demand to learn efficiently. Usually, in the PAC learning model, the efficiency is measured with respect to the number of examples needed and the amount of computing time needed, and in both cases the requirement is to learn with an amount that is polynomial in the "size of the problem." In order to arrive at a meaningful definition, one has to discuss the problem size and, in addition, to look at the asymptotic difficulty of the learning problem. That is, instead of studying the complexity of some fixed learning problem, we always look at infinite sequences of similar learning problems. Such infinite sequences are obtained by allowing the size (dimension) of the learning domain to grow or by allowing the complexity of the concepts considered to grow. In both cases we use n to denote the relevant parameter.

Definition

A learning method $\mathcal{A}$ is said to *probably approximately correctly learn a target concept c with respect to a hypothesis space $\mathcal{H}$* and with sample complexity $s = s(\varepsilon, \delta)$ (or $s = s(\varepsilon, \delta, n)$), if for any distribution D over X and for all $\varepsilon, \delta \in (0, 1)$, it makes s calls to the oracle $EX(\ )$, and after having received the answers produced by $EX(\ )$ (with respect to the target c), it always stops and outputs a representation of a hypothesis $h \in \mathcal{H}$ such that

$$\Pr(d(c, h) \leq \varepsilon) \geq 1 - \delta.$$

A learning method $\mathcal{A}$ is said to *probably approximately correctly identify a target concept class $\mathcal{C}$ with respect to a hypothesis space $\mathcal{H}$* and with sample complexity $s = s(\varepsilon, \delta)$, if it probably approximately correctly identifies every concept $c \in \mathcal{C}$ with respect to $\mathcal{H}$ and with sample complexity s.

A learning method $\mathcal{A}$ is said to be *efficient*, if there exists a polynomial *pol* such that the running time of $\mathcal{A}$ and the number s of examples seen are at most $pol(1/\varepsilon, 1/\delta, n)$.

Remarks

This looks complicated, and so, some explanation is in order. First, the inequality

$$\Pr(d(c, h) \leq \varepsilon) \geq 1 - \delta$$

says that with high probability (quantified by δ), there is not too much difference (quantified by ε) between the conjectured concept (described by h) and the target c. Formally, let $\mathcal{A}$ be any fixed learning method, and let c be any fixed target concept. For any fixed $\varepsilon, \delta \in (0, 1)$, let $s = s(\varepsilon, \delta)$ be the actual sample size. We have to consider all possible outcomes of $\mathcal{A}$ when run on every labeled s-sample $S(c, \bar{x}) = (x_1, c(x_1), \ldots, x_s, c(x_s))$ returned by $EX(\ )$. Let $h(S(c, \bar{x}))$ be the hypothesis produced by $\mathcal{A}$ when processing $S(c, \bar{x})$. Then we have to consider the set W of all s-tuples over X such that $d(c, h(S(c, \bar{x}))) \leq \varepsilon$. The condition $\Pr(d(c, h) \leq \varepsilon) \geq 1 - \delta$ can now be formally rewritten as $\Pr(W) \geq 1 - \delta$. Clearly, one has to require that

$\Pr(W)$ is well defined. Note that the sample size is *not* allowed to depend on the distribution D.

To exemplify this approach, recall that our set of all concepts describable by a monomial over $\mathcal{L}_n$ refers to the set of all things. We consider a hypothetical learner (e.g., a student, a robot) that has to learn the concept of a chair. Imagine that the learner is told by a teacher whether or not particular things visible by the learner are instances of a chair. What things are visible depends on the environment the learner is in. The formal description of this dependence is provided by the unknown distribution D. For example, the learner might be led to a kitchen, a sitting room, a bookshop, a beach, etc. Clearly, it would be unfair to teach the concept of a chair in a bookshop and then testing the learning success at a beach. Thus, the learning success is measured with respect to the same distribution D with respect to which the sampling oracle has drawn its examples. However, the learner is required to learn with respect to any distribution. That is, independently of whether the learner is led to a kitchen, a bookshop, a sitting room, a beach, etc., it has to learn with respect to the place it has been led to. The sample complexity refers to the amount of information needed to ensure successful learning. Clearly, the smaller the required distance of the hypothesis produced and the higher the confidence desired, the more examples are usually needed. But there might be atypical situations. To have an extreme example, the kitchen the learner is led to turned out to be empty. Since the learner is required to learn with respect to a typical kitchen (described by the distribution D), it may well fail under this particular circumstance. Such failure has to be restricted to atypical situations, and this is expressed by demanding the learner to be successful with confidence $1 - \delta$.

This corresponds to real-life situations. For example, a student who has attended a course in learning theory might well suppose that she is examined in learning theory and not in graph theory. However, a good student, say in computer science, has to pass all examinations successfully, independently of the particular course attended. That is, she must successfully pass examinations in computability theory, complexity theory, cryptology, parallel algorithms, etc. Hence, she has to learn a whole concept class. The sample complexity refers to the time of interaction performed by the student and teacher. Also, the student may come up with a different representation of the concepts taught than the teacher. If we require $\mathcal{C} = \mathcal{H}$, then the resulting model is referred to as *proper* PAC learning.

The Finite Case

Having reached this point, it is natural to ask which concept classes are (efficiently) PAC learnable. We start with the finite case, i.e., learning domains X of finite cardinality. As before, the s-sample of c generated by $\bar{x}$ is denoted by $S(c, \bar{x}) = (x_1, c(x_1), \ldots, x_s, c(x_s))$. A hypothesis $h \in \mathcal{H}$ is called *consistent* for an s-sample $S(c, \bar{x})$, if $h(x_i) = c(x_i)$ for all $1 \leq i \leq s$. A learner is said to be *consistent* if all its outputs are consistent hypotheses. Then the following strategy (also known as ▸ Occam's razor) may be used to design a PAC learner:

(1) Draw a sufficiently large sample from the oracle $EX(\,)$, say s examples.
(2) Find some $h \in \mathcal{H}$ that is consistent with all the s examples drawn.
(3) Output h.

This strategy has a couple of remarkable features. First, provided the learner can find a consistent hypothesis, it allows for a uniform bound of the number of examples needed. That is,

$$s \geq \frac{1}{\varepsilon}\left(\ln|\mathcal{H}| + \ln\left(\frac{1}{\delta}\right)\right) \tag{2}$$

examples will always suffice (here $|S|$ denotes the cardinality of any set S).

The first insight obtained here is that increasing the confidence is exponentially cheaper than reducing the error.

Second, we see why we have to look at the asymptotic difficulty of the learning problem. If we fix $\{0, 1\}^n$ as learning domain and define $\mathcal{C}$ to be the set of all concepts describable by a Boolean function, then there are 2^{2^n} many concepts over $\{0,1\}^n$. Consequently, $\ln|\mathcal{H}| = O(2^n)$ resulting in a sample complexity that is for sure infeasible if $n \geq 50$. Thus, we set $X_n = \{0,1\}^n$, consider $\mathcal{C}_n \subseteq \wp(X_n)$, and study the relevant learning problem for $(X_n, \mathcal{C}_n)_{n\geq 1}$. So, finite means that all X_n are finite.

Third, using Inequality (2), it is not hard to see that the set of all concepts over $\{0,1\}^n$ that are describable by a monomial is efficiently PAC learnable. Let $\mathcal{H}_n$ be the set of all monomials containing each literal from $\mathcal{L}_n$ at most once plus the conjunction of all literals (denoted by m_{all}) (representing the empty concept). Since there are $3^n + 1$ monomials in $\mathcal{H}_n$, by (2), we see that $O(1/\varepsilon \cdot (n + \ln(1/\delta)))$ many examples suffice. Note that $2n$ is also an upper bound for the size of any concept from $\mathcal{H}_n$.

Thus it remains to deal with the problem to find a consistent hypothesis. The learning algorithm can be informally described as follows. After having received the s examples, the learner disregards all negative examples received and uses the positive ones to delete all literals from m_{all} that evaluate to 0 on at least one positive example. It then returns the conjunction of the literals not deleted from m_{all}. After a bit of reflection, one verifies that this hypothesis is consistent. This is essentially Haussler's (1987) Wholist algorithm and its running time is $O(1/\varepsilon \cdot (n^2 + \ln(1/\delta)))$. Also note that the particular choice of the representation for the empty concept was crucial here. It is worth noticing that the sample complexity is tight up to constant factors.

Using similar ideas one can easily show that the class of all concepts over $\{0,1\}^n$ describable by a k-CNF or k-DNF (where k is fixed) is efficiently PAC learnable by using as hypothesis space all k-CNF and k-DNF, respectively (cf. Valiant 1984). Note that a k-CNF is a conjunctive normal form in which each clause has at most k literals, and a k-DNF is a disjunctive normal form in which each monomial has at most k literals.

So, what can we say in general concerning the problem to find a consistent hypothesis? Answering this question gives us the insight to understand why it is sometimes necessary to choose a hypothesis space that is different from the target concept class. This phenomenon was discovered by Pitt and Valiant (1988). First, we look at the case where we have to efficiently PAC learn any $\mathcal{C}_n$ with respect to $\mathcal{C}_n$. Furthermore, an algorithm is said to *solve the consistency problem for* $\mathcal{C}_n$ if, on input any s-sample $S(c, \bar{x})$, where $c \subseteq X_n$, it outputs a hypothesis consistent with $S(c, \bar{x})$ provided there is one, and "there is no consistent hypothesis," otherwise.

Since we are interested in efficient PAC learning, we have to make the assumption that $|\mathcal{C}_n| \leq 2^{pol(n)}$ (cf. Inequality (2)). Also, it should be noted that for the proof of the following result, the requirement that $h(x)$ is polynomial time computable is essential (cf. our discussion of representations). Furthermore, we need the notion of an $\mathcal{RP}$-algorithm (randomized polynomial time). The input is any s-sample $S(c, \bar{x})$, where $c \subseteq X_n$ and the running time is uniformly bounded by a polynomial in the length of the input. In addition to its input, the algorithm can flip a coin in every step of its computation and then branch in dependence of the outcome of the coin flip. If there is no hypothesis consistent with $S(c, \bar{x})$, the algorithm must output "there is no consistent hypothesis," independently of the sequence of coin flips made. If there is a hypothesis consistent with $S(c, \bar{x})$, then the $\mathcal{RP}$-algorithm is allowed to fail with probability at most δ.

Interestingly, under the assumptions made above, then one can prove the following equivalence for efficient PAC learning.

PAC learning $\mathcal{C}_n$ with respect to $\mathcal{C}_n$ is equivalent to solving the consistency problem for $\mathcal{C}_n$ by an $\mathcal{RP}$-algorithm.

We continue by looking at the class of all concepts describable by a k-term DNF$_n$. A term is a conjunction of literals from $\mathcal{L}_n$, and a k-term DNF$_n$ is a disjunction of at most k terms. Consequently, there are $(3^n + 1)^k$ many k-term DNFs and thus the condition $|\mathcal{C}_n| \leq 2^{pol(n)}$ is fulfilled. Then one can show the following (see Pitt and Valiant 1988).

For all integers $k \geq 2$, if there is an algorithm that efficiently learns k-term DNF$_n$ *with respect to* k-term DNF$_n$, *then $\mathcal{RP} = \mathcal{NP}$.*

For a formal definition of the complexity classes $\mathcal{RP}$ and $\mathcal{NP}$, we refer the reader to Arora and Barak (2009). This result is proved by showing that deciding the consistency problem for k-term DNF$_n$ is $\mathcal{NP}$-complete for every $k \geq 2$. The difference between deciding and solving the consistency problem is that we only have to decide if there is a consistent hypothesis in k-term DNF$_n$. However, by the equivalence established above, we know that an efficient proper PAC learner for k-term DNF$_n$ can be transformed into an $\mathcal{RP}$-algorithm even solving the consistency problem. It should be noted that we currently do not know whether or not $\mathcal{RP} = \mathcal{NP}$ (only $\mathcal{RP} \subseteq \mathcal{NP}$ has been shown), but it is widely believed that $\mathcal{RP} \neq \mathcal{NP}$. On the other hand, it easy to see that every concept describable by a k-term DNF$_n$ is also describable by a k-CNF$_n$ (but not conversely). Thus, we can finally conclude that there is an algorithm that efficiently PAC learns k-term DNF$_n$ with respect to k-CNF$_n$.

For more results along this line of research, we refer the reader to Pitt and Valiant (1988), Blum and Singh (1990), and Jerrum (1994). As long as we do not have more powerful lower bound techniques allowing one to separate the relevant complexity classes $\mathcal{RP}$ and $\mathcal{NP}$ or $\mathcal{P}$ and $\mathcal{NP}$, no unconditional negative result concerning PAC learning can be shown. Another approach to show hardness results for PAC learning is based on cryptographic assumptions (cf., e.g., Kearns and Valiant 1989, 1994), and recently one has also tried to base cryptographic assumptions on the hardness of PAC learning (cf., e.g., Xiao (2009) and the references therein).

Further positive results comprise the efficient proper PAC learnability of rank k ▸ decision trees (cf. Ehrenfeucht and Haussler 1989) and of k-▸ decision lists for any fixed k (cf. Rivest 1987).

Finally, it must be noted that the bounds on the sample size obtained via Inequality (2) are *not* the best possible. Sometimes, better bounds can be obtained by using the ▸ VC dimension (see Inequality (4) below).

The Infinite Case

Let us start our exposition concerning infinite concept classes with an example due to Blumer et al. (1989). Consider the problem of learning concepts such as "medium built" animals. For the sake of presentation, we restrict ourselves to the parameters "weight" and "length." To describe "medium built," we use intervals "from-to." For example, a medium built cat might have a weight ranging from 3 to 7 kg and a length ranging from 25 cm to 50 cm. By looking at a finite database of randomly chosen animals giving their respective weight and length and their *classification* (medium built or not), we want to form a rule that *approximates* the true concept of "medium built" for each animal under consideration.

This learning problem can be formalized as follows. Let $X = \mathbb{E}^2$ be the two-dimensional Euclidean space, and let $\mathcal{C} \subseteq \wp(\mathbb{E}^2)$ be the set of all axis-parallel rectangles, i.e., products of intervals on the x-axis with intervals on the y-axis. Furthermore, let D be any probability distribution over X. Next we show that $\mathcal{C}$ is efficiently PAC learnable with respect to $\mathcal{C}$ by the following Algorithm **LR** (cf. Blumer et al. 1989):

Algorithm **LR**: "On input any $\varepsilon, \delta \in (0,1)$, call the oracle $EX(\ )$ s times, where $s = 4/\varepsilon \cdot \ln(4/\delta)$. Let $(r_1, c(r_1), r_2, c(r_2), \ldots, r_s, c(r_s))$ be the s-sample returned by $EX(\ )$, where $r_i = (x_i, y_i)$, $i = 1, \ldots s$.

$$\begin{aligned}\text{Compute } x_{\min} &= \min\{x_i \mid 1 \leq i \leq s,\ c(r_i) = 1\}\\ x_{\max} &= \max\{x_i \mid 1 \leq i \leq s,\ c(r_i) = 1\}\\ y_{\min} &= \min\{y_i \mid 1 \leq i \leq s,\ c(r_i) = 1\}\\ y_{\max} &= \max\{y_i \mid 1 \leq i \leq s,\ c(r_i) = 1\}\end{aligned}$$

Output $h = [x_{\min}, x_{\max}] \times [y_{\min}, y_{\max}]$. In case there is no positive example, return $h = \emptyset$.
end."

It remains to show that Algorithm **LR** PAC learns the concept class $\mathcal{C}$ with respect to $\mathcal{C}$. Let $c = [a,b] \times [c,d]$ be the target concept. Since **LR** computes its hypothesis from positive examples, only, we get $h \subseteq c$. That is, h is consistent. We have to show that $d(c,h) \leq \varepsilon$ with probability at least $1 - \delta$. We distinguish the following cases.

Case 1. $D(c) \le \varepsilon$

Then $d(c,h) = \sum_{r \in c \triangle h} D(r) = \sum_{r \in c \setminus h} D(r) \le D(c) \le \varepsilon$.

Hence, in this case we are done.

Case 2. $D(c) > \varepsilon$

We define four minimal side rectangles within c that each cover an area of probability of at least $\varepsilon/4$. Let

Left $= [a,x] \times [c,d]$, where $x = \inf\{\tilde{x} \mid D([a,\tilde{x}] \times [c,d]) \ge \varepsilon/4\}$,

Right $= [z,b] \times [c,d]$, where $z = \inf\{\tilde{x} \mid D([\tilde{x},b] \times [c,d]) \ge \varepsilon/4\}$,

Top $= [a,b] \times [y,d]$, where $y = \inf\{\tilde{x} \mid D([a,b] \times [\tilde{x},d]) \ge \varepsilon/4\}$, and

Bottom $= [a,b] \times [c,t]$, where $t = \inf\{\tilde{x} \mid D([a,b] \times [c,\tilde{x}]) \ge \varepsilon/4\}$.

All those rectangles are contained in c, since $D(c) > \varepsilon$. If the sample size is s, the probability that a *particular* rectangle from $\{$*Left*, *Right*, *Top*, *Bottom*$\}$ contains no positive example is at most $(1-\varepsilon/4)^s$. Thus, the probability that *some* of those rectangles does not contain any positive example is at most $4(1-\varepsilon/4)^s$. Hence, incorporating $s = 4/\varepsilon \cdot \ln(4/\delta)$ gives

$$4(1-\varepsilon/4)^s < 4e^{-(\varepsilon/4)s} = 4e^{-\ln(4/\delta)} = \delta \,.$$

Therefore, with probability at least $1-\delta$, *each* of the four rectangles *Left*, *Right*, *Top*, and *Bottom* contains a positive example. Consequently, we get

$$d(c,h) = \sum_{r \in c \triangle h} D(r) \\ = \sum_{r \in c \setminus h} D(r) = D(c) - D(h) \,.$$

Furthermore, by construction

$$D(h) \ge D(c) - D(\mathit{Left}) - D(\mathit{Right}) \\ - D(\mathit{Top}) - D(\mathit{Bottom}) \ge D(c) - \varepsilon \,,$$

and hence $d(c,h) \le \varepsilon$.

Having reached this point, it is only natural to ask what makes infinite concept classes PAC learnable. Interestingly, there is a single parameter telling us whether or not a concept class is PAC learnable. This is the so-called Vapnik-Chervonenkis dimension commonly abbreviated as ▸ VC dimension. In our example of axis-parallel rectangles, the VC dimension of $\mathcal{C}$ is 4.

In order to state this result, we have to exclude trivial concept classes. A concept class $\mathcal{C}$ is said to be *trivial* if $|\mathcal{C}| = 1$ or $\mathcal{C} = \{c_1, c_2\}$ with $c_1 \cap c_2 = \emptyset$ and $X = c_1 \cup c_2$. A concept class $\mathcal{C}$ is called nontrivial if $\mathcal{C}$ is not trivial. Then Blumer et al. (1989) showed the following:

A nontrivial well-behaved concept class is PAC learnable if and only if its VC dimension is finite.

Moreover, if the VC dimension is finite, essentially the same strategy as in the finite case applies, i.e., it suffices to construct a consistent hypothesis from $\mathcal{C}$ (or from a suitably chosen hypothesis space $\mathcal{H}$ which must be well behaved) in random polynomial time.

So, it remains to estimate the sample complexity. Let d be the VC dimension of $\mathcal{H}$. Blumer et al. (1989) showed that

$$s \ge \max\left\{\frac{4}{\varepsilon}\log\frac{2}{\delta}, \ \frac{8d}{\varepsilon}\log\frac{13}{\varepsilon}\right\} \tag{3}$$

examples do suffice. This upper bound has been improved by Anthony et al. (1990) to

$$s \ge \frac{1}{\varepsilon(1-\sqrt{\varepsilon})}\left[\log\left(\frac{d/(d-1)}{\delta}\right) + 2d\log\left(\frac{6}{\varepsilon}\right)\right] . \tag{4}$$

Based on the work of Blumer et al. (1989) (and the lower bound they gave), Ehrenfeucht et al. (1988) showed that if $\mathcal{C}$ is nontrivial, then no learning function exists (for any $\mathcal{H}$) if $s < \frac{1-\varepsilon}{2\varepsilon}\log\frac{2}{\delta} + \frac{d-1}{64\varepsilon}$. These results give a precise characterization of the number of examples needed (apart from the gap of a factor of $O(\log \frac{1}{\varepsilon}))$ in terms of the VC dimension. Also note the sharp dichotomy here, either any consistent learner (computable or not) will do or no learner at all exists.

Two more remarks are in order here. First, these bounds apply to *uniform* PAC learning, i.e., the learner is taking ε and δ as input, only. As outlined in our discussion just before we gave the formal definition of PAC learning, it is meaningful to look at the asymptotic difficulty of learning. In the infinite case, we can increment the dimension n of the learning domain as we did in the finite case. We may set $X_n = \mathbb{E}^n$ and then consider similar concept classes $\mathcal{C}_n \subseteq \wp(X_n)$. For example, the concept classes similar to axis-parallel rectangles are axis-parallel parallelepipeds in $\mathbb{E}^n$. Then the VC dimension of $\mathcal{C}_n$ is $2n$, and all that is left is to add n as input to the learner and to express d as a function of n in the bound (4). Clearly, the algorithm **LR** can be straightforwardly generalized to a learner for $(X_n, \mathcal{C}_n)_{n \geq 1}$.

Alternatively, we use n to parameterize the complexity of the concepts to be learned. As an example consider $X = \mathbb{E}$ and let $\mathcal{C}_n$ be the set of all unions of at most n (closed or open) intervals. Then the ▸ VC dimension of $\mathcal{C}_n$ is $2n$, and one can design an efficient learner for $(X, \mathcal{C}_n)_{n \geq 1}$. Another example is obtained for $X = \mathbb{E}^2$ by defining $\mathcal{C}_n$ to be the class of all convex polygons having at most n edges (cf. Linial et al. 1991).

Second, all the results discussed so far are dealing with *static sampling*, i.e., any sample containing the necessary examples is drawn before any computation is performed. So, it is only natural to ask what can be achieved when *dynamic sampling* is allowed. In dynamic sampling mode, a learner alternates between drawing examples and performing computations. Under this sampling mode, even concept classes having an infinite VC dimension are learnable (cf. Linial et al. 1991 and the references therein). The main results in this regard are that enumerable concept classes and decomposable concept classes are PAC learnable when using dynamic sampling.

Let us finish the general exposition of PAC learning by pointing to another interesting insight, i.e., learning is in some sense data compression. As we have seen, finding consistent hypotheses is a problem of fundamental importance in the area of PAC learning. Clearly, the more expressive the representation language for the hypothesis space, the easier it may be to find a consistent hypothesis, but it may be increasingly difficult to say something concerning its accuracy (in machine learning this phenomenon is also known as the over-fitting problem). At this point, ▸ Occam's razor comes into play. If there is more than one explanation for a phenomenon, then Occam's razor requires to "prefer simple explanations." So, an Occam algorithm is an algorithm which, given a sample of the target concept, outputs a consistent and relatively simple hypothesis. That is, it is capable of some *data compression*. Let us first look at the Boolean case, i.e., $X_n = \{0,1\}^n$. Then an Occam algorithm is a randomized polynomial time algorithm $\mathcal{A}$ such that there is a polynomial p and a constant $\alpha \in [0,1)$ fulfilling the following demands:

For every $n \geq 1$, every target concept $c \in \mathcal{C}_n$ of size at most m and every $\varepsilon \in (0,1)$, on input any s-sample for c, algorithm $\mathcal{A}$ outputs with probability at least $1 - \varepsilon$ the representation of a consistent hypothesis from $\mathcal{C}_n$ having size at most $p(n, m, 1/\varepsilon) \cdot s^{\alpha}$.

So, the parameter $\alpha < 1$ expresses the amount of compression required. If we have such an Occam algorithm, then $(X_n, \mathcal{C}_n)$ is properly PAC learnable (cf. Blumer et al. 1987). The proof is based on the observations that a hypothesis with large error is unlikely to be consistent with a large sample and that there are only few short hypotheses. If we replace in the definition of an Occam algorithm the demand on the existence of a short hypothesis by the existence of a hypothesis space having a small VC dimension, then a similar result can be obtained for the continuous case (cf. Blumer et al. 1989). To a certain extent, the converse is also true, that is, under quite general conditions, PAC learnability implies the existence of an Occam algorithm. We refer the reader to Kearns and Vazirani (1994) for further details.

Variations

Further variations of PAC learning are possible and have been studied. So far, we have only considered one sampling oracle. Hence, a natural variation is to have two sampling oracles $EX_{+}(\ )$ and $EX_{-}(\ )$ and two distributions D_{+} and D_{-}, i.e., one for positive examples and one for negative examples. Clearly, further natural variations are possible. A larger number of them has been shown to be roughly equivalent and we refer the reader to Haussler et al. (1991) for details.

We continue with another natural variation that turned out to have a fundamental impact to the whole area of machine learning, i.e., weak learning.

Weak Learning

An interesting variation of PAC learning is obtained if we weaken the requirements concerning the confidence and the error. That is, instead of requiring the PAC learner to succeed for every ε and δ, one may relax this demand as follows. We only require the learner to succeed for $\varepsilon = 1/2 - 1/pol(n)$ (n is as above) and $\delta = 1/poly(n)$ (n is as above), where *pol* and *poly* are any two fixed polynomials. The resulting model is called *weak* PAC learning.

Quite surprisingly, Schapire (1990) could prove that every weak learner can be efficiently transformed into an ordinary PAC learner. While it is not too difficult to *boost* the confidence, *boosting* the error is much more complicated and has subsequently attracted a lot of attention. We refer the reader to Schapire (1990, 1999) as well as Kearns and Vazirani (1994) and the references therein for a detailed exposition. Interestingly enough, the techniques developed to prove the equivalence of weak PAC learnability and PAC learnability have an enormous impact to machine learning and may be subsumed under the title ▸ boosting.

Relations to Other Learning Models

Finally, we point out some relations of PAC learning to other learning models. Let us start with the mistake bound model also called online prediction model. The mistake bound model has its roots in ▸ inductive inference and was introduced by Littlestone (1988). It is conceptionally much simpler than the PAC model, since it does not involve probabilities. For the sake of presentation, we assume a finite learning domain X_n and any $\mathcal{C}_n \subseteq \wp(X_n)$ here.

In this model the following scenario is repeated indefinitely. The learner receives an instance x and has to predict $c(x)$. Then it is given the true label $c(x)$. If the learner's prediction was incorrect, then a *mistake* occurred. The learner is successful, if the total number of mistakes is finite. In order to make this learning problem nontrivial, one additionally requires that there is a polynomial *pol* such that for every $c \in \mathcal{C}_n$ and any ordering of the examples, the total number of mistakes is bounded by $pol(n, size(c))$. In the mistake bound model, a learner is said to be efficient if its running time per stage is uniformly polynomial in n and $size(c)$.

Then, the relation to PAC learning is as follows:

If algorithm $\mathcal{A}$ learns a concept class $\mathcal{C}$ in the mistake bound model, then $\mathcal{A}$ also PAC learns $\mathcal{C}$. Moreover, if $\mathcal{A}$ makes at most M mistakes, then the resulting PAC learner needs $\frac{M}{\varepsilon} \cdot \ln \frac{M}{\delta}$ many examples.

So, efficient mistake bound learning translates into efficient PAC learning.

Another interesting relation is obtained when looking at the ▸ query-based learning model, where the only queries allowed are equivalence queries. As pointed out by Angluin (1988, 1992), any learning method that uses equivalence queries only and achieves *exact* identification can be transformed into a PAC learner. The number of equivalence queries necessary to achieve success in the query learning model is polynomially related to the number of calls made to the sample oracle.

However, the converse is not true. This insight led to the definition of a *minimally adequate teacher* (cf. Angluin (1988) and the references therein). In this setting, the teacher answers equivalence queries and membership queries. Maas and Turán (1990) provide a detailed discussion of the relationship between the different models.

These results in turn led to another modification of the PAC model, where the learner is, in addition to the s-sample returned, also allowed to ask membership queries, i.e., PAC learning with membership queries. This and the original PAC learning model may be further modified by restricting the class of probability distributions, e.g., by considering PAC learning (with or without membership queries) with respect to the uniform distribution. Having the additional power of membership queries allowed for a series of positive polynomial time learnability results, e.g., the class of deterministic finite automata (cf. Angluin 1987), monotone DNF formulae (cf. Angluin 1988), polynomial size decision trees (cf. Bshouty 1993), and sparse multivariate polynomials over a field (cf. Schapire and Sellie 1996). Furthermore, Jackson (1997) showed the class of DNF formulae to be PAC learnable with membership queries under the uniform distribution, and Bshouty et al. (2004) presented a modification of Jackson's (1997) algorithm that substantially improves its asymptotic efficiency. Further variations of the PAC learning model are presented in Bshouty et al. (2005).

Let us finish this entry by mentioning that the PAC model has been criticized for two reasons. The first one is the independence assumption, that is, the requirement to learn with respect to any distribution. This is, however, also a very strong part of the theory, since it provides universal performance guarantees. Clearly, if one has additional information concerning the underlying distributions, one may be able to prove better bounds. The second reason is the "noise-free" assumption, i.e., the requirement to the sample oracle to return exclusively correct labels. Clearly, in practice we never have noise-free data. So, one has also studied learning in the presence of noise, and we refer the reader to Kearns and Vazirani (1994) as well as to conference series COLT and ALT for results along this line.

Parallel Corpus

A parallel corpus (pl. corpora) is a document collection composed of two or more disjoint subsets, each written in a different language, such that documents in each subset are translations of documents in each other subset. Moreover, it is required that the translation relation is known, i.e., that given a document in one of the subset (i.e., languages), it is known what documents in the other subset are its translations. The statistical analysis of parallel corpora is at the heart of most methods for ▸ cross-language text mining.

Synonyms

Belief state Markov decision processes; Dual control; Dynamic decision networks; POMDPs

Definition

A partially observable Markov decision process (POMDP) refers to a class of sequential decision-making problems under uncertainty. This class includes problems with partially observable states and uncertain action effects. A POMDP is formally defined by a tuple $\langle \mathcal{S}, \mathcal{A}, \mathcal{O}, T, Z, R, b_0, h, \gamma \rangle$ where $\mathcal{S}$ is the set of states s, $\mathcal{A}$ is the set of actions a, $\mathcal{O}$ is the set of observations o, $T(s, a, s') = \Pr(s\prime|s, a)$ is the transition function indicating the probability of reaching s' when executing a in s, $Z(a, s', o') = \Pr(o'|a, s')$ is the observation function indicating the probability of observing o' in state s' after executing a, $R(s, a) \in \Re$ is the reward function indicating the (immediate) expected utility of executing a in s, $b_0 = \Pr(s_0)$ is the distribution over the initial state (also known as initial belief), h is the planning horizon (which may be finite or infinite), and $\gamma \in [0, 1]$ is a discount factor indicating by how much rewards should be discounted at each time step. Given a POMDP, the goal is to find a policy to select actions that maximize rewards over the planning horizon.

Motivation and Background

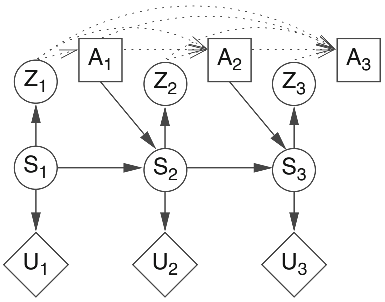
Partially observable Markov decision processes (POMDPs) were first introduced in the Operations Research community (Drake 1962; Aström 1965) as a framework to model stochastic dynamical systems and to make optimal decisions. This framework was later considered by the artificial intelligence community as a principled approach to planning under uncertainty (Kaelbling et al. 1998). Compared to other methods, POMDPs have the advantage of a well-founded theory. They can be viewed as an extension of the well-known, fully observable ▶ Markov decision process (MDP) model (Puterman 1994), which is rooted in probability theory, utility theory, and decision theory. POMDPs do not assume that states are fully observable, but instead that only part of the state features are observable, or more generally, that the observable features are simply correlated with the underlying states. This naturally captures the fact that in many real-world problems, the information available to the decision maker is often incomplete and typically measured by noisy sensors. As a result, the decision process is much more difficult to optimize. POMDP applications include robotics (Pineau and Gordon 2005), assistive technologies (Hoey et al. 2010), health informatics (Hauskrecht and Fraser 2010), spoken dialogue systems (Thomson and Young 2010), and fault recovery (Shani and Meek 2009).

Structure of Model and Solution Algorithms

We describe below the POMDP model, some policy representations, the properties of optimal value functions, and some solution algorithms.

POMDP Model

Figure 1 shows the graphical representation of a POMDP, using the notation of influence diagrams: circles denote random variables (e.g., state variables S_t and observation variables O_t), squares denote decision variables (e.g., action variables A_t), and diamonds denote utility variables (e.g., U_t's). The variables are indexed by time and grouped in time slices, reflecting the fact that each variable may take a different value at each time step. Arcs indicate how nodes influence each other over time. There are two types of arcs: probabilistic and informational arcs. Arcs pointing to a chance node or a utility node indicate

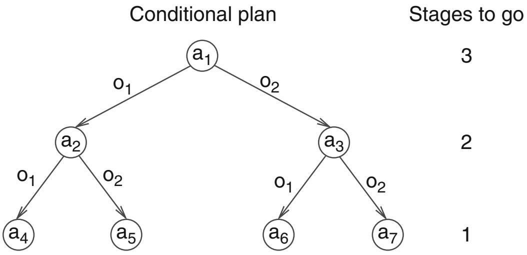


Partially Observable Markov Decision Processes, Fig. 1 POMDP represented as an influence diagram a probabilistic dependency between a child and its parents, whereas arcs pointing to a decision node indicate the information available to the decision maker (i.e., which nodes are observable at the time of each decision). Probabilistic dependencies for the state and observation variables are quantified by the conditional distributions $\Pr(S_{t+1}|S_t, A_t)$ and $\Pr(O_{t+1}|S_{t+1}, A_t)$, which correspond to the transition and observation functions. Note that the initial state variable S_0 does not have any parent, hence its distribution $\Pr(S_0)$ is unconditioned and corresponds to the initial belief b_0 of the decision maker. Probabilistic dependencies for the utility variables are also quantified by a conditional distribution $\Pr(U_t|S_t, A_t)$ such that its expectation $\sum_u \Pr(u|S_t,\ A_t)u\ =\ R(S_t,\ A_t)$ corresponds to the reward function.

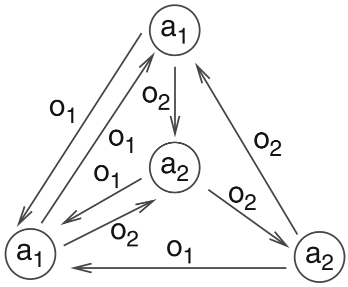
Fully observable MDPs are a special case of POMDPs since they arise when the observation function deterministically maps each state to a different unique observation. POMDPs can also be viewed as ▸ hidden Markov models (HMMs) (Rabiner 1989) extended with decision and utility nodes since the transition and observation distributions essentially define an HMM. POMDPs also correspond to a special case of decision networks called *dynamic decision networks* (Buede 1999) where it is assumed that the transition, observation, and reward functions are *stationary* (i.e., they do not depend on time) and *Markovian* (i.e., the parents of each variable are in the same time slice or immediately preceding time slice).

Policies

Given a tuple $\langle \mathcal{S}, \mathcal{A}, \mathcal{O}, T, Z, R, b_0, h, \gamma \rangle$ specifying a POMDP, the goal is to find a policy π to select actions that maximize the rewards. The informational arcs indicate that each action *at* can be selected based on the history of past actions and observations. Hence, in its most general form, a policy $\pi : \langle b_0, h_t \rangle \rightarrow a_t$ is a mapping from initial beliefs b_0 and histories $h_t = \langle o_0, a_0, o_1, a_1, \ldots, o_{t-1}, a_{t-1}, o_t$r to actions a_t. For a fixed initial belief, the mapping can be represented by a tree such as the one in Fig. 2. We will refer to such policy trees as conditional plans since in general a policy may consist of several conditional plans for different initial beliefs. The execution of a conditional plan follows a branch from the root to some leaf by executing the actions of the nodes traversed and following the edges labeled by the observations received.



Partially Observable Markov Decision Processes, Fig. 2 Three representation of a three-step conditional plan



Partially Observable Markov Decision Processes, Fig. 3 Finite state controller for a simple POMDP with two actions and two observations

Unfortunately, as the number of steps increases, the number of histories grows exponentially and it is infeasible to represent mappings over all such histories. Furthermore, infinite-horizon problems require mappings over arbitrarily long histories, which limit the use of trees to problems with a short horizon. Note, however, that it is possible to have mappings over infinite *cyclic* histories. Such mappings can be represented by a *finite state controller* (Hansen 1997), which is essentially a cyclic graph of nodes labeled by actions and edges labeled by observations (see Fig. 3 for an example). Similar to conditional plans, finite state controllers are executed by starting at an initial node, executing the actions of the nodes traversed, and following the edges of the observations received.

Alternatively, it is possible to summarize histories by a sufficient statistic that encodes all the relevant information from previous actions and observations for planning purposes. Recall that the transition, reward, and observation functions exhibit the Markov property, which means that the outcome of future states, rewards, and observations depend only on the current state and action. If the decision maker knew the current state of the world, then she would have all the desired information to make an optimal action choice. Thus, histories of past actions and observations are only relevant to the extent that they provide information about the current state of the world. Let b_t be the belief of the decision maker about the state of the world at time step t, which we represent by a probability distribution over the state space $\mathcal{S}$. Using Bayes theorem (see Bayes Rules), one can compute the current belief b_t from the previous belief b_{t-1}, previous action a_{t-1}, and current observation o_t:

$$b_t(s') = k \sum_{s \in \mathcal{S}} b_{t-1}(s) \Pr(s'|s, a_{t-1}) \Pr(o_t|a_{t-1}, s') \tag{1}$$

where k denotes a normalizing constant. Hence, a policy π can also be represented as a mapping from beliefs b_t to actions a_t. While this gets around the exponentially large number of histories, the space of beliefs is an $|\mathcal{S}| - 1$-dimensional continuous space, which is also problematic. However, a key result by Smallwood and Sondik (1973) allows us to circumvent the continuous nature of the belief space. But first, let us introduce value functions and then discuss Smallwood and Sondik's solution.

Value Functions

Given a set of policies, we need a mechanism to evaluate and compare them. Roughly speaking, the goal is to maximize the amount of reward earned over time. This loosely defined criterion can be formalized in several ways: one may wish to maximize *total* (accumulated) or *average* reward, *expected* or *worst-case* reward, *discounted* or *undiscounted* reward. The rest of this article assumes an *expected total discounted* reward criterion, since it is by far the most popular in the literature. We define the value $V^\pi(b_0)$ of executing some policy π starting at belief b_0 to be the expected sum of the discounted rewards earned at each time step:

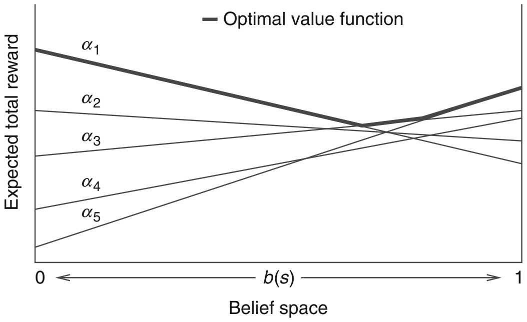
$$V^\pi(b_0) = \sum_{t=0}^{h} \gamma^t \sum_{s \in \mathcal{S}} b_t(s) R(s, \pi, (b_t)) \tag{2}$$

where $\pi(b_t)$ denotes the action prescribed by policy π at belief b_t. A policy π^* is optimal when its value function V^* is at least as high as any other policy for all beliefs (i.e., $V^*(b) \geq V^\pi(b) \forall b$).

As with policies, representing a value function can be problematic because its domain is an $(|\mathcal{S}| - 1)$-dimensional continuous space corresponding to the belief space. However, Smallwood and Sondik (1973) showed that optimal value functions for finite-horizon POMDPs are piecewise-linear and convex. The value of executing a conditional plan from any state is constant. If we do not know the precise underlying state, but instead we have a belief corresponding to a distribution over states, then the value of the belief is simply a weighted average (according to b) of the values of the possible states. Thus, the value function $V^\beta(b)$ of a conditional plan β is linear with respect to b. This means that $V^\beta(b)$ can be represented by a vector α_β of size $|\mathcal{S}|$ such that $V^\beta(b) = \Sigma_s b(s) \alpha_\beta(s)$.

For a finite horizon h, an optimal policy π^h consists of the best conditional plans for each initial belief. More precisely, the best conditional plan β^* for some belief b is the one that yields the highest value: $\beta^* = \operatorname{argmax}_\beta V^\beta(b)$. Although there are uncountably many beliefs, the set of h-step conditional plans is finite and therefore an h-step optimal value function can be represented by a finite collection Γ^h of α-vectors. For infinite horizon problems, the optimal value function may require an infinite number of α-vectors.

Figure 4 shows an optimal value function for a simple two-state POMDP. The horizontal axis represents the belief space and the vertical axis indicates the expected total reward. Assuming the two world states are s and $\bar{s}$, then a belief is completely determined by the probability of s. Therefore, the horizontal axis represents a continuum of beliefs determined by the probability



Partially Observable Markov Decision Processes, Fig. 4 Geometric view of value function

$b(s)$. Each line in the graph is an α-vector, which corresponds to the value function of a conditional plan. The upper surface of those α-vectors is a piecewise-linear and convex function corresponding to the optimal value function $V^* = \max_{\alpha \in \Gamma^h} \alpha(b)$.

Note that an optimal policy can be recovered from the optimal value function represented by a set Γ of α-vector. Assuming that an action is stored with each α-vector (this would typically be the root action of the conditional plan associated with each α-vector), then the decision maker simply needs to look up the maximal α-vector for the current belief to retrieve the action. Hence, value functions represented by a set of α-vectors, each associated with an action, implicitly define a mapping from beliefs to actions.

Optimal value functions also satisfy *Bellman's equation*

$$V^{h+1}(b) = \max_a R(b,a) + \gamma \sum_{o'} \Pr(o'|b,a) V^h(b^{ao'}) \quad (3)$$

where $R(b,a) = \sum_s b(s)R(s,a)$, $\Pr(s'|s,a)$ $\Pr(o'|s',a)$, and $b^{ao'}$ is the updated belief after executing a and observing b according to Bayes theorem (Eq. 1). Intuitively, this equation says that the optimal value for $h+1$ steps to go consists of the highest sum of the current reward with the future rewards for the remaining h steps. Since we do not know exactly what rewards will be earned in the future, an expectation (with respect to the observations) is used to estimate future rewards. For discounted infinite horizon problems, the optimal value function V^* is a fixed point of Bellman's equation:

$$V^*(b) = \max_a R(b,a) + \gamma \sum_{o'} \Pr(o'|b,a) V^*(b^{ao'})$$

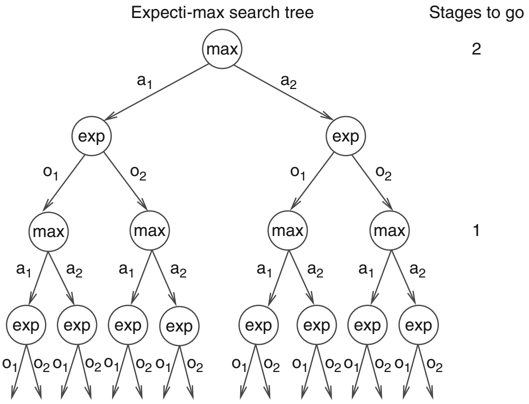
Solution Algorithms

There are two general classes of solution algorithms to optimize a policy. The first class consists of *online* algorithms that plan while executing the policy by growing a search tree. The second class consists of *offline* algorithms that precompute a policy which can be executed with minimal online computation. In practice, it is best to combine online and offline techniques since we may as well obtain the best policy possible in an offline phase and then refine it with an online search at execution time.

Forward Search

Online search techniques generally optimize a conditional plan for the current belief by performing a forward search from that belief. They essentially build an *expecti-max* search tree such that expectations over observations and maximizations over actions are performed in alternation. Figure 5 illustrates such a tree for a two-step horizon (i.e., two alternations of actions and observations). An optimal policy is obtained by computing the beliefs associated with each node in a forward pass, followed by a backward pass that computes the optimal value at each node. A recursive form of this approach is described in Algorithm 1. Beliefs are propagated forward according to Bayes theorem, while rewards are accumulated backward according to Bellman's equation.

Since the expecti-max search tree grows exponentially with the planning horizon h, in practice, the computation can often be simplified by pruning suboptimal actions by branch and bound and sampling a small set of observations instead of doing an exact expectation (Ross et al. 2008). Also, the depth of the search can be reduced by using an approximate value function at the leaves instead of 0.



Partially Observable Markov Decision Processes, Fig. 5 Two-step expecti-max search tree

    $V^{ao'} \leftarrow forward\ Search(b^{ao'}, h-1)$
  end for
  $V^* \leftarrow \max_a R(b,a) + \gamma \sum_{o'} \Pr(o'|b,a) V^{ao'}$
end if
```

The value functions computed by offline techniques can often be used for this purpose.

Value Iteration

Value iteration algorithms form an important class of offline algorithms that iteratively estimate the optimal value function according to Bellman's equation (3). Most algorithms exploit the piecewise-linear and convex properties of optimal value functions to obtain a finite representation. In other words, optimal value functions Vh are represented by a set Γ^h of α-vectors that correspond to conditional plans. Algorithm 2 shows how to iteratively compute Γ^t by dynamic programming for an increasing number of time steps t.

Algorithm 2 Value iteration

```
Inputs: horizon $h$
Outputs: Optimal value function $\Gamma^h$.
$\Gamma^0 \leftarrow \{0\}$
for $t = 1$ to $h$ do
  for all $a \in \mathcal{A}, < \alpha_1, \ldots, \alpha_{|\mathcal{O}|} > \in (\Gamma^{t-1})^{|\mathcal{O}|}$ do
    $\alpha'(s) \leftarrow R(s,a) +$
    $\gamma \sum_{o',s'} \Pr(s'|s,a)\Pr(o'|s',a)\alpha_{o'}(s')\forall s$
    $\Gamma^t \leftarrow \Gamma^t \cup \{\alpha'\}$
    end for
  end for
```

Algorithm 3 Point based value iteration

```
Inputs: Horizon $h$ and set of beliefs $\mathcal{B}$
Outputs: Value function $\Gamma^h$.
$\Gamma^0 \leftarrow \{0\}$
for $t = 1$ to $h$ do
  for all $b \in \mathcal{B}$ do
    for all $a \in \mathcal{A}, o' \in \mathcal{O}$ do
      $b^{ao'}(s') \leftarrow k \sum_s b(s)\Pr(s'|s,a)\Pr(o'|s',a)\forall s'$
      $\alpha^{ao'} \leftarrow \text{argmax}_{alpha \in \Gamma^{t-1}} \alpha(b^{ao'})$
    end for
    $a^* \leftarrow \text{argmax}_a R(b,a) + \gamma \sum_{o'} \Pr(s'|s,a)\Pr\alpha^{ao'}$
    $\alpha'(s) R(s,a) + \gamma \sum_{o',s'} \Pr(s'|s,a)\Pr(o'|s',a)$
    $\alpha_{o'}(s')\forall s$
    $\Gamma^t \leftarrow \Gamma^t \cup \{\alpha'\}$
  end for
end for
```

Unfortunately, the number of α-vectors in each Γ^t increases exponentially with $\mathcal{O}$ and doubly exponentially with t. While several approaches can be used to prune α-vectors that are not maximal for any belief, the number of α-vectors still grows exponentially for most problems. Instead, many approaches compute a parsimonious set of α-vectors, which defines a lower bound on the optimal value function. The class of *point-based value iteration* (Pineau et al. 2006) algorithms computes the maximal α-vectors only for a set $\mathcal{B}$ of beliefs. Algorithm 3 describes how the parsimonious set Γ^h of α-vectors associated with a given set $\mathcal{B}$ of beliefs can be computed in time linear with h and $|\mathcal{O}|$ by dynamic programming. Most point-based techniques differ in how they choose $\mathcal{B}$ (which may vary at each iteration), but the general rule of thumb is to include beliefs reachable from the initial belief b_0 since these are the beliefs that are likely to be encountered at execution time.

Policy Search

Another important class of offline algorithms consists of policy search techniques. These techniques search for the best policy in a predefined space of policies. For instance, finite state controllers are a popular policy space due to their generality and simplicity. The search for the best (stochastic) controller of N nodes can be formulated as a non-convex quadratically constrained optimization problem (Amato et al. 2007):

$$\max_{x,y,z} \sum_s b_0(s)\, \underbrace{\alpha_0(s)}_{x}$$

$$\text{s.t. } \underbrace{\alpha_n(s)}_{x} = \sum_a [\underbrace{\Pr(a|n)}_{y}\, R(S,a)$$

$$+\gamma \sum_{s',0',n'} \Pr(s'|s,a)$$

$$\Pr(0'|s',a)\, \underbrace{\Pr(a,n'|n,0')}_{z}\, \underbrace{\alpha_{n'}(s')}_{x}]\ \forall s,n$$

$$\underbrace{\Pr(a,n'|n,0')}_{x} \geq 0 \forall a,n',n,0'$$

$$\sum_{n'a} \underbrace{\Pr(a,n'|n,0)}_{z} = 1 \forall n,0$$

$$\sum_{n'} \underbrace{\Pr(a,n'|n,0')}_{z} = \underbrace{\Pr(a|n)}_{y}\ \forall a,n,0'$$

The variables of the optimization problem are the α-vectors and the parameters of the controller ($\Pr(a|n)$ and $\Pr(a,\ n'|n,o')$). Here, $\Pr(a|n)$ is the action distribution for each node n and $\Pr(a,\ n'|n,o') = \Pr(a|n)\Pr(n'|a,n,o')$ is the product of the action distribution and successor node distribution for each n,o'-pair. While there does not exist any algorithm that reliably finds the global optimum due to the non-convex nature of the problem, several techniques can be used to find locally optimal policies, including sequential quadratic programming, bounded policy iteration, expectation maximization, stochastic local search, and gradient descent.

Related Work

Although this entry assumes that states, actions, and observations are defined by a single variable, multiple variables can be used to obtain a *factored POMDP* (Boutilier and Poole 1996). As a result, the state, observation, and action spaces often become exponentially large. Aggregation (Shani et al. 2008; Sim et al. 2008) and compression techniques (Poupart and Boutilier 2004; Roy et al. 2005) are then used to speed up computation. POMDPs can also be defined for problems with continuous variables. The piecewise-linear and convex properties of optimal value functions still hold in continuous spaces, which allows value iteration algorithms to be easily extended to continuous POMDPs (Porta et al. 2006). When a planning problem can naturally be thought as a hierarchy of subtasks, *hierarchical POMDPs* (Theocharous and Mahadevan 2002; Pineau et al. 2003; Toussaint et al. 2008) can be used to exploit this structure.

In this article, we also assumed that the transition, observation, and reward functions are known, but in many domains they may be (partially) unknown and therefore the decision maker needs to learn about them while acting. This is a problem of *reinforcement learning*. While several policy search techniques have been adapted to simultaneously learn and act (Meuleau et al. 1999; Aberdeen and Baxter 2002), it turns out that one can treat the unknown parameters of the transition, observation, and reward functions as hidden state variables, which lead to a *Bayes-adaptive POMDP* (Ross et al. 2007; Poupart and Vlassis 2008). We also assumed a single decision maker, however POMDPs have been extended for multiagent systems. In particular, *decentralized POMDPs* (Amato et al. 2009) can model multiple cooperative agents that share a common goal and *interactive POMDPs* (Gmytrasiewicz and Doshi 2005) can model multiple competing agents.

Particle Swarm Optimization

The Canonical Particle Swarm

The particle swarm is a population-based stochastic algorithm for optimization which is based on social–psychological principles. Unlike ▸evolutionary algorithms, the particle swarm does not use selection; typically, all population members survive from the beginning of a trial until the end. Their interactions result in iterative improvement of the quality of problem solutions over time.

A numerical vector of D dimensions, usually randomly initialized in a search space, is conceptualized as a point in a high-dimensional Cartesian coordinate system. Because it moves around the space testing new parameter values, the point is well described as a particle. Because a number of them (usually $10 < N < 100$) perform this behavior simultaneously, and because they tend to cluster together in optimal regions of the search space, they are referred to as a *particle swarm*.

Besides moving in a (usually) Euclidean problem space, particles are typically enmeshed in a topological network that defines their communication pattern. Each particle is assigned a number of neighbors to which it is linked bidirectionally.

The most common type of implementation defines the particles' behaviors in two formulas. The first adjusts the velocity or step size of the particle, and the second moves the particle by adding the velocity to its previous position.

On each dimension d:

$$v_{id}^{(t+1)} \leftarrow \alpha v_{id}^{(t)} + U(0,\beta)\left(p_{id} - x_{id}^{(t)}\right) + U(0,\beta)\left(p_{gd} - x_{id}^{(t)}\right) \quad (1)$$

$$x_{id}^{(t+1)} \leftarrow x_{id}^{(t)} + v_{id}^{(t+1)} \quad (2)$$

where i is the target particle's index, d is the dimension, $\vec{x}_i$ is the particle's position, $\vec{v}_i$ is the velocity, $\vec{p}_i$ is the best position found so far by i, g is the index of i's best neighbor, α and β are constants, and $U(0, \beta)$ is a uniform random number generator.

Though there is variety in the implementations of the particle swarm, the most standard version uses $\alpha = 0.7298$ and $\beta = \psi/\ 2$, where $\psi = 2.9922$, following an analysis published in Clerc and Kennedy (2002). The constant α is called an *inertia weight* or *constriction coefficient*, and β is known as the *acceleration constant*.

The program evaluates the parameter vector of particle i in a function $f(\vec{x})$ and compares the result to the best result attained by i thus far, called $pbest_i$. If the current result is i's best so far, the vector $\vec{p}_i$ is updated with the current position $\vec{x}_i$, and the previous best function result $pbest_i$ is updated with the current result.

When the system is run, each particle cycles around a region centered on the centroid of the previous bests $\vec{p}_i$ and $\vec{p}_g$; as these variables are updated, the particle's trajectory shifts to new regions of the search space, the particles begin to cluster around optima, and improved function results are obtained.

The Social–Psychological Metaphor

Classical social psychology theorists considered the pursuit of *cognitive consistency* to be an important motivation for human behavior (Heider 1958; Festinger 1957; Abelson et al. 1968). Cognitive elements might have emotional or logical aspects to them which could be consistent or inconsistent with one another; several theorists identified frameworks for describing the degree of consistency and described the kinds of processes that an individual might use to increase consistency or balance, or decrease inconsistency or cognitive dissonance.

Contemporary social and cognitive psychologists frequently cast these same concepts in terms of connectionist principles. Cognitive elements are conceptualized as a network with positive and negative vertices among a set of nodes. In some models, the elements are given and the task is to reduce error by adjusting the signs and values of the connections between them, and in other models the connections are given and the goal of optimization is to find activation values that maximize coherence (Thagard 2000), harmony (Smolensky 1986), or some other measure of consistency. Typically, this optimization is performed by gradient-descent programs which psychologically model processes that are private to the individual and are perfectly rational, that is, the individual always decreases error or increases consistency among elements. The particle swarm simulates the optimization of these kinds of structures through social interaction; it is commonly observed, not only in the laboratory but in everyday life, that a person faced with a problem typically solves it by talking with other people.

A direct precursor of the particle swarm is seen in Nowak et al. (1990) cellular automaton simulation of social impact theory's predictions about interaction in human social populations. Social impact theory predicted that an individual was influenced to hold an attitude or belief in proportion to the Strength, Immediacy, and Number of sources of influence holding that position, where Strength was a measure of the persuasiveness or prestige of an individual, Immediacy was their proximity, and Number was literally the number of sources of influence holding a particular attitude or belief. In the simulation, individuals iteratively interacted, taking on the prevalent state of a binary attitude in their neighborhood, until the system reached equilibrium.

The particle swarm extends this model by supposing that various states can be evaluated, for instance, that different patterns of cognitive elements may be more or less dissonant; it assumes that individuals hold more than one attitude or belief, and that they are not necessarily binary; and Strength is replaced with a measure of self-presented success. One feature usually found in particle swarms and not in the paper by Nowak et al. is the phenomenon of persistence or momentum, the tendency of an individual to keep changing or moving in the same direction from one time-step to the next.

Thus, the particle swarm metaphorically represents the interactions of a number of individuals, none knowing what the goal is, each knowing its immediate state and its best performance in the past, each presenting its neighbors with its best success-so-far at solving a problem, each functioning as both source and target of influence in the dynamically evolving system. As individuals emulate the successes of their neighbors, the population begins to cluster in optimal regions of a search space, reliably discovering good solutions to difficult problems featuring, for instance, nonlinearity, high dimension, deceptive gradients, local optima, etc.

The Population Topology

Several kinds of topologies have been most widely used in particle swarm research; the topic is a current focus of much research. In the *gbest* topology, the population is conceptually fully connected; every particle is linked to every other. In practice, with the best neighbor canonical version, this is simpler to implement than it sounds, as it only means that every particle receives influence from the best performing member of the population.

The *lbest* topology of degree K_i comprises a ring lattice, with the particle linked to its K_i nearest neighbors on both sides in the wrapped population array.

Another structure commonly used in particle swarm research is the von Neumann or "square" topology. In this arrangement, the population is laid out in rows and columns, and each individual is connected to the neighbors above, below, and on each side of it in the toroidally wrapped population. Numerous other topologies have been used, including random (Suganthan 1999), hierarchical (Janson and Middendorf 2005), and adaptive ones (Clerc 2006).

The most important effect of the population topology is to control the spread of proposed problem solutions through the population. As a particle finds a good region of the search space, it may become the best neighbor to one of the particles it is connected to. That particle then will tend to explore in the vicinity of the first particle's success, and may eventually find a good solution there, too; it could then become the best neighbor to one of its other neighbors. In this way, information about good regions of the search space migrates through the population.

When connections are parallel, e.g., when the mean degree of particles is relatively high, then information can spread quickly through the population. On unimodal problems this may be acceptable, but where there are local optima there may be a tendency for the population to converge too soon on a suboptimal solution. The *gbest* topology has repeatedly been shown to be vulnerable to the lure of locally optimal attractors.

On the other hand, where the topology is sparse, as in the *lbest* model, problem solutions spread slowly, and subpopulations may search diverse regions of the search space in parallel. This increases the probability that the population will end up near the global optimum. It also means that convergence will be slower.

Vmax and Convergence

The particle swarm has evolved very much since it was first reported by Kennedy and Eberhart (1995) and Eberhart and Kennedy (1995). Early versions required a system constant *Vmax* to limit the velocity. Without this limit, the particles' trajectories would swing wildly out of control.

Following presentation of graphical representations of a deterministic form of the particle swarm by Kennedy (1998), early analyses by Ozcan and Mohan (1999) led to some understanding of the nature of the particle's trajectory. Analytical breakthroughs by Clerc (reported in Clerc and Kennedy (2002)), and empirical discoveries by Shi and Eberhart (1998), resulted in the application of the α constant in concert with appropriate values of the acceleration constant β. These parameters brought the particle under control, allowed convergence under appropriate conditions, and made *Vmax* unnecessary. It is still used sometimes, set to very liberal values such as a half or third of the initialization range of a variable for more efficient swarm behavior, but it is not necessary.

Step Size and Consensus

Step size in the particle swarm is inherently scaled to consensus among the particles. A particle goes in one direction on each dimension until the sign of its velocity is reversed by the accumulation of $(p - x)$ differences; then it turns around and goes the other way. As it searches back and forth, its oscillation on each dimension is centered on the mean of the previous bests $(p_{id} + p_{gd})/2$, and the standard deviation of the distribution of points that are tested is scaled to the difference between them. In fact this function is a very simple one: the standard deviation of a particle's search, when p_{id} and p_{gd} are constants, is approximately $|(p_{id} - p_{gd})|$. This means that when the particles' previous best points are far from one another in the search space, the particles will take big steps, and when they are nearer the particles will take little steps.

Over time, this usually means that exploring behavior is seen in early iterations and exploiting behavior later on as particles come to a state of consensus. If it happens, however, that a particle that has begun to converge in one part of the search space receives information about a good region somewhere else, it can return to the exploratory mode of behaving.

The Fully Informed Particle Swarm (FIPS)

Mendes (2004) reported a version of swarm that featured an alternative to the best neighbor strategy. While the canonical particle is influenced by its own previous success and the previous success of its best neighbor, the fully informed particle swarm (FIPS) allowed influence by all of a particle's neighbors. The acceleration constants were set to $\beta = \psi/\ 2$ in the traditional version; it was defined in this way because what mattered was their sum, which could be distributed among any number of difference terms. In the standard algorithm there were two of them, and thus the sum was divided by 2. In FIPS a particle of K_i degree has coefficients $\beta = \psi/K_i$.

The FIPS particle swarm removed two aspects that were considered standard features of the algorithm. First of all, the particle i no longer influenced itself directly, e.g., there is no $\vec{p}_i$ in the formula. Second, the best neighbor is now averaged in with the others; it was not necessary to compare the successes of all neighbors to find the best one.

Mendes found that the FIPS swarm was more sensitive than the canonical versions to the differences in topology. For instance, while in the standard versions the fully connected *gbest* topology meant influence by the best solution known to the entire population, in FIPS *gbest* meant that the particle was influenced by a stochastic average of the best solutions found by all members of the population; the result tended to be near-random search.

The lesson to be learned is that the *meaning* of a topology depends on the mode of interaction. Topological structure (and Mendes tested more than 1,340 of them) affects performance, but the way it affects the swarm's performance depends on how information is propagated from one particle to another.

Generalizing the Notation

Equation 2 above shows that the position is derived from the previous iteration's position plus the current iteration's velocity. By rearranging the terms, it can be shown that the current iteration's velocity $\vec{v}_i^{(t+1)}$ is the difference between the new position and the previous one: $\vec{v}_i^{(t+1)} = \vec{x}_i^{(t+1)} - \vec{x}_i^{(t)}$. Since this happened on the previous time-step as well, it can be shown that $\vec{v}_i^{(t)} = \vec{x}_i^{(t)} - \vec{x}_i^{(t-1)}$; this fact makes it possible to combine the two formulas into one:

$$x_{id}^{(t+1)} \leftarrow x_{id}^{(t)} + \alpha \left(x_{id}^{(t)} - x_{id}^{(t-1)} \right) + \sum U \left(0, \frac{\Psi}{K_i} \right) \left(p_{kd} - x_{id}^{(t)} \right) \qquad (3)$$

where K_i is the degree of node i, k is the index of i's kth neighbor, and adapting Clerc's (Clerc and Kennedy 2002) scheme $\alpha = 0.7298$ and $\psi = 2.9922$.

In the canonical best neighbor particle swarm, $K_i = 2, \forall i : i = 1, 2, \ldots, N$ and $k \in (i, g)$, that is, k takes the values of the particle's own index and its best neighbor's index. In FIPS, K_i may vary, depending on the topology, and k takes on the indexes of each of i's neighbors. Thus, Eq.3 is a generalized formula for the trajectories of the particles in the particle swarm.

This notation can be interpreted verbally as:

$$\begin{aligned} & NEW\ POSITION \\ & = CURRENT\ POSITION \\ & + PERSISTENCE \\ & + SOCIALINFLUENCE \end{aligned} \qquad (4)$$

That is, on every iteration, every particle on every dimension starts at the point it last arrived at, persists some weighted amount in the direction it was previously going, then makes some adjustments based on the differences between the best previous positions of its sources of influence and its own current position in the search space.

The Evolving Paradigm

The particle swarm paradigm is young, and investigators are still devising new ways to understand, explain, and improve the method. A divergence or bifurcation of approaches is observed: some researchers seek ways to simplify the algorithm (Peña et al. 2006; Owen and Harvey 2007), to find its essence, while others improve performance by adding features to it, e.g., Clerc (2006). The result is a rich unfolding research tradition with innovations appearing on many fronts.

Although the entire algorithm is summarized in one simple formula, it is difficult to understand how it operates or why it works. For instance, while the *Social Influence* terms point the particle in the direction of the mean of the influencers' successes, the *Persistence* term offsets that movement, causing the particle to bypass what seems to be a reasonable target. The result is a spiral-like trajectory that goes past the target and returns to pass it again, with the spiral tightening as the neighbors come to consensus on the location of the optimum.

Further, while authors often talk about the particle's velocity carrying it "toward the previous bests," in fact the velocity counterintuitively carries it *away from* the previous bests as often as toward them. It is more accurate to say the particle "explores around" the previous bests, and it is hard to describe this against-the-grain movement as "gradient descent," as some writers would like.

It is very difficult to visualize the effect of ever-changing sources of influence on a particle. A different neighbor may be best from one iteration to the next; the balance of the random numbers may favor one or another or some compromise of sources; the best neighbor could remain the same one, but may have found a better $\vec{p}_i$ since the last turn; and so on. The result is that the particle is pulled and pushed around in a complex way, with many details changing over time.

The paradoxical finding is that it is best not to give the particle information that is too good, especially early in the search trial. Premature convergence is the result of amplified consensus resulting from too much communication or overreliance on best neighbors, especially the population best. Various researchers have proposed ways to slow the convergence or clustering of particles in the search space, such as occasional reinitialization or randomization of particles, repelling forces among them, etc., and these techniques typically have the desired effect. In many cases, however, implicit methods work as well and more parsimoniously; the effect of topology on convergence rate has been mentioned here, for instance.

Binary Particle Swarms

A binary particle swarm is easily created by treating the velocity as a probability threshold (Kennedy and Eberhart 1997). Velocity vector elements are squashed in a sigmoid or other function, for instance $S(\upsilon) = 1/(1 + exp(-\upsilon))$, producing a result in (0..1). A random number is generated and compared to $S(\upsilon_{id})$ to determine whether x_{id} will be a 0 or a 1. Though discrete systems of higher cardinality have been proposed, it is difficult to define such concepts as distance and direction in a meaningful way within nominal data.

Alternative Probability Distributions

As was noted above, the particle's search is centered around the mean of the previous bests that influence it, and its variance is scaled to the differences among them. This has suggested to several researchers that perhaps the trajectory formula can be replaced, wholly or partly, by some type of random number generator that directly samples the search space in a desirable way.

Kennedy (2003) suggested simple Gaussian sampling, using a random number generator (RNG) $G(mean, s.d.)$ with the mean centered between $\vec{p}_i$ and $\vec{p}_g$, and with the standard deviation defined on each dimension as $s.d. = |(p_{id} - p_{gd})|$. This "bare bones" particle swarm eliminated the velocity component; it performed rather well on a set of test functions, but not as well as the usual version.

Krohling (2004) simply substituted the absolute values of Gaussian-distributed random numbers for the uniformly distributed values in the canonical particle swarm. He and his colleagues have had success on a range of problems using this approach. Richer and Blackwell (2006) replaced the Gaussian distribution of bare bones with a Lévy distribution. The Lévy distribution is bell-shaped like the Gaussian but with fatter tails. It has a parameter α which allows interpolation between the Cauchy distribution ($\alpha = 1$) and Gaussian ($\alpha = 2$) and can be used to control the fatness of the tails. In a series of trials, Richer and Blackwell (2006) were able to emulate the performance of a canonical particle swarm using $\alpha = 1.4$. Kennedy (2005) used a Gaussian RNG for the social influence term of the usual formula, keeping the "persistence" term found in the standard particle swarm. Variations on this format produced results that were competitive with the canonical version.

Numerous other researchers have begun exploring ways to replicate the overall behavior of the particle swarm by replacing the traditional formulas with alternative probability distributions. Such experiments help theorists understand what is essential to the swarm's behavior and how it is able to improve its performance on a test function over time.

Simulation of the canonical trajectory behavior with RNGs is a topic that is receiving a great deal of attention at this time, and it is impossible to predict where the research is leading. As numerous versions have been published showing that the trajectory formulas can be replaced by alternative strategies for selecting a series of points to sample, it becomes apparent that the essence of the paradigm is not to be found in the details of the movements of the particles, but in the nature of their interactions over time, the structure of the social network in which they are embedded, and the function landscape with which they interact, with all these factors working together gives the population the ability to find problem solutions.

Partitional Clustering

Xin Jin[1] and Jiawei Han[2]
[1]PayPal Inc., San Jose, CA, USA
[2]University of Illinois at Urbana-Champaign, Urbana, IL, USA

Abstract

Partitional clustering is a type of clustering algorithms that divide a set of data points into disjoint subsets. Each data point is in exactly one subset.

Synonyms

Objective function

Definition

Partitional clustering (Han et al. 2011) decomposes a data set into a set of disjoint clusters. Given a data set of N points, a partitioning method constructs K ($N \geq K$) partitions of the data with each partition representing a cluster. That is, it classifies the data into K groups by satisfying the following requirements: (1) each group contains at least one point, and (2) each point belongs to exactly one group. For fuzzy partitioning, a point can belong to more than one group. The quality of the solution is measured by clustering criteria.

Some partitional clustering algorithms work by minimizing an objective function. For example, in K-means and K-medoids, the function (also referred as the distortion function) is

$$\sum_{i=1}^{K} \sum_{j=1}^{|C_i|} Dist(x_j, center(i)) \qquad (1)$$

where $|C_i|$ is the number of points in cluster i and $Dist(x_j, center(i))$ is the distance between point x_j and center i. Depending on the need of the applications, different distance functions can be used, such as Euclidean distance and L_1 norm.

Major Algorithms

Many algorithms can be used to perform partitional data clustering; representative technologies include K-means (Lloyd 1957), K-medoids (Kaufman and Rousseeuw 2005), quality threshold (QT) (Heyer et al. 1999), expectation-maximization (EM) (Dempster et al. 1977), mean shift (Comaniciu and Meer 2002), locality-sensitive hashing (LSH) (Gionis et al. 1999), K-way spectral clustering (Luxburg 2007), etc. In the K-means algorithm, each cluster is represented by the mean value of the points in the cluster. For the K-medoids algorithm, each cluster is represented by one of the points located near the center of the cluster. Instead of setting the cluster number K, the QT algorithm uses the maximum cluster diameter as a parameter to find clusters with guaranteed quality. Expectation-maximization clustering performs expectation-maximization analysis based on statistical modeling of the data distribution, and it has more parameters. Mean shift is a nonparameter algorithm to find any shape of clusters using density estimator. Locality-sensitive hashing-based method performs clustering by hashing similar points to the same bin. K-way spectral clustering algorithm represents the data as a graph and performs graph partitioning to find clusters.

Synonyms

Statistical physics of learning; Threshold phenomena in learning; Typical complexity of learning

Definition

Phase transition (PT) is a term originally used in physics to denote a sudden transformation of a system from one state to another, such as from liquid to solid or to gas state (phase). It is used, by extension, to describe any abrupt change in one of the *order* parameters describing an arbitrary system, when a *control* parameter approaches a *critical* value.

Far from being limited to physical systems, PTs are ubiquitous in sciences, notably including computational science. Typically, hard combinatorial problems display a PT with regard to the probability of existence of a solution. Note that the notion of PT cannot be studied in relation to single-problem instances: it refers to emergent phenomena in an *ensemble* of problem instances, governed by a given probability distribution.

Motivation and Background

Cheeseman et al. (1991) were most influential in starting the study of PTs in artificial intelligence, experimentally showing the presence of a PT containing the most difficult instances for various **NP**-complete problems. Since then, the literature flourished both in breadth and depth, witnessing an increasing transfer of knowledge and results between statistical physics and combinatorics.

As far as machine learning (ML) can be formulated as a combinatorial optimization problem (Mitchell 1982), it is no surprise that PTs emerge in many of its facets. Early results have been obtained in the field of relational learning, either logic (Botta et al. 2003; Giordana and Saitta 2000) or kernel (Gaudel et al. 2008) based. PTs have been studied in neural networks (Demongeot and Sené 2008; Engel and Van den Broeck 2001), grammatical inference (Cornuéjols and Sebag 2008), propositional classification (Baskiotis and Sebag 2004; Rückert and De Raedt 2008), and sparse regression (Donoho and Tanner 2005).

Two main streams of research emerge from the study of PT in computational problems. On the one hand, locating the PT enables very difficult problem instances to be generated, those which are most relevant to benchmarks and comparative assessment of new algorithms. On the other hand, PT studies stimulate the analysis of algorithmic *typical case complexity*, as opposed to the standard worst-case analysis of algorithmic complexity. It is well known that while many algorithms require exponential resources in the worst case, they are effective for a vast majority of problem instances. Studying their typical runtime thus makes sense in a probabilistic perspective. The typical runtime not only reflects the most probable runtime; overall, the probability of deviating from this typical complexity goes to zero as the problem size increases.

Relational Learning

In a seminal paper, Mitchell characterized ML as a search problem (Mitchell 1982). Much attention has ever since been devoted to every component of a search problem: the search space, the search goal, and the search engine.

The search space $\mathcal{H}$ reflects the language $\mathcal{L}$ chosen to express the target knowledge, termed ▶ *hypothesis language*. The reader is referred to other entries of the encyclopedia (▶ *Attribute-value* representation, ▶ *First-order logic*, ▶ *Relational learning*, and ▶ *Inductive Logic Programming*) for a comprehensive presentation of the hypothesis languages and related learning approaches.

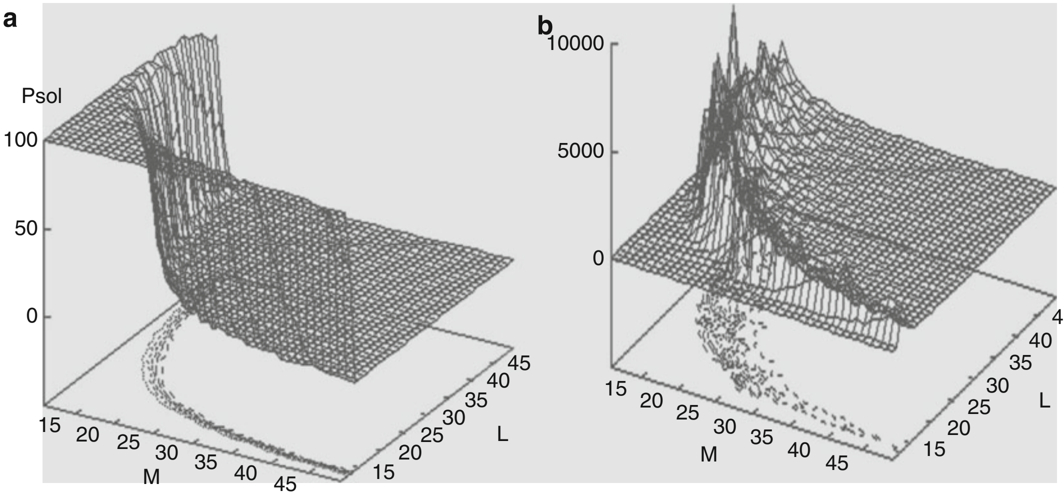
Typically, a learner proceeds iteratively: given a set $\mathcal{E}$ of examples labeled after a target concept ω, the learner maintains a list of candidate hypotheses, assessing their *completeness* (the proportion of positive examples they cover) and their *consistency* (the proportion of negative examples they do not cover) using a ▶ *covering test*. The covering test, checking whether some hypothesis h covers some example e, is thus a key component of the learning process, launched a few hundred thousand times in each learning run on medium-size problems.

While in propositional learning the covering test is straightforward and computationally efficient, in first-order logics, one must distinguish between *learning from interpretation* (h covers a set of facts e iff e is a model for h) and *learning from entailment* (h covers a clause e iff h entails e) (De Raedt 1997). A correct, but incomplete covering test, the ▶ θ-subsumption test defined by Plotkin (1970), is most often used for its decidability properties, and much attention has been paid to optimizing it (Maloberti and Sebag 2004).

As shown by Giordana and Saitta (2000), the θ-subsumption test is equivalent to a constraint satisfaction problem (CSP). A finite CSP is a tuple ($\mathbf{X}$, $\mathbf{R}$, D), where $\mathbf{X} = \{x_1, \ldots x_n\}$ is a set of variables, $\mathbf{R} = \{R_1, \ldots R_c\}$ is a set of constraints (relations), and D is the variable domain. Each relation R_h involves a subset of variables $x_{i_1}, \ldots, x_{i_k}$ in $\mathbf{X}$; it specifies all tuples of values $(a_{i_1}, \ldots, a_{i_k})$ in D^k such that the assignment $([x_{i_1} = a_{i_1}] \wedge \ldots \wedge [x_{i_k} = a_{i_k}])$ satisfies R_h. A CSP is satisfiable if there exists a tuple $(a_1, \ldots, a_n) \in D^n$ such that the assignment $([x_i = a_i], i = 1, \ldots, n)$ satisfies all relations in $\mathbf{R}$. Solving a CSP amounts to finding such a tuple (solution) or showing that none exists.

The probability for a random CSP instance to be satisfiable shows a PT with respect to the constraint density (control parameter $p_1 = \frac{2c}{n(n-1)}$) and constraint tightness ($p_2 = 1 - \frac{N}{L^2}$), where N denotes the cardinality of each constraint (assumed to be equal for all constraints) and L is the number of constants in the example (the universe).

The relational covering test being a CSP, a PT was expected and has been confirmed by empirical evidence (Botta et al. 1999; Giordana and Saitta 2000). The order parameter is the probability of hypothesis h to cover example e; the control parameters are the number m of predicates and the number n of variables in h, on the one hand, and the number N of literals built on each predicate symbol (relation) and the number L of constants in the example e, on the other hand. As shown in Fig. 1a, the covering probability is close to 1 (YES region) when h is general comparatively to e; it abruptly decreases to 0 (NO region) as the number m of predicates in h increases and/or the number L of constants in e decreases. In the PT region, a high peak



Phase Transitions in Machine Learning, Fig. 1 PT of the covering test (h, e) versus the number m of predicates in h and the number L of constants in e. The number n of variables is set to 10, and the number N of literals per predicate is set to 100. (**a**) Percentage of times the covering test succeeds. (**b**) Runtime of the covering test, averaged over 100 pairs (h, e) independently generated for each pair (m, L)

of empirical complexity of the covering test is observed (Fig. 1b).

The PT of the covering test has deep and far-reaching effects on relational learning. By definition, nontrivial hypotheses (covering some examples but not all) mostly belong to the PT region. The learner, searching for hypotheses covering the positive and rejecting the negative examples, must explore this region and thus cannot avoid the associated computational cost. More generally, the PT region acts as an *attractor* for any learner aimed at complete and consistent hypotheses.

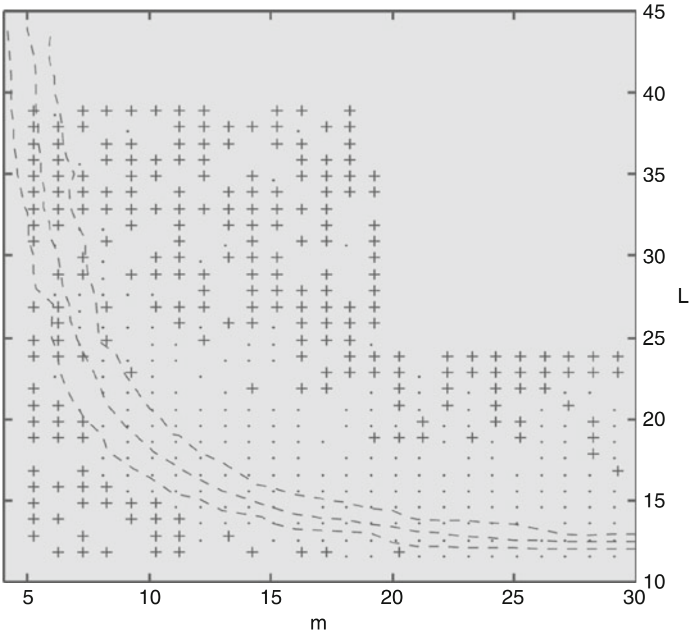
Secondly, top-down learners must traverse the plateau of overly general hypotheses (YES region) before arriving at the PT region. In the YES region, as all hypotheses cover most examples, the learner does not have enough information to make relevant choices; the chance of gradually arriving at an accurate description of the target concept thus becomes very low. Actually, a *blind spot* has been identified close to the PT (Botta et al. 2003): when the target concept lies in this region (relatively to the available examples), every state-of-the-art top-down relational learner tends to build random hypotheses, that is, the learned hypotheses behave like random guessing on the test set (Fig. 2).

This negative result has prompted the design of new relational learners aimed at learning in the PT region and using either prior knowledge about the size of the target concept (Ales Bianchetti et al. 2002) or near-miss examples (Alphonse and Osmani 2008).

Relational Kernels and MIL Problems

Relational learning has been revisited through the so-called kernel trick (Cortes and Vapnik 1995), first pioneered in the context of ▶ Support Vector Machines. Relational kernels, inspired from Haussler's convolutional kernels (Haussler 1999), have been developed for, e.g., strings, trees, or graphs. For instance, $K(\mathbf{x}, \mathbf{x}')$ might count the number of patterns shared by relational structures $\mathbf{x}$ and $\mathbf{x}'$. Relational kernels thus achieve a particular type of ▶ propositionalization (Kramer et al. 2001), mapping every relational example onto a propositional space defined after the training examples.

The question of whether relational kernels enable to avoid the PT faced by relational learning, described in the previous section, was investigated by Gaudel et al. (2007), focusing on the so-called ▶ multi-instance learning



Phase Transitions in Machine Learning, Fig. 2 Competence map of FOIL versus number m of predicates in the target concept and number L of constants in the examples. The target concept involves $n = 4$ variables and each example contains $N = 100$ literals built on each predicate symbol. For each pair (m, L), a target concept ω has been generated independently, balanced 200-example training, and test sets have been generated and labeled after ω. FOIL has been launched on the training set, and the predictive accuracy of the hypothesis has been assessed on the test set. Symbol “—” indicates a predictive accuracy greater than 90 %; symbol “—” indicates a predictive accuracy close to 50 % (akin random guessing)

(MIL) setting. The MIL setting, pioneered by Dietterich et al. (1997), is considered to be the “missing link” between relational and propositional learning (De Raedt 1998).

Multi-instance Learning: Background and Kernels

Formally, an MI example $\mathbf{x}$ is a bag of (propositional) instances noted $x^{(1)}$, …, $x^{(N)}$, where $x^{(j)} \in \mathbf{R}^d$. In the original MI setting (Dietterich et al. 1997), an example is labeled positive iff it includes at least one instance satisfying some target concept C:

$$pos(\mathbf{x}) \text{ iff } \exists\, i \in 1 \ldots N \; s.t.\; C(x^{(i)}).$$

More generally, in application domains such as image categorization, the example label might depend on the properties of several instances:

$$pos(\mathbf{x}) \text{ iff } \forall\, j = 1 \ldots m,\ \exists\, i_j \in 1 \ldots N \; s.t.\; C_j (x^{(i_j)}).$$

In this more general setting, referred to as *presence-based* setting, it has been shown that MIL kernels also have a PT (Gaudel et al. 2007).

Let us consider bag kernels K, built on the top of propositional kernels k on $\mathbf{R}^d$ as follows:

$$K(\mathbf{x}, \mathbf{x}') = f(\mathbf{x}).f(\mathbf{x}') \sum_{k=1}^{N} \sum_{\ell=1}^{N'} k(x^{(k)}, x'^{(\ell)}) \tag{1}$$

where $\mathbf{x} = (x^{(1)}, \ldots, x^{(N)})$ and $\mathbf{x}' = (x'^{(1)}, \ldots, x'^{(N')})$ denote two MI examples and $f(\mathbf{x})$ corresponds to a normalization term, e.g., $f(\mathbf{x}) = 1$ or $1/N$ or $1/\sqrt{K(\mathbf{x}, \mathbf{x})}$.

By construction, such MI-kernels thus consider the average similarity among the example instances, while relational learning is usually concerned with finding existential concepts.

The MI-SVM PT

After Botta et al. (2003) and Giordana and Saitta (2000), the competence of MI-kernels was experimentally assessed using artificial problems. Each problem involves m sub-concept s C_i: a given sub-concept corresponds to a region of the d-dimensional space, and it is satisfied by an MI example **x** if at least one instance in **x** belongs to this region. An instance is said to be relevant if it belongs to some C_i region.

Let n (respectively n') denote the number of relevant instances in positive (respectively negative) examples. Let further τ denote the number of sub-concept s not satisfied by negative examples (by definition, a positive example satisfies all sub-concept s).

Empirical investigations (Gaudel et al. 2007) show that:

- The $n = n'$ region is a failure region, where hypotheses learned by relational MI-SVMs do no better than random guessing (Fig. 3). In other words, while MI-SVMs grasp the notion of relevant instances, they still fail in the "truly relational region" where positive and negative examples only differ in the distribution of the relevant instances.
- The width of the failure region increases as τ increases, i.e., when fewer sub-concept s are satisfied by negative examples. This unexpected result is explained from the variance of the kernel-based propositionalization: the larger τ, the more the distribution of the positive and negative propositionalized examples overlap, hindering the discrimination.

Propositional Learning and Sparse Coding

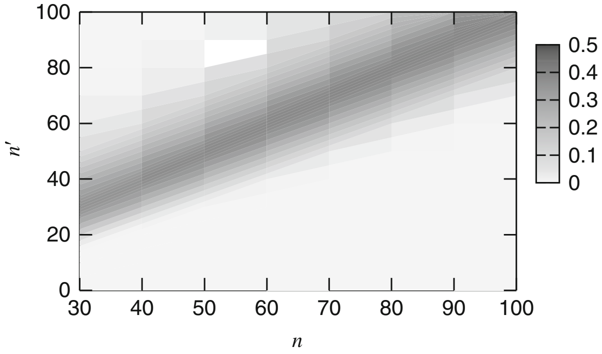
Interestingly, the emergence of a PT is not limited to relational learning. In the case of (context-free) *grammar induction*, for instance (Cornuéjols and Sebag 2008), the coverage of the candidate grammar was found to abruptly go to 1 along (uniform) generalization, as depicted in Fig. 4.

Propositional learning also displays some PTs both in the classification (Baskiotis and Sebag 2004; Rückert and De Raedt 2008) and in the regression (Cands 2008; Donoho and Tanner 2005) context.

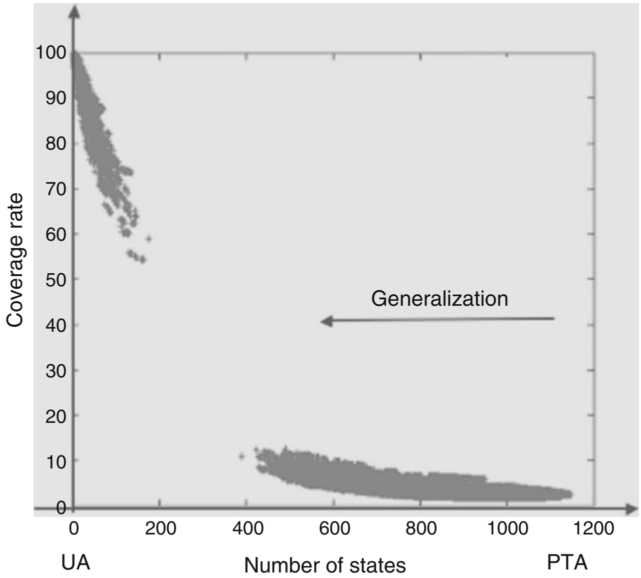
Propositional Classification

Given a target hypothesis language, classification in discrete domains most often aims at the simplest expression complying with the training examples.

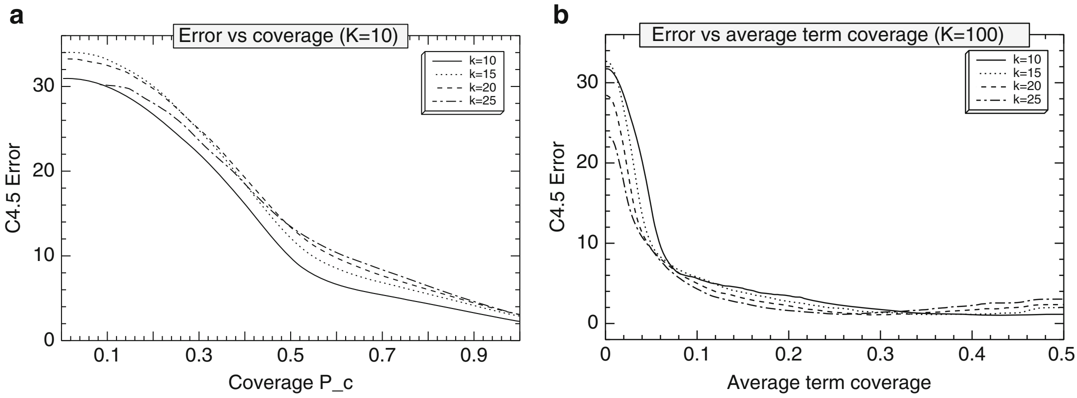
Considering randomly generated positive and negative examples, Rückert and De Raedt (2008) investigated the existence of k-term DNF solutions (disjunction of at most k conjunctions of literals) and showed that the probability of solution abruptly drops as the number of negative examples increases. They proposed a combinatorial optimization algorithm to find a k-term DNF



Phase Transitions in Machine Learning, Fig. 3 MI-SVM failure region in the (n, n') plane. Each (n, n') point reports the test error, averaged on 40 artificial problems



Phase Transitions in Machine Learning, Fig. 4 Gap emerging during learning in the relationship between the number of nodes of the inferred grammar and the coverage rate



Phase Transitions in Machine Learning, Fig. 5 C4.5 error versus concept coverage (**a**) and average term coverage (**b**) in k-term DNF languages. The reported curve is obtained by Gaussian convolution with empirical data (15,000 learning problems, each one involving a 800-example dataset)

complying with the training examples except at most $\varepsilon\,\%$ of them (Rückert and De Raedt 2008).

Considering positive and negative examples generated after some k-term DNF target concept ω, Baskiotis and Sebag examined the solutions built by C4.5 Rules (Quinlan 1993), among the oldest and still most used discrete learning algorithms. The observed variable is the generalization error on a test set; the order variables are the coverage of ω and the average coverage of the conjuncts in ω. Interestingly, C4.5 displays a PT behavior (Fig. 5): the error abruptly increases as the coverage and average coverage decrease.

Propositional Regression

▶ Linear regression aims at expressing the target variable as the weighted sum of the N descriptive variables according to some vector $\mathbf{w}$. When the number N of variables is larger than the number n of examples, one is interested in finding the most sparse $\mathbf{w}$ complying with the training examples (s.t. $< \mathbf{w}, \mathbf{x_i} >= \mathbf{y_i}$). The sparsity criterion consists of minimizing the L_0 norm of

w (number of nonzero coefficients in **w**), which defines an NP optimization problem. A more tractable formulation is obtained by minimizing the L_1 norm instead:

$$\text{Find } \arg\min_{\mathbf{w}\in\mathrm{R}^N}\{||\mathbf{w}||_1 \text{ subject to } < \mathbf{w}, \mathbf{x_i} > = \mathbf{y_i}, i = 1\ldots n\}. \tag{2}$$

A major result in the field of sparse coding can be stated as: *Let* $\boldsymbol{w}^*$ *be the solution of Eq.* (2)*; if it is sufficiently sparse,* $\boldsymbol{w}^*$ *also is the most sparse vector subject to* $< \boldsymbol{w}, \boldsymbol{x_i} > = \boldsymbol{y_i}$ (Donoho and Tanner 2005). In such cases, the L_0 norm minimization can be solved by L_1 norm minimization (an NP optimization problem is solved using linear programming). More generally, the equivalence between L_0 and L_1 norm minimization shows a PT behavior: when the sparsity of the solution is lower than a given threshold w.r.t the problem size (lower curve in Fig. 6), the NP/LP equivalence holds strictly; further, there exists a region (between the upper and lower curves in Fig. 6) where the NP/LP equivalence holds with high probability.

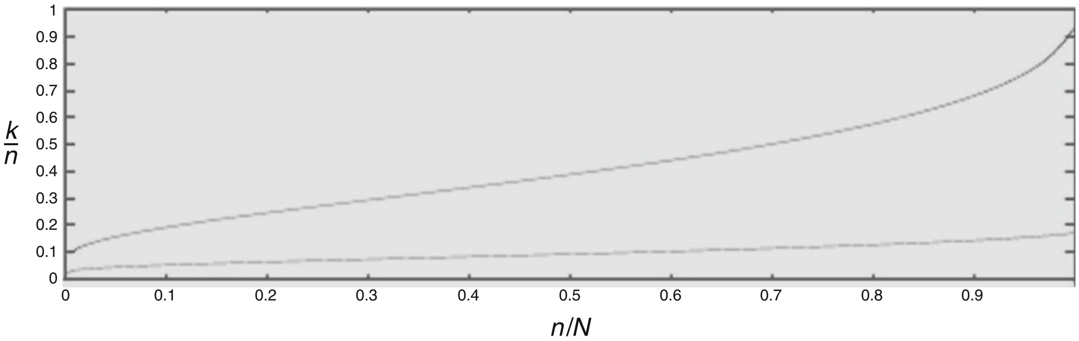
This highly influential result bridges the gap between the statistical and algorithmic objectives. On the statistical side, the importance of sparsity in terms of robust coding (hence learning) is acknowledged since the beginnings of information theory; on the algorithmic side, the sparsity criterion cannot be directly tackled as it boils down to solving a combinatorial optimization problem (minimizing a L_0 norm). The above result reconciles sparsity and tractability by noting that under some conditions, the solution of the L_0 minimization problem can be found by solving the (tractable) L_1 minimization problem: whenever the solution of the latter problem is "sufficiently" sparse, it is also the solution of the former problem.

Perspectives

Since the main two formulations of ML involve constraint satisfaction and constrained optimization, it is no surprise that CSP PTs manifest themselves in ML. The diversity of these manifestations, ranging from relational learning (Botta et al. 2003) to sparse regression (Donoho and Tanner 2005), has been illustrated in this entry, without pretending exhaustivity.

Along this line, the research agenda and methodology of ML can benefit from the lessons learned in the CSP field. Firstly, algorithms must be assessed on problems lying in the PT region; results obtained on problems in the easy regions are likely to be irrelevant (*playing in the sandbox* Hogg et al. 1996).

In order to do so, the PT should be localized through defining control and order parameters, thus delineating several regions in the control parameter space (ML landscape). These regions expectedly correspond to different types of ML difficulty, beyond the classical computational complexity perspective.



Phase Transitions in Machine Learning, Fig. 6 Strong and weak PT in sparse regression (Donoho and Tanner 2005). The x-axis is the ratio between the number n of constraints and the number N of variables; the y-axis is the ratio between the number k of variables involved in the solution and n

Secondly, the response of a given algorithm to these difficulties can be made available through a competence map, depicting its average performance conditionally to the value of the control parameters as shown in Figs. 2 and 3.

Finally, such competence maps can be used to determine whether a given algorithm is a priori relevant in a given region of the control parameter space and support the algorithm selection task (a.k.a. meta-learning; see, e.g., http://www.cs.bris.ac.uk/Research/MachineLearning/metal.html).

Recently, phase transitions have also emerged in learning more complex structures, such as complex networks. For instance, Xhang et al. (Zhang et al. 2014), following previous work, investigated the transitions occurring in the possibility of discovering communities in sparse networks using a semisupervised clustering approach. In their approach, the control parameter is the fraction α of nodes in the network, whose label is known, and they found both a first-order and a second-order phase transition.

Abstract

Already Richard Bellman suggested that searching in policy space is fundamentally different from value function-based reinforcement learning — and frequently advantageous, especially in robotics and other systems with continuous actions. Policy gradient methods optimize in policy space by maximizing the expected reward using a direct gradient ascent. We discuss their basics and the most prominent approaches to policy gradient estimation.

Definition

A policy gradient method is a ▶ reinforcement learning approach that directly optimizes a parametrized control policy by a variant of gradient descent. These methods belong to the class of ▶ policy search techniques that maximize the expected return of a policy from a fixed class, in contrast with ▶ value function approximation approaches that derive policies indirectly from an estimated value function. Policy gradient approaches have various advantages: they enable the straightforward incorporation of domain knowledge in policy parametrization; often an optimal policy is more compactly represented than the corresponding value function; many such methods guarantee to convergence to at least a locally optimal policy; the methods naturally handle continuous states and actions and often even imperfect state information. The countervailing drawbacks include difficulties in off-policy settings, the potential for very slow convergence and high sample complexity, as well as identifying local optima that are not globally optimal.

Structure of the Learning System

Policy gradient methods center around a parametrized policy π_θ, also known as a ▶ direct controller, with parameters θ that defines the selection of actions a given the state s. Such a policy may either be deterministic $a = \pi_\theta(s)$ or stochastic $a \sim \pi_\theta(a|s)$. This choice also affects the class of policy gradient algorithms applicable (stochastic policies often lead to smooth differentiable objective with gradients that can be estimated via likelihood ratio methods (Williams 1992), where a deterministic policy may lead to a non-smooth optimization problem), influences how the exploration-exploitation dilemma is addressed (e.g., a stochastic policy naturally chooses novel actions while a deterministic policy requires the perturbation of policy parameters or sufficient stochasticity in the system to achieve exploration), and may affect the quality of optimal solution (e.g., for a time-invariant or stationary policy, the optimal policy can be stochastic Sutton et al. 2000). Frequently used policy classes include Gibbs distributions $\pi_\theta(a|s) = \exp(\phi(s,a)^T\theta)/\sum_b \exp(\phi(s,b)^T\theta)$ for discrete problems (Sutton et al. 2000; Bagnell 2004) and, for continuous problems, Gaussian policies $\pi_\theta(a|s) = \mathcal{N}(\phi(s,a)^T\theta_1, \theta_2)$ with an exploration parameter θ_2 (Williams 1992; Peters and Schaal 2008).

Expected Return

Policy gradient methods seek to optimize the expected return of a policy π_θ,

$$J(\theta) = Z_\gamma E\left\{\sum_{k=0}^{H} \gamma^k r_k\right\},$$

where $\gamma \in [0,1]$ denotes a discount factor, a normalization constant Z_γ, and H the planning horizon. For finite H, we have an episodic reinforcement learning scenario where the truly optimal policy is nonstationary and the normalization does not matter. For an infinite horizon $H = \infty$, we choose the normalization to be $Z_\gamma \equiv (1-\gamma)$ for $\gamma < 1$ and $Z_1 \equiv \lim_{\gamma\to 1}(1-\gamma) = 1/H$ for ▶ average reward reinforcement learning problem where $\gamma = 1$.

Gradient Descent in Policy Space

Policy gradient methods follow an estimate the gradient of the expected return

$$\theta_{k+1} = \theta_k + \alpha_k g(\theta_k),$$

where $g(\theta_k) \approx \nabla_\theta J(\theta)|_{\theta=\theta_k}$ is a gradient estimate for the policy with parameters $\theta = \theta_k$ after update k (with an initial policy θ_0) and α_k denotes a learning rate. If the gradient estimator is unbiased, $\sum_{k=0}^{\infty} \alpha_k \to \infty$ while $\sum_{k=0}^{\infty} \alpha_k^2$ remains bounded, convergence to a local minimum can be guaranteed. In optimal control, model-based gradient methods have been used for optimizing policies since the 1960s (Pontryagin et al. 1962). While these are used machine learning community (e.g., differential dynamic programming with learned models), they may be numerically brittle and must rely on accurate, deterministic models. Hence, they may suffer significantly from optimization biases (i.e., if possible, they will reach a higher average return on the approximate model than possible on the real system by exploiting the shortcomings of the model) and are not generally applicable as learning problems often include discrete elements and maybe very difficult to learn effective predictive models.

Several model-free alternatives can be found in the simulation-based optimization literature (Fu 2006), including, e.g., finite-difference gradients, likelihood ratio approaches, response-surface methods, and mean-valued, weak derivatives. The advantages and disadvantages of these different approaches remain a fiercely debated topic (Fu 2006). In machine learning, the first two approaches have largely dominated gradient-based approaches to ▶ policy search, although response surface methods are arriving especially in the context of Bayesian optimization for policy search.

Finite Difference Gradients

The simplest policy gradient approaches with perhaps the most practical applications (see Bagnell (2004) and Peters and Schaal (2008) for robotics application of this method) estimate the gradient by perturbing the policy parameters. For a current policy θ_k with expected return $J(\theta_k)$, this approach will create perturbed policies $\hat{\theta}_i = \theta_k + \delta\theta_i$ with the approximated expected returns given by $J(\hat{\theta}_i) \approx J(\theta_k) + \delta\theta_i^T g$ where $g = \nabla_\theta J(\pi_\theta)|_{\theta=\theta_k}$. Such returns are typically estimated by simulation. The gradient can then be estimated by linear regression; i.e., we obtain

$$g = (\Delta\Theta^T\Delta\Theta)^{-1}\Delta\Theta^T\Delta J,$$

with parameter perturbations $\Delta\Theta = [\delta\theta_1, \ldots, \delta\theta_n]$ and mean-subtracted roll-out returns $\delta J_n = J(\hat{\theta}_i) - \overline{J(\theta_k)}$ form $\Delta J = [\delta J_1, \ldots, \delta J_n]$. The choice of the parameter perturbation largely determines the performance of the approach (Spall 2003). Limitations particular to this approach include the need for many exploratory samples, the sensitivity of the system with respect to each parameter may differs by orders of magnitude, small changes in a single parameter may render a system unstable, and stochasticity requires particular care in optimization (e.g., multiple samples, fixed random seeds, etc.), see Glynn (1990) and Spall (2003). This method is additionally referred to as the *naive Monte-Carlo policy gradient.*

Likelihood Ratio Gradients

The likelihood ratio method relies upon the stochasticity of either the policy for model-free approaches, or the system in the model-based case. Hence, it requires no explicit parameter exploration and may cope better with noise as well as parameter perturbation sensitivity problems. Moreover, in the model-free setting, in contrast with naive Monte-Carlo estimation, it potentially benefits from more assumptions on the policy parameterization. Denoting a time-indexed sequence of states, actions, and rewards of the joint system composed of the policy and environment as a *path*, a parameter setting induces a path distribution $p_\theta(\tau)$ and rewards $R(\tau) = Z_\gamma \sum_{k=0}^{H} \gamma^k r_k$ along a path τ. Thus, we may write the gradient of the expected return as

$$\begin{aligned}\nabla_\theta J(\theta) &= \nabla_\theta \int p_\theta(\tau) R(\tau) d\tau \\ &= \int p_\theta(\tau) \nabla_\theta \log p_\theta(\tau) R(\tau) d\tau \\ &= E\{\nabla_\theta \log p_\theta(\tau) R(\tau)\}.\end{aligned}$$

If our system $p(s'|s,a)$ is Markovian, we may use $p_\theta(\tau) = p(s_0) \prod_{h=0}^{H} p(s_{k+1}|s_k, a_k) \pi_\theta(a_k|s_k)$ for a stochastic policy $a \sim \pi_\theta(a|s)$ to obtain the model-free policy gradient estimator known as Episodic REINFORCE (Williams 1992)

$$\nabla_\theta J(\theta) = Z_\gamma E\left\{\sum_{h=0}^{H} \gamma^k \nabla_\theta \log \pi_\theta(a_k|s_k) \sum_{k=h}^{H} \gamma^{k-h} r_k\right\},$$

and for the deterministic policy $a = \pi_\theta(s)$, the model-based policy gradient

$$\nabla_\theta J(\theta) = Z_\gamma E\left\{\sum_{h=0}^{H} \gamma^k \left(\nabla_a \log p(s_{k+1}|s_k, a_k)^T \nabla_\theta \pi_\theta(s)\right) \sum_{k=h}^{H} \gamma^{k-h} r_k\right\},$$

follows from $p_\theta(\tau) = p(s_0) \prod_{h=0}^{H} p(s_{k+1}|s_k, \pi_\theta(s_k))$.

Note that all rewards preceding an action may be omitted as the cancel out in expectation. Using a state-action value function $Q^{\pi_\theta}(s,a,h) = E\left\{\sum_{k=h}^{H} \gamma^{k-h} r_k \middle| s, a, \pi_\theta\right\}$ (see ▶ value function approximation), we can rewrite REINFORCE in its modern form

$$\nabla_\theta J(\theta) = Z_\gamma E\left\{\sum_{h=0}^{H} \gamma^k \nabla_\theta \log \pi_\theta(a_k|s_k) \left(Q^{\pi_\theta}(s,a,h) - b(s,h)\right)\right\},$$

known as the policy gradient theorem where the baseline $b(s,h)$ is an arbitrary function that may be used to reduce the variance, and $Q^{\pi_\theta}(s,a,h)$ represents the action-▶ value function.

While likelihood ratio gradients have been known since the late 1980s, they have recently experienced an upsurge of interest due to their demonstrated effectiveness in applications; see, e.g., Peters and Schaal (2008)), progress toward variance reduction using optimal baselines (Lawrence et al. 2003), rigorous understanding of the relationships between value functions and policy gradients (Sutton et al. 2000), policy gradients in reproducing kernel Hilbert space (Bagnell 2004), as well as faster, more robust convergence using natural policy gradients (Bagnell 2004; Peters and Schaal 2008)

A recent major development (Silver et al. 2014) demonstrates that many of the key results from model-free stochastic policy search can be transferred to deterministic policy classes by considering the limiting case of a likelihood ratio method. Importantly, this estimation of a deterministic policy gradient can be much more sample efficient than existing techniques; the caveat remains that the total return may indeed fail to be differentiable and both practical performance and theory in such settings are poorly understood.

POS Tagging

Walter Daelemans
CLIPS University of Antwerp, Antwerpen, Belgium

Synonyms

Grammatical tagging; Morphosyntactic disambiguation; Part of speech tagging; Tagging

Definition

Part-of-speech tagging (POS tagging) is a process in which each word in a text is assigned its appropriate morphosyntactic category (for example *noun-singular*, *verb-past*, *adjective*, *pronoun-personal*, and the like). It therefore provides information about both morphology (structure of words) and syntax (structure of sentences). This disambiguation process is determined both by constraints from the lexicon (what are the possible categories for a word?) and by constraints from the context in which the word occurs (which of the possible categories is the right one in this context?). For example, a word like *table* can be a noun-singular, but also a verb-present (as in *I table this motion*). This is lexical knowledge. It is the context of the word that should be used to decide which of the possible categories is the correct one. In a sentence like *Put it on the table,* the fact that *table* is preceded by the determiner *the*, is a good indication that it is used as a noun here. Systems that automatically assign parts of speech to words in text should take into account both lexical and contextual constraints, and they are typically found in implementations as a lookup module and a disambiguation module.

Motivation and Background

In most natural language processing (NLP) applications, POS tagging is one of the first steps to allow abstracting away from individual words. It is not to be confused with *lemmatization*, a process that reduces morphological variants of words to a canonical form (the citation form, for example, infinitive for verbs and singular for nouns). Whereas lemmatization allows abstraction over different forms of the same word, POS tagging abstracts over sets of different words that have the same function in a sentence. It should also not be confused with *tokenization*, a process that detects word forms in text, stripping off punctuation, handling abbreviations, and so on. For example, the string *don't* could be converted to *do not*. Normally, a POS tagging system would take tokenized text as input. More advanced tokenizers may even handle multiword items, for example treating *in order to* not as three separate words but as a single lexical item.

Applications. A POS tagger is the first disambiguation module in text analysis systems. In order to determine the syntactic structure of a sentence (and its semantics), we have to know the parts of speech of each word. In earlier approaches to syntactic analysis (parsing), POS tagging was part of the parsing process. However, individually trained and optimized POS taggers have increasingly become a separate module in shallow or deep syntactic analysis systems. By extension, POS tagging is also a foundational module in text mining applications ranging from information extraction and terminology/ontology extraction to summarization and question answering.

Apart from being one of the first modules in any text analysis system, POS tagging is also useful in linguistic studies (corpus linguistics) – for example for computing frequencies of disambiguated words and of superficial syntactic structures. In speech technology, knowing the part of speech of a word can help in speech synthesis (the verb "subJECT" is pronounced differently from the noun "SUBject"), and in speech recognition, POS taggers are used in some approaches to language modeling. In spelling and grammar checking, POS tagging plays a role in increasing the precision of such systems.

Part-of-speech tag sets. The inventory of POS tags can vary from tens to hundreds depending on the richness of morphology and syntax that is represented and on the inherent morphological complexity of a language. For English, the tag sets most used are those of the Penn Treebank (45 tags; Marcus et al. 1993), and the CLAWS C7 tag set (146 tags; Garside and Smith 1997). Tag sets are most often developed in the context of the construction of annotated corpora. There have been efforts to standardize the construction of tag sets to increase translatability between different tag sets, such as Eagles. (http://www.ilc.cnr.it/EAGLES96/browse.html) and ISO/TC 37/SC 4. (http://www.tc37sc4.org/)

The following example shows both tag sets. By convention, a tagged word is represented by attaching the POS tag to it, separated by a slash.

Pierre/NNP Vinken/NNP ,/, 61/CD years/NNS old/JJ ,/, will/MD join/VB the/DT board/NN as/IN a/DT nonexecutive/JJ director/NN Nov./NNP 29/CD ./. [Penn Treebank]

Pierre/NP1 Vinken/NP1 ,/, 61/MC years/NNT2 old/JJ ,/, will/VM join/VVI the/AT Board/NN1 as/II a/AT1 nonexecutive/JJ director/NN1 Nov./NPM1 29/MC ./. [CLAWS C7]

As can be seen, the tag sets differ in level of detail. For example, NNT2 in the C7 tag set indicates a plural temporal noun (as a specialization of the word class noun), whereas the Penn

Treebank tag set only specializes to plural noun (NNS).

Like most tasks in NLP, POS tagging is a disambiguation task, and both linguistic knowledge-based handcrafting methods and corpus-based learning methods have been proposed for this task. We will restrict our discussion here to the statistical and machine learning approaches to the problem, which have become mainstream because of the availability of large POS tagged corpora and because of better accuracy in general than handcrafted systems. A state of the art system using a knowledge-based approach is described in Karlsson et al. (1995).

A decade old now, but still a complete and informative book-length introduction to the field of POS tagging is van Halteren (1999). It discusses many important issues that are not covered in this article (performance evaluation, history, handcrafting approaches, tag set development issues, handling unknown words, and more.). A more recent introductory overview is Chap. 5 in Jurafsky and Martin (2008).

Statistical and Machine Learning Approaches to Tagging

In the late 1970s, statistical approaches based on n-gram probabilities (probabilities that sequences of n tags occur in a corpus) computed on frequencies in tagged corpora have already been proposed by the UCREL team at the University of Lancaster (Garside and Smith 1997). These early models lacked a precise mathematical framework and a principled solution to working with zero- or low probability frequencies. It was realized that Hidden Markov Models (HMM) in use in speech recognition were applicable to the tagging problem as well.

HMMs

HMMs are probabilistic finite state automata that are flexible enough to combine n-gram information with other relevant information to a limited extent. They allow supervised learning by computing the probabilities of n-grams from tagged corpora, and unsupervised learning using the Baum-Welch algorithm. Finding the most probable tag sequence given a sequence of words (decoding) is done using the Viterbi search. In combination with smoothing methods for low-frequency events and special solutions for handling unknown words, this approach results in a state-of-the-art tagging performance. A good implementation is TnT (Trigrams'n Tags Brants 2000).

Transformation-Based Error-Driven Learning (Brill-Tagging)

Transformation-based learning is an eager learning method in which the learner extracts a series of rules, each of which transforms a tag into another tag given a specific context. Learning starts with an initial annotation (e.g., tag each word in a text by the POS tag it is most frequently associated with in a training corpus), and compares this annotation with a gold standard annotation (annotated by humans). Discrepancies trigger the generation of rules (constrained by templates), and in each cycle, the best rule is chosen. The best rule is the one that most often leads to a correct transformation in the whole training corpus (Brill 1995a). An unsupervised learning variant (using a lexicon with word-tag probabilities) is described in Brill (1995b). Fully unsupervised POS tagging can also be achieved using distributional clustering techniques, as pioneered by Schutze (1995). However, these methods are hard to evaluate and compare to supervised approaches. The best way to evaluate them is indirectly, in an application-oriented way, as in Ushioda (1996).

Other Supervised Learning Methods

As a supervised learning task, POS tagging has been handled mostly as in a *sliding window* representation. Instances are created by making each word in each sentence a focus feature of an instance, and adding the left and right context as additional features. The class to be predicted is the POS tag of the focus word. Instead of using the words themselves as features, information about them can be used as features as well (e.g., capitalized or not, hyphenated or not, the POS tag of the word for left context words as predicted by the tagger previously, a symbol representing the possible lexical categories of the focus word and right context words, first and last letters of the word in each position, and so on.).

The following table lists the structure of instance representations for part of the sentence shown earlier. In this case the words themselves are feature values, but most often other derived features would replace these because of sparseness problems.

		Focus		Class	
=	=	Pierre	Vinken		NNP
=	Pierre	Vinken		61	NNP
Pierre	Vinken		61	years	
Vinken		61	years	old	CD

Most classification-based, supervised machine learning methods can be, and have been applied to this problem, including decision tree learning (Schmid 1994b), memory-based learning (Daelemans et al. 1996), maximum entropy models (Ratnaparkhi 1996), neural networks (Schmid 1994a), ensemble methods (van Halteren et al. 2001), and many others. All these methods seem to converge to a 96–97 % accuracy rate on the Wall Street Journal corpus using the Penn Treebank tag set. In a systematic comparison of some of the methods listed here, van Halteren et al. (2001) found that TnT outperforms maximum entropy and memory-based learning methods, which in turn outperform Brill tagging. Nonpropositional supervised learning methods have been applied to the task as well (Cussens 1997) with grammatical structure as background knowledge with similar results. The best results reported on the WSJ corpus so far is bidirectional perceptron learning (Shen et al. 2007) with a 97.33 % accuracy.

Because of these high scores, POS tagging (at least for English) is considered by many a solved problem. However, as for most machine-learning based NLP systems, domain adaptation is still a serious problem for POS tagging. A tagger trained to high accuracy on newspaper language will fail miserably on other types of text, such as medical language.

Positive Definite

▶ Positive Semidefinite

Positive Predictive Value

▶ Precision

Positive Semidefinite

Synonyms

Positive definite

Definition

A symmetric $m \times m$ matrix K satisfying $\forall x \in c^m : x^* Kx \geq 0$ is called positive semidefinite. If the equality only holds for $x = \vec{0}$ the matrix is positive definite.

A function $k : X \times X \rightarrow c, X \neq \emptyset$, is positive (semi-) definite if for all $m \in n$ and all $x_1, \ldots, x_m \in X$ the $m \times m$ matrix $\vec{K}$ with elements $K_{ij} := k(x_i, x_j)$ is positive (semi-) definite.

Sometimes the term strictly positive definite is used instead of positive definite, and positive definite refers then to positive semidefiniteness.

Posterior

Posterior Probability

Geoffrey I. Webb
Faculty of Information Technology, Monash University, Victoria, Australia

Synonyms

Posterior

Definition

In Bayesian inference, a *posterior probability* of a value x of a random variable X given a context a value y of a random variable Y, $\mathrm{P}(X = x | Y = y)$, is the probability of X assuming the value x in the context of $Y = y$. It contrasts with the ▶ prior probability, $\mathrm{P}(X = x)$, the probability of X assuming the value x in the absence of additional information.

For example, it may be that the prevalence of a particular form of cancer, *exoma*, in the population is 0.1 %, so the prior probability of exoma, P(exoma = true), is 0.001. However, assume 50 % of people who have skin discolorations of greater than 1 cm width (sd > 1 cm) have exoma. It follows that the posterior probability of exoma given sd >1 cm, P(exoma = true | sd >1 cm = true), is 0.500.

Actual class	Positive	True positive (TP)	False negative (FN)
	Negative	False positive (FP)	True negative (TN)

We can employ the same terminology used in a ▶ confusion matrix to define these two measures. Let relevant documents be positive examples and irrelevant documents, negative examples. The two measures can be redefined with reference to a special case of the confusion matrix, with two classes: one designated the *positive* class and the other the *negative* class, as indicated in Table 1.

Precision = True positives/total number of positives predicted = TP/(TP + FP)

Recall = True positives/total number of actual positives = TP/(TP + FN)

Instead of two measures, they are often combined to provide a single measure of retrieval performance called the ▶ F-measure as follows:

F-measure = 2 * recall * precision/(recall + precision)

Predicate

A *predicate* or predicate symbol is used in logic to denote properties and relationships. Formally, if P is a predicate with arity n, and $t_1, \ldots, t_n$ is a sequence of n terms (i.e., constants, variables, or compound terms built from function symbols), then $P(t_1, \ldots, t_n)$ is an atomic formula or *atom*. Such an atom represents a statement that can be either true or false. Using logical connectives, atoms can be combined to build well-formed formulae in ▶ first-order logic or ▶ clauses in ▶ logic programs.

Predicate Invention

Definition

Predicate invention is used in ▶ inductive logic programming to refer to the automatic introduction of new relations or predicates in the hypothesis language. Inventing relevant new predicates is one of the hardest tasks in machine learning, because there are so many possible ways to introduce such predicates and because it is hard to judge their quality. As an example, consider a situation where in the predicates `fatherof` and `motherof` are known. Then it would make sense to introduce a new predicate that is true whenever `fatherof` or `motherof` is true. The new predicate that would be introduced this way corresponds to the `parentof` predicate. Predicate invention has been introduced in the context of inverse resolution.

Predictive software models

Introduction

Software engineering (SE) is a knowledge- and decision-intensive activity. From the initial stages of the software life cycle (i.e., requirement analysis), to the later stage of testing the system, and finally maintaining the software through its operational life, decisions need to be made which impact both its success and failure. For instance, during project planning one needs to be able to forecast or predict the required resources to build the system. At the later stages such as testing or maintenance it is desirable to know which parts of the system may be impacted by a change, or are more risky or will require more intensive testing.

The process of developing software can potentially create a large amount of data and domain knowledge. The nature of the data, of course, depends on the phase in which the data were generated. During the requirement analysis, this data most times is manifested in the form of documentations. As the process moves forward, other types of artifacts such as code and test cases are generated. However, what, when, how accurately, and how much is recorded varies from one organization to the next. More mature organizations have a tendency to maintain larger amount of data about the software systems they develop.

The data generated as part of the software engineering process captures a wide range of latent knowledge about the system. Having such a source of information, the question one needs to ask is that whether there is any technology that can leverage this potentially vast amount of data to:

- Better understand a system
- Make more informative decisions as needed through the life of an existing system
- Apply lessons learned from building other systems to the creation of a new system

As this chapter will show, machine learning (ML), which provides us with a host of algorithms and techniques to learn from data, is such a technology. In preparing this entry we have drawn from over two decades of research in applying ML to various software engineering problems. The number of potential uses of ML in SE is practically enormous and the list of applications is expanding over time. The focus of this chapter is a subset of these applications, namely the ones that aim to create models for the purpose of making a prediction regarding some aspect of a software system. One could dedicate a separate article for some of these prediction tasks, as there is a large body of research covering different aspects of interest, such as algorithms, estimation methods, features used, and the like. However, due to space constraints, we will only mention a few representative research examples. The more general topic of the application of ML in SE can be studied from different points of view. A good discussion of many such aspects and applications can be found in Zhang and Tsai (2003).

Traditionally, regression-based techniques have been used in software engineering for building predictive models. However, this requires making a decision as to what kind of regression method should be used (e.g., linear or quadratic), or alternatively what kind of curve should be fit to the data. This means that the general shape of the function is determined first, and then the model is built. Some researcher, have used ML as a way to delegate such decisions to the algorithm. In other words, it is the algorithm that would produce the best fit to the data. Some of the most common replacements in the case of regression problems have been neural networks (NN) and genetic programming (GP). However, obviously the use of such methods still requires other types of decisions, such as the topology of the network, the number of generations, or the probability of mutations to be made by humans. Sometimes, a combination of different methods such as genetic algorithms and neural networks are used, where one method explores possible parameters for the actual method used to build the model.

Software engineering-related datasets, similar to many other real world datasets, are known to contain noise. Another justification for the use of ML in software engineering applications is that it provides algorithms that are less sensitive to noise.

The Process of Applying ML to SE

To apply ML to SE, similar to other applications, one needs to follow certain steps, which include:

Understanding the problem. This is an essential step that heavily influences the decisions to follow. Examples of typical problems in the software engineering domain are the need to be able to estimate the cost or effort involved in developing a software, or to be able to characterize the quality of a software system, or to be able to predict what modules in a system are more likely to have a defect.

Casting the original problem as a learning problem. To use ML technology, one needs to decide on how to formulate the problem as a learning task. For instance, the problem of finding modules that are likely to be faulty can be cast as a classification problem, (e.g., is the module faulty or not) or a numeric prediction problem (e.g., what the estimated fault density of a module is). This mapping is not always straightforward, and may require further refinement of the original problem statement or breaking down the original problem into sub-problems, for some of them ML may provide an appropriate solution.

Collection of data and relevant background knowledge. Once the ML problem for a particular SE application is identified, one needs to collect the necessary data and background knowledge in support of the learning task. In many SE applications data is much more abundant or easier to collect than the domain theory or background knowledge relevant to a particular application. For instance, collecting data regarding faults discovered in a software system and changes applied to the source to correct a fault is a common practice in software projects. On the other hand, there is no comprehensive and agreed upon domain theory describing software systems. Having said that, in the case of some applications, if we limit ourselves to incomplete background knowledge, then it can be automatically generated by choosing a subset that is considered to be relevant. For instance, in Cohen and Devanbu (1999), the authors apply inductive logic programming to the task of predicting faulty modules in a software system. They describe the software system in terms of cohesion and coupling-based relations between classes, which are generated by parsing the source code.

Data preprocessing and encoding. Preprocessing the data includes activities such as reducing the noise, selecting appropriate subsets of the collected data, and determining a proper subset of features that describe the concept to be learned. This cleaner data will be input to a specific algorithm and implementation. Therefore, the data and background knowledge, if any, may need to be described and formatted in a manner that complies with the requirements of the algorithm used.

Applying machine learning and evaluating the results. Running a specific ML algorithm is fairly straightforward. However, one needs to measure the goodness of what is learned. For instance, in the case of classification problems, models are frequently assessed in terms of their accuracy by using methods such as holdout and cross-validation. In case of numeric prediction, other standard measures such as mean magnitude of relative error (MMRE) are commonly used. Additionally, software engineering researchers have sometimes adopted other measures for certain applications. For instance PRED(x), which is percentage of the examples (or samples) with magnitude of relative error (MRE)$\leq x$. According to Pfleeger and Atlee (2003), most managers use PRED(25) to assess cost, effort, and schedule models, and consider the model to function well if the value of PRED(25) is greater than 75 %. As for MMRE, a value of less than 25 % is considered to be good; however, other researchers, such as Boehm, would recommend a value of 10 % or less. Assessing the usefulness of what is learned sometimes requires feedback from domain experts or from end users. If what is learned is determined to be inadequate, one may need to either retry this step by adjusting the parameters of the algorithms used, or reconsider the decisions made in earlier stages and proceed accordingly.

Field testing and deployment. Once what is learned is assessed to be of value, it needs to actually be used by the intended users (e.g., project managers and software engineers). Unfortunately, despite the very large body of research in software engineering in general and use of ML in specific applications in SE, the number of articles discussing the actual use and impact of the research in industry is relatively very small. Very often, the reason for this is the lack of desire to share what the industry considers to be confidential information. However, there are numerous research articles that are based on industrial data, which is an indication of the practical benefits of ML in real-world SE.

Applications of Predictive Models in SE

The development of predictive models is probably the most common application of ML in software engineering. This observation is consistent with findings of previous research (Zhang and Tsai 2003). In this section, we mention some of the predictive models one can learn from software engineering data. Our goal is to provide examples of both well established and newer applications. It should be noted that the terminology used by researchers in the field is not always consistent. As such, one may argue that some of these examples belong to more than one category. For instance, in Fenton and Neil (1999) the authors consider predicting faults as a way of estimating software quality and maintenance effort. The paper could potentially belong to any of the categories of fault, quality, or maintenance effort prediction.

Software Size Prediction

Software size estimation is the process of predicting the size of a software system. As software size is usually an input to models that estimate project cost schedule and planning, an accurate estimation of software size is essential to proper estimation of these dependent factors. Software size can be measured in different ways, most common of which is the number of lines of code (LOC); however, other alternatives, such as function points, which are primarily for effort estimation, also provide means to convert the measure to LOC. There are different methods for software sizing, one of which is the component-based method (CBM). In a study to validate the CBM method, Dolado (2000) compared models generated by multiple ▸ linear regression (MLR) with the ones obtained by neural networks and genetic programming. He concluded that both NN- and GP-based models perform as well or better than the MLR models. One of the cited benefits of NN was its ability to capture nonlinear relations, which is one of the weaknesses of MLR, while GP was able to generate models that were interpretable. Regolin et al. (2003) also used NN- and GP-based models to predict software size in terms of LOC. They use both function points and number of components metrics for this task. Pendharkar (2004) uses decision tree regression to predict the size of OO components. The total size of the system can be calculated after the size of its components is determined.

Software Quality Prediction

The ISO 9126 quality standard decomposes quality to functionality, reliability, efficiency, usability, maintainability, and portability factors. Other models such as McCall's, also define quality in terms of factors that are themselves composed of quality criteria. These quality criteria are further associated with measurable attributes called quality metrics, for instance fault or change counts (Fenton and Pfleeger 1998) However, as stated in Fenton and Pfleeger (1998), many software engineers have a narrower view of quality as the lack of software defects. A de facto standard for software quality is fault density. Consequently, it is not surprising to see that in many published articles the problem of predicting the quality of a system is formulated as prediction of faults. To that end, there has been a large body of work over the years that has applied various ML techniques to build models to assess the quality of a system. For instance, Evett and Khoshgoftar (1998) used genetic programming to build models that predict the number of faults expected in each module. Neural networks have appeared in a number of software quality modeling applications such as Khoshgoftaar et al. (1997), which applied the technique to a large industrial system to classify modules as fault-prone or not fault-prone, or Quah and Thwin (2003) who used object-oriented design metrics as features in developing the model. In El Emam et al. (2001) the authors developed fault prediction models for the purpose of identifying high-risk modules. In this study, the authors investigated the effect of various parameter settings on the accuracy of these models. The models were developed using data from a large real-time system. More recently, Xing et al. (2005) used SVMs and Seliya and Khoshgoftaar (2007) used an EM semi-supervised learning algorithm to develop software quality models. Both these works cite the ability of these algorithms to generate models with good performance in the presence of a small amount of labeled data.

Software Cost Prediction

Software cost prediction typically refers to the process of estimating the amount of effort needed to develop a software system. As this definition suggests, cost and effort estimations are often used interchangeably. Various kinds of cost estimations are needed throughout the software life cycle. Early estimation allows one to determine the feasibility of a project. More detailed estimation allows managers to better plan for the project. As there is less information available in the early stages of the project, early predictions have a tendency to be the least accurate. Software cost and effort estimation models are among some of the oldest software process prediction models. There are different methods of estimating costs including:

(1) Expert opinion; (2) analogy based on similarity to other projects; (3) decomposition of the project in terms of components to deliver or tasks to accomplish, and to generate a total estimate from the estimates of the cost of individual components or activities; and (4) the use of estimation models (Fenton and Pfleeger 1998).

In general, organization-specific cost estimation datasets tend to be small, as many organizations deal with a limited number of projects and do not systematically collect process level data, including the actual time and effort expenditure for completion of a project. As cost estimation models are numeric predictors, many of the original modeling techniques were based on regression methods.

The study in Briand et al. (1999) aims to identify methods that generate more accurate cost models, as well as to investigate the effects of the use of organization-specific versus multi-organization datasets. The authors compared the accuracy of models generated by using ordinary least squares regression, stepwise ANOVA, CART, and analogy. The measures used were MMRE, median of MRE (MdMRE), and PRED(25). While their results did not show a statistical difference between models obtained from these methods, they suggest that CART models are of particular interest due to their simplicity of use and interpretation.

Shepperd and Schofield (1997) describes the use of analogies for effort prediction. In this method, projects are characterized in terms of attributes such as the number of interfaces, the development method, or the size of the functional requirements document. The prediction for a specific project is made based on the characteristics of projects most similar to it. The similarity measure used in Shepperd and Schofield (1997) is Euclidean distance in n-dimensional space of project features. The proposed method was validated on nine different industrial datasets, covering a total of 275 projects. In all cases, the analogy-based method outperforms algorithmic models based upon stepwise regression when measured in terms of MMRE. When results are compared using PRED(25) the analogy-based method generates more accurate models in seven out of nine datasets. Decision tree and neural network-based models are also used in a number of studies on effort estimation models.

In a more recent paper, (Oliveira 2006), a comparative study of support vector regression (SVR), radial basis function ▶ neural networks (RBFNs), and ▶ linear regression-based models for estimation of a software project effort is presented. Both linear as well as RBF kernels were used in the construction of SVR models. Experiments using a dataset of software projects from NASA showed that SVR significantly outperforms RBFNs and linear regression in this task.

Software Defect Prediction

In research literature one comes across different definitions for what constitutes a defect: fault and failure. According to Fenton and Pfleeger (1998) a fault is a mistake in some software product due to a human error. Failure, on the other hand, is the departure of the system from its required behavior. Very often, defects refer to faults and failures collectively. In their study of defect prediction models, Fenton and Neil observed that, depending on the study, defect count could refer to a post-release defect, the total number of known defects, or defects that are discovered after some arbitrary point in the life cycle. Additionally, they note that defect rate, defect density, and failure rate are used almost interchangeably in the literature (Fenton and Neil 1999). The lack of an agreed-upon definition for such a fundamental measure makes comparison of the models or published results in the literature difficult. Two major reasons cited in research literature for developing defect detection models are assessing software quality and focusing testing or other needed resources on modules that are more likely to be defective. As a result, we frequently find ourselves in a situation where a model could be considered both a quality prediction model and a defect prediction model. Therefore, most of the publications we have mentioned under software quality prediction could also be referred to in this subsection. Fenton and Neil suggest using Bayesian Belief Networks as an alternative to other existing methods (Fenton and Neil 1999).

Software Reliability Prediction

The ANSI Software Reliability Standard defines software reliability as:

> “the probability of failure-free operation of a computer program for a specified time in a specified environment.”

Software reliability is an important attribute of software quality. There are a number of publications on the use of various neural network-based reliability prediction models, including Sitte (1999) where NN-based software reliability growth models are compared with models obtained through recalibration of parametric models. Results show that neural networks are not only much simpler to use than the recalibration method, but that they are equal or better trend predictors. In Pai and Hong (2006) the authors use SVMs to predict software reliability. They use simulated annealing to select the parameters of the SVM model. Results show that an SVM-based model with simulated annealing performs better than existing Bayesian models.

Software Reusability Prediction

The use of existing software artifacts or software knowledge is known as software reuse. The aim of software reuse is to increase the productivity of software developers, and increase the quality of end product, both of which contribute to overall reduction in software development costs. While the importance of software reuse was recognized as early as 1968 by Douglas McIlroy, applications of ML in predicting reusable components are relatively few and far between. The typical approach is to label the reusable piece of code (i.e., a module or a class) as one of reusable or non-reusable, and to then use software metrics to describe the example of interest. An early work by Esteva (1990) used ID3 to classify Pascal modules from different application domains as either reusable or not-reusable. These modules contained different number of procedures. Later work in Mao et al. (1998) uses models built using C4.5 as a means to verify three hypothesis of correlation between reusability and the quantitative attributes of a piece of software: inheritance, coupling, and complexity. For each hypothesis, a set of relevant metrics (e.g., complexity metrics for a hypothesis on the relation between complexity and reuse) is used to describe examples. Each example is labeled as one of four classes of reusability, ranging from “totally reusable” to “not reusable at all.” If the learned model performs well then this is interpreted as the existence of a hypothesized relation between reuse and one of the abovementioned quantitative attributes.

Other Applications

In this section, we discuss some of the more recent uses of ML techniques in building predictive models for software engineering applications that do not fall into one the above widely researched areas.

In Padberg et al. (2004) models are learned to predict the defect content of documents after software inspection. Being able to estimate how many defects are in a software document (e.g., specifications, designs) after the inspection, allows managers to decide whether to re-inspect the document to find more defects or pass it on to the next development step. To capture the non-linear relation between the inspection process metrics, such as total number of defects found by the inspection team and the number of defects in the document, the authors train a neural network. They conclude that these models yield much more accurate estimates than standard estimation methods such as capture-recapture and detection profile.

Predicting the stability of object-oriented software, defined as the ease by which a software system or component can be changed while maintaining its design, is the subject of research in Grosser et al. (2002). More specifically, stability is defined as preservation of the class interfaces through evolution of the software. To accomplish the above task, the authors use Cased-Base Reasoning. A class is considered stable if its public interface in revision J is included in revision $J + 1$. Each program class or case is represented by structural software metrics, which belong to one of the four categories of coupling, cohesion, inheritance, and complexity.

Models that predict which defects will be escalated are developed in Ling et al. (2006). Escalated defects are the ones that were not addressed prior to release of the software due to factors such as deadlines and limited resources. However, after the release, these defects are escalated by the customer and must be immediately resolved by the vendor at a very high cost. Therefore, the ability to predict the risk of escalation for existing defect reports will prevent many escalations, and result in large savings for the vendor. The authors in this paper show how the problem of maximizing net profit (the difference in cost of following predictions made by the escalation prediction model versus the existing alternative policy) can be converted to cost-sensitive learning. The assumption here is that net profit can be represented as a linear combination of true positive, false positive, true negative, and false negative prediction counts, as is done for cost-sensitive learning that attempts to minimize the weighted cost of the abovementioned four factors. The results of the experiments performed by the authors show that an improved version of the CSTree algorithm can produce comprehensible models that generate a large positive unit net profit.

Most predictive models developed for software engineering applications, including the ones cited in this article, make prediction regarding a single entity – for instance, whether a module is defective, how much effort is needed to develop a system, is a piece of code reusable, and so on. Sayyad Shirabad et al. (2007) introduced the notion of relevance relations among multiple entities in software systems. As an example of such relations, the authors applied historic problem report and software change data to learned models for the Co-update relation among files in a large industrial telecom system. These models predict whether changing one source file may require a change in another file. Different sets of attributes, including syntax-based software metrics as well as textual attributes such as source file comments and problem reports, are used to describe examples of the Co-update relation. The C5.0 decision tree induction algorithm was used to learn these predictive models. The authors concluded that text-based attributes outperform syntactic attributes in this model-building task. The best results are obtained for text-based attributes extracted from problem reports. Additionally, when these attributes are combined with syntactic attributes, the resulting models perform slightly better.

Future Directions

As we mentioned earlier due to its decision-intensive nature, there is potential for learning a large number of predictive models for software engineering tasks. A very rich area of research for future applications of predictive models in software engineering is in *Autonomic Computing*. Autonomic computing systems, as was put forward in Ganek and Corbi (2003), should be:

- *Self-configuring*: able to adapt to changes in the system in a dynamic fashion.
- *Self-optimizing*: able to improve performance and maximize resource allocation and utilization to meet end users' needs while minimizing human intervention.
- *Self-healing*: able to recover from mistakes by detecting improper operations proactively or reactively and then initiate actions to remedy the problem without disrupting system applications.
- *Self-protecting*: able to anticipate and take actions against intrusive behaviors as they occur, so as to make the systems less vulnerable to unauthorized access.

Execution of actions in support of the capabilities mentioned above follows the detection of a triggering change of state in the environment. In some scenarios, this may entail a prediction about the current state of the system; in other scenarios, the prediction may be about the future state of the system. In a two-state scenario, the system needs to know whether it is in a normal or abnormal (undesired) state. Examples of undesired states are *needs optimization* or *needs healing*. The detection of the state of a system can be cast as a classification problem. The decision as to what attributes should be used to represent each example of a normal or an abnormal state depends on the specific prediction model that we would like to build and on the monitoring capabilities of the system. Selecting the best attributes among a set of potential attributes will require empirical analysis. However, the process can be further aided by:

- *Expert knowledge*: Based on their past experience, hardware and software experts typically have evidence or reasons to believe that some attributes are better indicators of desired or undesired states of the system.
- *Documentation*: System specification and other documents sometimes include the range of acceptable values for certain parameters of the system. These parameters could be used as attributes.
- *Feature selection*: This aims to find a subset of available features or attributes that result in improving a predefined measure of goodness, such as the accuracy of the model. Reducing the number of features may also result in a simpler model. One of the benefits of such simpler models is the higher prediction speed, which is essential for timely responses by the autonomic system to changes in the environment.

Obviously, given enough examples of different system states, one can build multi-class models, which can make finer predictions regarding the state of the system.

In the context of autonomic computing, besides classification models, numeric predictors can also be used for resource estimation (e.g., what is the appropriate database cache size considering the current state of the system). Furthermore, an autonomic system can leverage the ability to predict the future value of a variable of interest, such as the use of a particular resource based on its past values. This can be accomplished through ▶ time series predictions. Although researchers have used neural networks and support vector machines for time series prediction in various domains, we are not aware of an example of the usage of such algorithms in autonomic computing.

Preference Learning

Johannes Fürnkranz[1,3] and Eyke Hüllermeier[2]
[1]Knowledge Engineering Group, TU Darmstadt, Darmstadt, Deutschland
[2]Department of Computer Science, Paderborn University, Paderborn, Germany
[3]Department of Information Technology, University of Leoben, Leoben, Austria

Abstract

Preference learning refers to the task of learning to predict (contextualized) preferences on a collection of alternatives, which are often represented in the form of an order relation, on the basis of observed or revealed preference information. Supervision in preference learning is typically weak, in the sense that only partial information about sought structures or indirect information about an underlying value function are provided; a common example is feedback in the form of pairwise comparisons between alternatives. Especially important in preference learning are ranking problems, in which preferences are represented in terms of total or partial order relations. Such problems can be approached in two fundamentally different ways, either by learning binary preferences on pairs of alternatives or by inducing an underlying (latent) value function on single alternatives.

Synonyms

Comparison training; Constraint classification; Learning from preferences

Motivation and Background

Preference information plays a key role in automated decision-making and appears in various guises in artificial intelligence (AI) research (Domshlak et al. 2011). In particular, the formal modeling of preferences can be considered an essential aspect of autonomous agent design. Yet, in spite of the existence of formalisms for representing preferences in a compact way, such as CP-networks (Boutilier et al. 2004), modeling preferences by hand is a difficult task. This is an important motivation for preference *learning*, which is meant to support and partly automatize the design of preference models. Roughly speaking, preference learning is concerned with the automated acquisition of preference models from observed or revealed preference information, that is, data from which (possibly uncertain) preference representations can be deduced in a direct or indirect way.

Computerized methods for revealing the preferences of individuals (users) are useful not only in AI but also in many other fields showing a tendency for *personalization* of products and services, such as computational advertising, e-commerce, and information retrieval, where such techniques are also known as ▸ learning to rank (Liu 2011). Correspondingly, a number of methods and tools have been proposed with the goal of leveraging the manifold information that users provide about their preferences, either explicitly via ratings, written reviews, etc. or implicitly via their behavior (shopping decisions, websites visited, and so on). Typical examples include ▸ recommender systems and ▸ collaborative filtering, which can be viewed as special cases of preference learning. A first attempt at setting a common framework for this emerging subfield of machine learning was made by Fürnkranz and Hüllermeier (2010).

Ranking is one of the key tasks in the realm of preference learning. One can distinguish between two important types of ranking problems, namely, learning from object and learning from label preferences. A ranking is a special type of preference structure, namely, a *strict total order*, that is, a binary relation $\succ$ on a set $\mathcal{A}$ of alternatives that is total, irreflexive, and transitive. In agreement with our preference semantics, $a \succ b$ suggests that alternative a is preferred to alternative b. However, in a wider sense, the term "preference" can simply be interpreted as any kind of order relation. For example, $a \succ b$ can also mean that a is an algorithm that outperforms b on a certain problem or that a is a student finishing her studies before another student b.

Structure of the Learning System

An important difference between object and label ranking concerns the formal representation of the preference context and the alternatives to be ordered. In object ranking, the alternatives themselves are characterized by properties, typically in terms of a feature vector (attribute-value representation). Thus, the learner has the possibility to generalize via properties of the alternatives, whence a ranking model can be applied to arbitrary sets of such alternatives. In label ranking, the alternatives to be ranked are labels as in classification learning, i.e., mere identifiers without associated properties. Instead, the ranking context is characterized in terms of an instance from a given instance space, and the task of the model is to rank alternatives depending on properties of the context. Thus, the context may change (as opposed to object ranking, where it is implicitly fixed), but the objects to be ranked remain the same. Stated differently, object ranking is the problem to rank varying sets of objects under invariant preferences, whereas label ranking is the problem to rank an invariant set of objects under varying preferences.

Both problems can be approached in two principal ways, either by learning a *value function* that induces the sought ranking by *evaluating individual alternatives* or by comparing pairs of alternatives, that is, learning a *binary preference relation*. Note that the first approach implicitly assumes an underlying total order relation, since numerical (or at least totally ordered) utility scores enforce the comparability of alternatives. The second approach is more general in this regard, as it also allows for partial order relations. On the other hand, this approach may lead to additional complications, since a set of *hypothetical* binary preferences induced from empirical data may exhibit inconsistencies in the form of preferential cycles.

Learning from Object Preferences

The most frequently studied problem in learning from preferences is to induce a *ranking function* $r(\cdot)$ that is able to order any (finite) subset $\mathcal{O}$ of an underlying (possibly infinite) class $\mathcal{X}$ of objects. That is, $r(\cdot)$ assumes as input a subset $\mathcal{O} \subseteq \mathcal{X}$ of objects and returns as output a permutation τ of $\{1, \ldots, |\mathcal{O}|\}$. The interpretation of this permutation is that, for objects $x_i, x_j \in \mathcal{O}$, the former is preferred to the latter whenever $\tau(i) < \tau(j)$. The objects themselves are typically characterized by a finite set of features as in conventional attribute-value learning. The training data consists of a set of exemplary pairwise preferences $x \succ x'$ with $x, x' \in \mathcal{X}$. A survey of object ranking approaches is given by Kamishima et al. (2010).

Note that, in order to evaluate the predictive performance of a ranking algorithm, an accuracy measure (or loss function) is needed that compares a predicted ranking with a given reference ranking. To this end, one can refer, for example, to statistical measures of ▸ rank correlation. Expected or empirical loss minimization is a difficult problem for measures of that kind, especially because they are not (instance-wise) decomposable.

Many ▸ learning to rank problems may be viewed as object ranking problems. For example, Joachims (2002) studies a scenario where the training information could be provided implicitly by the user who clicks on some of the links in a query result and not on others. This information can be turned into binary preferences by assuming a preference of the selected pages over those nearby pages that are not clicked on. Applications in information retrieval typically suggest loss functions that put more emphasis on the top and less on the bottom of a ranking; for this purpose, specific measures have been proposed, such as the (normalized) discounted cumulative gain (Liu 2011).

Learning from Label Preferences

In label ranking, preferences are contextualized by elements x of an instance space $\mathcal{X}$, and the goal is to learn a ranking function $\mathcal{X} \longrightarrow \mathcal{S}_m$ for a fixed $m \geq 2$. Thus, for any instance $x \in \mathcal{X}$ (e.g., a person), a prediction in the form of an associated ranking $\succ_x$ of a finite set $\mathcal{L} = \{\lambda_1, \ldots, \lambda_m\}$ of labels or alternatives is sought, where $\lambda_i \succ_x \lambda_j$ means that instance x prefers λ_i to λ_j. Again, the quality of a prediction of that kind is typically captured in terms of a rank correlation measure (or an associated loss function). The training information consists of a set of instances for which (partial) knowledge about the associated preference relation is available. More precisely, each training instance x is associated with a subset of all pairwise preferences. Thus, despite the assumption of an underlying ("true") target ranking, the training data is not expected to provide full information about such rankings (and may even contain inconsistencies, such as pairwise preferences that are conflicting due to observation errors).

The above formulation essentially follows Fürnkranz and Hüllermeier (2010), though similar formalizations have been proposed independently by several authors; for an overview, see the survey papers by Vembu and Gärtner (2010) and Zhou et al. (2014). Label ranking contributes to the general trend of extending machine learning methods to complex and structured output spaces (Tsochantaridis et al. 2005). Moreover, label ranking can be viewed as a generalization of several standard learning problems. In particular, the following well-known problems are special cases of learning label preferences: (i) ▸ classification, where a single class label λ is assigned to each instance x; this is equivalent to the set of preferences $\{\lambda \succ_x \lambda_j \,|\, \lambda_j \in \mathcal{L} \setminus \{\lambda\}\}$, and (ii) ▸ multi-label classification, where each training example x is associated with a subset $L \subseteq \mathcal{L}$ of possible labels. This is equivalent to the set of preferences $\{\lambda_i \succ_x \lambda_j \,|\, \lambda_i \in L, \lambda_j \in \mathcal{L} \setminus L\}$. In each of the former scenarios, the sought prediction can be obtained by post-processing the output of a ranking model $f : \mathcal{X} \longrightarrow \mathcal{S}_m$ in a suitable way. For example, in multi-class classification, where only a single label is requested, it suffices to project a label ranking to the top-ranked label.

Applications of this general framework can be found in various fields, for example, in marketing research; here, one might be interested in discovering dependencies between properties of clients and their preferences for products. Another application scenario is ▸ meta-learning, where the task is to rank learning algorithms according to their suitability for a new dataset, based on the characteristics of this dataset (Schäfer and Hüllermeier 2015). Moreover, every preference statement in the well-known CP-nets approach (Boutilier et al. 2004), a qualitative graphical representation that reflects conditional dependence and independence of preferences under a ceteris paribus interpretation, formally corresponds to a label ranking function that orders the values of a certain attribute depending on the values of the parents of this attribute (predecessors in the graph representation).

Other Settings

A number of variants of the above ranking problems have been proposed and studied in the literature. For example, a setting referred to as *instance ranking* is very similar to object ranking. However, instead of relative (pairwise) comparisons, training data consists of absolute ratings of alternatives; typically these ratings are taken from an ordinal scale, such as 1 to 5 stars. Moreover, a predicted ranking is not compared with another (ground-truth) ranking but with the multipartition induced by the rating of the alternatives (Fürnkranz et al. 2009).

Attempts have also been made at combining object and label ranking, that is, to exploit feature representations of both the preference context and the alternatives to be ranked. One approach is to combine both pieces of information by means of a *joint feature map* $\phi : \mathcal{X} \times \mathcal{Y} \longrightarrow \mathcal{Z}$ and to learn a value function $f : \mathcal{Z} \longrightarrow \mathbb{R}$; here, $\mathcal{Y}$ is a parametric or structured space of alternatives and $\mathcal{Z} \subseteq \mathbb{R}^d$ a joint feature space (Tsochantaridis et al. 2005; Schäfer and Hüllermeier 2015).

Learning Utility Functions

Evaluating alternatives in terms of a value or utility function is a very natural way of representing preferences, which has a long tradition in economics and decision theory (Fishburn 1969). In the object preferences scenario, such a function is a mapping $f : \mathcal{X} \longrightarrow \mathbb{R}$ that assigns a utility degree $f(x)$ to each object x and, thereby, induces a linear order on $\mathcal{X}$. In the label preferences scenario, a utility function $f_i : \mathcal{X} \longrightarrow \mathcal{U}$ is needed for every label λ_i, $i = 1, \ldots, m$. Here, $f_i(x)$ is the utility assigned to alternative λ_i in the context x. To obtain a ranking for x, the alternatives are ordered according to their utility scores, i.e., a ranking $\succ_x$ is derived such that $\lambda_i \succ_x \lambda_j$ implies $f_i(x) \geq f_j(x)$.

If the training data offers the utility scores directly, preference learning essentially reduces to a standard ▸regression or an ordinal regression problem, depending on the underlying utility scale. This information can rarely be assumed, however. Instead, usually only constraints derived from comparative preference information of the form "this alternative should have a higher utility score than that alternative" are given. Thus, the challenge for the learner is to find a value function that is as much as possible in agreement with a set of such constraints.

For object ranking approaches, this idea has first been formalized by Tesauro (1989) under the name *comparison training*. He proposed a symmetric neural-network architecture that can be trained with representations of two states and a training signal that indicates which of the two states is preferable. The elegance of this approach comes from the property that one can replace the two symmetric components of the network with a single network, which can subsequently provide a real-valued evaluation of single states. Similar ideas have also been investigated for training other types of classifiers, in particular support vector machines. We already mentioned Joachims (2002) who analyzed "click-through data" in order to rank documents retrieved by a search engine according to their relevance. Earlier, Herbrich et al. (1998) proposed an algorithm for training SVMs from pairwise preference relations between objects.

For the case of label ranking, a corresponding method for learning the functions $f_i(\cdot)$, $i = 1, \ldots, m$, from training data has been proposed in the framework of *constraint classification*, which allows for reducing a label ranking to a single binary classification problem (Har-Peled et al. 2002). The learning method proposed in this work constructs two training examples, a positive and a negative one, for each given preference $\lambda_i \succ_x \lambda_j$, where the original N-dimensional training example (feature vector) x is mapped into an $(m \times N)$-dimensional space. In this space, the learner finds a linear model (hyperplane) f that separates the positive from the negative examples. Finally, the model f is "split" into m linear value functions $f_1, \ldots, f_m$, one for each label.

Learning Preference Relations

An alternative to learning latent utility functions consists of learning binary preference relations, which essentially amounts to reducing preference learning to binary classification. For object ranking, the pairwise approach has been pursued in Cohen et al. (1999). The authors propose to solve object ranking problems by learning a binary preference predicate $Q(x, x')$, which predicts whether x is preferred to x' or vice versa. A final ordering is found in a second phase by deriving a ranking that is maximally consistent with these (possibly conflicting) predictions.

For label ranking, the pairwise approach has been introduced in Hüllermeier et al. (2008) as a natural extension of *pairwise classification*, a well-known ▸class binarization technique. The idea is to train a separate model (base learner) $\mathcal{M}_{i,j}$ for each pair of labels $(\lambda_i, \lambda_j) \in \mathcal{L}$, $1 \leq i < j \leq m$; thus, a total number of $m(m-1)/2$ models are needed. For training, a preference information of the form $\lambda_i \succ_x \lambda_j$ is turned into a (classification) example (x, y) for the learner $\mathcal{M}_{a,b}$, where $a = \min(i, j)$ and $b = \max(i, j)$. Moreover, $y = 1$ if $i < j$ and $y = 0$ otherwise. Thus, $\mathcal{M}_{a,b}$ is intended to learn the mapping that outputs 1 if $\lambda_a \succ_x \lambda_b$ and 0 if $\lambda_b \succ_x \lambda_a$. This mapping can be realized by any binary classifier. Instead of a $\{0, 1\}$-valued classifier, one can of course also employ a scoring classifier. For example, the output of a probabilistic classifier would be a number in the unit interval [0, 1] that can be interpreted as a probability of the preference $\lambda_a \succ_x \lambda_b$.

At classification time, a query $x_0 \in \mathcal{X}$ is submitted to the complete ensemble of binary learners. Thus, a collection of predicted pairwise preference degrees $\mathcal{M}_{i,j}(x)$, $1 \leq i, j \leq m$, is obtained. The problem, then, is to turn these pairwise preferences into a ranking of the label set $\mathcal{L}$. To this end, different ranking procedures can be used. The simplest approach is to extend the (weighted) voting procedure that is often applied in pairwise classification: For each label λ_i, a score

$$S_i = \sum_{1 \leq j \neq i \leq m} \mathcal{M}_{i,j}(x_0)$$

is derived (where $\mathcal{M}_{i,j}(x_0) = 1 - \mathcal{M}_{j,i}(x_0)$ for $i > j$), and then the labels are ordered according to these scores. Despite its simplicity, this ranking procedure has several appealing properties. Apart from its computational efficiency, it turned out to be relatively robust in practice, and, moreover, it possesses some provable optimality properties in the case where Spearman's rank correlation is used as an underlying accuracy measure. Roughly speaking, if the binary learners are unbiased probabilistic classifiers, the simple "ranking by weighted voting" procedure yields a label ranking that maximizes the expected Spearman rank correlation (Hüllermeier and Fürnkranz 2010). Finally, it is worth mentioning that, by changing the ranking procedure, the pairwise approach can also be adjusted to accuracy measures other than Spearman's rank correlation.

Other Approaches

Referring to the type of training data and the loss function to be minimized on this data, learning value functions and learning preference relations are sometimes called the "pointwise" and "pairwise" approach to preference learning, respectively. This is distinguished from the "listwise" approach, in which a loss is defined on a predicted ranking directly. This can be done, for example, on the basis of probabilistic models of ranking data, such as the Plackett-Luce model. The idea, then, is to learn the parameters of a probabilistic model using statistical methods such as maximum likelihood estimation (or, equivalently, minimizing logarithmic loss). Methods of this kind have been proposed both for object ranking (Cao et al. 2007) and label ranking (Cheng et al. 2010).

Yet another alternative is to resort to the idea of local estimation techniques as prominently represented, for example, by the ▶ nearest neighbor estimation principle: Considering the rankings observed in similar situations as representative, a ranking for the current situation is estimated on the basis of these neighbor rankings, namely, by finding a suitable consensus among them; essentially, this is a problem of rank aggregation (Cheng et al. 2009).

Future Directions

As already said, preference learning is an emerging branch of machine learning and still developing quite dynamically. In particular, new settings or variants of existing frameworks will certainly be proposed and studied in the future. As for ranking problems, for example, an obvious idea and reasonable extension is to go beyond strict total order relations and instead allow for *incomparability* or *indifference* between alternatives and for representing uncertainty about predicted relations (Cheng et al. 2012). Another interesting direction is to combine preference learning with ▶ online learning, i.e., to predict preferences in an online setting. First steps in the direction of online preference learning have recently been made with a preference-based variant of the ▶ multiarmed bandit problem (Busa-Fekete and Hüllermeier 2014).

Prior

Definition

In Bayesian inference, a *prior probability* of a value x of a random variable X, $\mathrm{P}(X = x)$, is the probability of X assuming the value x in the absence of (or before obtaining) any additional information. It contrasts with the ▶ posterior probability, $\mathrm{P}(X = x|Y = y)$, the probability of X assuming the value x in the context of $Y = y$.

For example, it may be that the prevalence of a particular form of cancer, *exoma*, in the population is 0.1 %, so the prior probability of exoma, P(exoma = true), is 0.001. However, assume 50 % of people who have skin discolorations of greater than 1 cm width (sd > 1 cm) have exoma. It follows that the posterior probability of exoma given sd > 1 cm, P(exoma = true | sd > 1 cm = true), is 0.500.

Privacy-preserving data mining

Definition

The privacy-preserving aspects and techniques of machine learning cover the family of methods and architectures developed to protect the privacy of people whose data are used by machine learning (ML) algorithms. This field, also known as privacy-preserving data mining (PPDM), addresses the issues of data privacy in ML and data mining. Most existing methods and approaches are intended to hide the original data from the learning algorithm, while there is emerging interest in methods ensuring that the learned model does not reveal private information. Another research direction contemplates methods in which several parties bring their data into the model-building process without mutually revealing their own data.

Motivation and Background

The key concept for any discussion of the privacy aspects of data mining is the definition of privacy. After Alan Westin, we understand privacy as the ability "of individuals . . . to determine for themselves when, how, and to what extent information about them is communicated to others" (Westin 1967). One of the main societal concerns about modern computing is that the storing, keeping, and processing of massive amounts of data may jeopardize the privacy of individuals whom the data represent. In particular, ML and its power to find patterns and infer new facts from existing data makes it difficult for people to control information about themselves. Moreover, the infrastructure normally put together to conduct large-scale model building (e.g., large data repositories and data warehouses), is conducive to misuse of data. Personal data, amassed in large collections that are easily accessed through databases and often available online to the entire world, become – as phrased by Moor in an apt metaphor (Moor 2004) – "greased." It is difficult for people to control the use of this data.

Theory/Solutions

Basic Dimensions of Privacy Techniques

Privacy-related techniques can be characterized by: (1) the kind of source data modification they perform, e.g., data perturbation, randomization, generalization, and hiding; (2) the ML algorithm that works on the data and how is it modified to meet the privacy requirements imposed on it; and (3) whether the data are centralized or distributed among several parties, and – in the latter case – on what the distribution is based. But even at a more basic level, it is useful to view privacy-related techniques along just two fundamental dimensions.

The first dimension defines what is protected as private – is it the data itself, or the model (the results of data mining)? As we show below, the knowledge of the latter can also lead to identifying and revealing information about individuals. The second dimension defines the protocol of the use of the data: are the data centralized and owned by a single owner, or are the data distributed among multiple parties? In the former case, the owner needs to protect the data from revealing information about individuals represented in the data when that data is being used to build a model by someone else. In the latter case, we assume that the parties have limited trust in each other: they are interested in the results of data mining performed on the union of the data of all the parties, while not trusting the other parties to see their own data without first protecting it against disclosure of information about individuals to other parties.

Moreover, work in PPDM has to apply a framework that is broader than the standard ML methodology. When privacy is an important goal, what matters in performance evaluation is not only the standard ML performance measures, but also some measure of the privacy achieved, as well as some analysis of the robustness of the approach to attacks.

In this article, we structure our discussion of the current work on PPDM in terms of the taxonomy proposed above. This leads to the following bird's-eye view of the field.

Protecting Centralized Data

This subfield emerged in 2000 with the seminal paper by Agrawal and Srikant (2000). They stated the problem as follows: given data in the standard ▸ attribute-value representation, how can an accurate ▸ decision tree be built so that, instead of using original attribute values x_i, the decision tree induction algorithm takes input values $x_i + r$, where r belongs to a certain distribution (Gaussian or uniform). This is a data perturbation technique: the original values are changed beyond recognition, while the distributional properties of the entire data set that decision tree ▸ induction uses remain the same, at least up to a small (empirically, less than 5 %) degradation in accuracy. There is a clear trade-off between the privacy assured by this approach and the quality of the model compared to the model obtained from the original data. This line of research has been continued in Evfimievski et al. (2002) where the approach is extended to association rule mining. As a note of caution about these results, Kargupta et al. (2003) have shown, in 2003, how the randomization approaches are sensitive to attack. They demonstrate how the noise that randomly perturbs the data can be viewed as a random matrix, and that the original data can be accurately estimated from the perturbed data using a spectral filter that exploits some theoretical properties of random matrices.

The simplest and most widely used privacy preservation technique is anonymization of data (also called de-identification). In the context of de-identification, it is useful to distinguish three types of attributes.

Explicit identifiers allow direct linking of an instance to a person (e.g., a cellular phone number or a driver's license number to its holder).

Quasi-identifiers, possibly combined with other attributes, may lead to other data sources capable of unique identification. For instance, Sweeney (2001) shows that the quasi-identifier triplet <date of birth, 5 digit postal code, gender>, combined with the voters' list (publicly available in the USA) uniquely identifies 87 % of the population of the country. As a convincing application of this observation, using quasi-identifiers, Sweeney was able to obtain health records of the governor of Massachusetts from a published dataset of health records of all state employees in which only explicit identifiers have been removed.

Finally, non-identifying attributes are those for which there is no known inference linking to an explicit identifier. Usually performed as part of data preparation, anonymization removes all explicit identifiers from the data.

While anonymization is by far the most common privacy-preserving technique used in practice, it is also the most fallible one. In August 2006, for the benefit of the Web Mining Research community, AOL published 20 million search records (queries and URLs the members had visited) from 658,000 of its members. AOL had performed what it believed was anonymization, in the sense that it removed the names of the members. However, based on the queries – which often contained information that would identify a small set of members or a unique person – it was easy, in many cases, to manually re-identify the AOL member using secondary public knowledge sources. An inquisitive New York Times journalist identified one member and interviewed her.

L. Sweeney is to be credited with sensitizing the privacy community to the fallacy of anonymization: "Shockingly, there remains a common incorrect belief that if the data look anonymous, it is anonymous" (Sweeney 2001). Even if information is de-identified today, future data sources may make re-identification possible. As anonymization is very commonly used prior to model building from medical data, it is interesting that this type of data is prone to specific kinds of re-identification, and therefore anonymization of medical data should be done with particular skill and understanding of the data. Malin (2005) shows how the four main de-identification techniques used in anonymization of genomic data are prone to known, published attacks that can re-identify the data. Moreover, he points out that there will never be certainty about de-identification for quasi-identifiers, as new attributes and data sources that can lead to a linkage to explicitly identifying attributes are constantly being engineered as part of genetics research.

Other perturbation approaches targeting binary data involve changing (flipping) values of selected attributes with a given probability (Du and Zhan 2003; Zhan and Matwin 2004), or replacing the original attribute with a value that is more general in some pre-agreed taxonomy (Iyengar 2002). Generalization approaches often use the concept of k-anonymity: any instance in the database is indistinguishable from other $k-1$ instances (for every row in the database there are $k-1$ identical rows). Finding the least general k-anonymous generalization of a database (i.e., moving the least number of edges upward in a given taxonomy) is an optimization task, known to be *NP*-complete. There are heuristic solutions proposed for it; e.g., Iyengar (2002) uses a ▸ genetic algorithm for this task. Friedman et al. (2006) shows how to build k-anonymity into the decision tree induction. Lately, PPDM researchers have pointed out some weaknesses of the k-anonymity approach. In particular, attacks on data with some properties (e.g., skewed distribution of values of a sensitive attribute, or specific background knowledge) have been described, and techniques to prevent such attacks have been proposed. The notion of p-sensitivity or l-diversity proposed in Machanavajjhala et al. (2007) addresses these weaknesses of k-anonymity by modifying k-anonymity techniques so that the abovementioned attacks do not apply. Furthermore, t-closeness (Ninghui et al. 2007) shows certain shortcomings of these techniques and the resulting potential attacks, and proposes a data perturbation technique which ensures that the distribution of the values of the sensitive attribute in any group resulting from anonymization is close to its distribution in the original table. Some authors, e.g., Domingo-Ferrer et al. (2008), propose the integration of several techniques addressing shortcomings of k-anonymity into a single perturbation technique. The drawback of these solutions is that they decrease the utility of the data more than the standard k-anonymity approaches.

Protecting the Model (Centralized Data)

Is it true that when the data are private, there will be no violation of privacy? The answer is no. In some circumstances, the model may reveal private information about individuals. Atzori et al. (2005) gives an example of such a situation for association rules: suppose the ▸ association rule $a_1 \wedge a_2 \wedge a_3 \Rightarrow a_4$ has support sup = 80, confidence conf = 98.7 %. This rule is 80-anonymous, but considering that

$$\begin{aligned}\sup(\{a_1, a_2, a_3\}) &= \frac{\sup(\{a_1, a_2, a_3, a_4\})}{\text{conf}} \\ &= \frac{80}{0.0987} \approx 81.05\end{aligned}$$

and given that the pattern $a_1 \wedge a_2 \wedge a_3 \wedge a_4$ holds for 80 individuals, and the pattern $a_1 \wedge a_2 \wedge a_3$ holds for 81 individuals, clearly the pattern $a_1 \wedge a_2 \wedge a_3 \wedge \neg a_4$ holds for just one person. Therefore, the rule unexpectedly reveals private information about a specific person. Atzori et al. (2005) proposes to apply k-anonymity to patterns instead of data, as in the previous section. The authors define inference channels as ▸ itemsets from which it is possible to infer other itemsets that are not k-anonymous, as in the above example. They then show an efficient way to represent and compute inference channels, which, once known, can be blocked from the output of an association rule finder. The inference channel problem is also discussed in Oliveira et al. (2004), where itemset "sanitization" removes itemsets that lead to sensitive (non-k-anonymous) rules.

This approach is an interesting continuation of Sweeney's classical work (Sweeney 2001), and it addresses an important threat to privacy ignored by most other approaches based on data perturbation or cryptographic protection of the data.

Distributed Data

Most of the work mentioned above addresses the case of centralized data. The distributed situation, however, is often encountered and has important applications. Consider, for example, several hospitals involved in a multi-site medical trial that want to mine the data describing the union of their patients. This increases the size of the population subject to data analysis, thereby increasing the scope and the importance of the trial. In another example, a car manufacturer performing data analysis on the set of vehicles exhibiting a given problem wants to represent data about different components of the vehicle originating in databases of the suppliers of these components. In general, if we abstractly represent the database as a table, there are two collaborative frameworks in which data is distributed. Horizontally partitioned data is distributed by rows (all parties have the same attributes, but different instances – as in the medical study example). Vertically partitioned data is distributed by columns (all parties have the same instances; some attributes belong to specific parties, and some, such as the class, are shared among all parties – as in the vehicle data analysis example).

An important branch of research on learning from distributed data while parties do not reveal their data to each other is based on results from computer security, specifically from cryptography and from the secure multiparty computation (SMC). Particularly interesting is the case when there is no trusted external party – all the computation is distributed among parties that collectively hold the partitioned data. SMC has produced constructive results showing how any Boolean function can be computed from inputs belonging to different parties, so that the parties never get to know input values that do not belong to them. These results are based on the idea of splitting a single data value between two parties into "shares," so that none of them knows the value but they can still do computation on the shares using a gate such as *exclusive or* Yao (1986). In particular, there is an SMC result known as secure sum: k parties have private values x_i and they want to compute $\sigma_I x_i$ without disclosing their x_i to any other party. This result, and similar results for value comparison and other simple functions, are the building blocks of many privacy-preserving ML algorithms. On that basis, a number of standard ▸ classifier induction algorithms, in their horizontal and vertical partitioning versions, have been published, including decision tree (ID3) induction (Friedman et al. 2006), Naïve Bayes, the ▸ Apriori association rule mining algorithm (Kantarcioglu and Clifton 2004; Vaidya and Clifton 2002), and many others.

We can observe that data privacy issues extend to the use of the learned model. For horizontal partitioning, each party can be given the model and apply it to the new data. For vertical partitioning, however, the situation is more difficult: the parties, all knowing the model, have to compute their part of the decision that the model delivers, and have to communicate with selected other parties after this is done. For instance, for decision trees, a node n applies its test and contacts the party holding the attribute in the child c chosen by the test, giving c the test to perform. In this manner, a single party n only knows the result of its test (the corresponding attribute value) and the tests of its children (but not their outcomes). This is repeated recursively until the leaf node is reached and the decision is communicated to all parties.

A different approach involving cryptographic tools other than Yao's circuits is based on the concept of homomorphic encryption (Paillier 1999). Encryption e is homomorphic with respect to some operation * in the message space if there is a corresponding operation $^{*\prime}$ in the ciphertext space, such that for any messages m1, m2, e(m1)$^{*\prime}$ e(m2) $=$ e(m1*m2). The standard RSA encryption is homomorphic with $^{*\prime}$ being logical multiplication and * logical addition on sequences of bytes. To give a flavor of the use of homomorphic encryption, let us see in detail how this kind of encryption is used in computing the scalar product of two binary vectors.

Assume just two parties, Alice and Bob. They both have their private binary vectors A$_{1,\ldots N}$, B$_{1,\ldots,N}$. In association rule mining, A$_i$ and B$_i$ represent A's and B's transactions projected on the set of items whose frequency is being computed. In our protocol, one of the parties is randomly chosen as a key generator. Assume Alice is selected as the key generator. Alice generates an encryption key (e) and a decryption key (d). She applies the encryption key to the sum of each value of A and a digital envelope $R_i{}^*X$ of A_i (i.e., $e(A_i i + R_i{}^*X)$), where R_i is a random integer and X is an integer that is greater than N. She then sends $e(A_i + R_i{}^*X)$s to Bob. Bob computes the multiplication $M = \prod_{j=1}^{N} [e(A_j + R_i{}^*X) \times B_j]$ when $B_j = 1$ (as when $B_j = 0$, the result of multiplication does not contribute to the frequency count). Now, $M = e(A_1 + A_2 + \cdots + A_j + (R_1 + R_2 + \cdots + R_1)^*X)$ due to the property of homomorphic encryption. Bob sends

the result of this multiplication to Alice, who computes $[d(e(A_1 + A_2 + \cdots + A_j + (R_1 + R_2 + \cdots + R_1)^* X)]) \bmod X = (A_1 + A_2 + \cdots + A_1 + (R_1 + R_2 + \cdots + R_j)^* X) \bmod X$ and obtains the scalar product. This scalar product is directly used in computing the frequency count of an itemset, where N is the number of items in the itemset, and A_i, B_i are Alice's and Bob's transactions projected on the itemset whose frequency is computed.

While more efficient than the SMC-based approaches, homomorphic encryption methods are more prone to attack, as their security is based on a weaker security concept (Paillier 1999) than Yao's approach. In general, cryptographic solutions have the advantage of protecting the source data while leaving it unchanged: unlike data modification methods, they have no negative impact on the quality of the learned model. However, they have a considerable cost impact in terms of complexity of the algorithms, computation cost of the cryptographic processes involved, and the communication cost for the transmission of partial computational results between the parties (Subramaniam et al. 2004). Their practical applicability on real-life-sized datasets still needs to be demonstrated.

The discussion above focuses on protecting the data. In terms of our diagram in Table 1, we have to address its right column. Here, methods have been proposed to mainly address mainly the north-east entry of the diagram. In particular, in Vaidya and Clifton (2002) propose a method to compute association rules in an environment where data is distributed. In particular, their method addresses the case of vertically partitioned data, where different parties hold different attribute sets for the same instances. The problem is solved without the existence of a trusted third party, using SMC. Independently, we have obtained a different solution to this task using homomorphic encryption techniques (Zhan et al. 2007). Many papers have presented solutions for both vertically and horizontally partitioned data, and for different data mining tasks, e.g., Friedman et al. (2006) and Vaidya et al. (2006).

Moreover, Jiang and Atzori (2006) have obtained a solution for the model-protection case in a distributed setting (south-east quadrant in Table 1). Their work is based on a cryptographic technique, and addresses the case of vertical partitioning of the data among parties.

Evaluation

The evaluation of privacy-related techniques must be broader than standard ML evaluation. Besides evaluating the performance of the ML component using the appropriate tool (e.g., ▸ accuracy, ▸ ROC, support/confidence), one also needs to evaluate the various privacy aspects of a learned model. This is difficult, as there is no commonly accepted definition of privacy. Even if there were one, it would not be in quantitative, operational terms that can be objectively measured, but most certainly with references to moral and social values. For instance, Clifton (2005) points out that a definition of privacy as the "freedom from unauthorized intrusion" implies that we need to understand what constitutes an intrusion and that we can measure its extent. For these reasons, most definitions in current privacy-preserving data mining research are method-specific, without any comparison between different methods. For example, the classic work of Agrawal and Srikant (2000) measures privacy after data perturbation as the size of the interval to which the original value can be estimated. If we know that the original value was 0.5, and following a perturbation its best estimate is, with 95 % confidence, within the interval [0.3, 0.7], then the amount of privacy is the size of this interval, (i.e., 0.4, with a confidence of 95 %). Later, Agrawal and Aggarwal (2001) proposed a more general measure of data privacy measuring this property of a dataset that has been subject to one of the data perturbation techniques. The idea is that if noise from a random variable A is added to the data, we can measure the uncertainty of the perturbed values using differential entropy inherent in A. Specifically, if we add noise from a random variable A, the privacy is

$$\prod(A) = 2^{-f_{\Omega A}^{fA(a)\log_2 f_A(a)da}},$$

where Ω_A is the domain of A. Privacy is 0 if the exact value is known (the entropy is ∞); if it is known that the data is in the interval of length $a, \prod(A) = a$.

Clifton (2005) argues that if disclosure is only possible to a group of people rather than a single person, then the size of the group is a natural measure of privacy. This is the case for k-anonymity methods. He further argues that a good evaluation measure should not only capture the likelihood of linking an ML result to an individual, but should also capture how intrusive this linking is. For instance, an association rule with a support value of 50 and a confidence level of 100 % is 50-anonymous, but it also reveals the consequent of the rule to all 50 participants.

Finally, the style of evaluation needs to take into account attack analysis, as in Malin (2005).

Future Directions

One of the most pressing challenges for the community is to work out a quantifiable and socially comprehensible definition of privacy for the purpose of privacy-preserving techniques. This is clearly a difficult problem, likely not solvable by ML or even computer science alone. As privacy has basic social and economic dimensions, economics may contribute to an acceptable definition, as already explored in Rossi (2004).

Another important question is the ability to analyze data privacy, including inference from data using ML, in the context of specific rules and regulations, e.g., HIPAA (Health and Services 2003) or the European Privacy Directive (1995). First forays in this direction using formal methods have already been made, e.g., Barth et al. (2006) and Felty and Matwin (2002).

Finally, the increasing abundance and availability of data tracking mobile devices will bring new challenges to the field. People will become potentially identifiable by knowing the trajectories their mobile devices leave in fixed times and time intervals. Clearly such data, already collected, present an important asset from the public security point of view, but also a very considerable threat from a privacy perspective. There is early work in this area (Gianotti and Pedreschi 2008). Such data are already being collected. This is an important asset for public security, but also a considerable threat for privacy.

Synonyms

PCFG

Definition

In formal language theory, formal grammar (phrase-structure grammar) is developed to capture the generative process of languages (Hopcroft and Ullman 1979). A formal grammar is a set of productions (rewriting rules) that are used to generate a set of strings, that is, a *language*. The productions are applied iteratively to generate a string, a process called *derivation*. The simplest kind of formal grammar is a *regular* grammar.

Context-free grammars (CFG) form a more powerful class of formal grammars than regular grammars and are often used to define the syntax of programming languages. Formally, a CFG consists of a set of nonterminal symbols N, a terminal alphabet Σ, a set P of productions (rewriting rules), and a special nonterminal S called the start symbol. For a nonempty set X of symbols, let X^* denote the set of all finite strings of symbols in X. Every CFG production has the form $S \rightarrow \alpha$, where $S \in N$ and $\alpha \in (N \cup \Sigma)^*$. That is, the left-hand side consists of one nonterminal and there is no restriction on the number or placement of nonterminals and terminals on the right-hand side. The *language generated* by a CFG G is denoted $L(G)$.

A *probabilistic context-free grammar* (PCFG) is obtained by specifying a probability for each production for a nonterminal A in a CFG, such that a probability distribution exists over the set of productions for A.

A CFG $G = (N, \Sigma, P, S)$ is in *Chomsky normal form* if each production rule is of the form $A \rightarrow BC$ or $A \rightarrow a$, where $A, B, C \in N$ and $a \in \Sigma$.

Given a PCFG G and a string $w = a_1 \ldots a_m$, there are three basic problems:

1. Calculating the probability $\Pr(w|G)$ that the grammar G assigns to w
2. Finding the most likely derivation (parse tree) of w by G
3. Estimating the parameters of G to maximize $\Pr(w|G)$

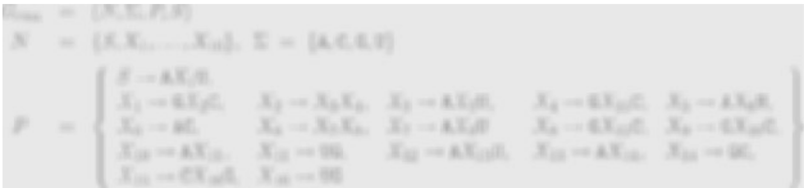
The first two problems, calculating the probability $\Pr(w|G)$ of a given string w assigned by a PCFG G and finding the most likely derivation of w by G, can be solved using dynamic programming methods analogous to the Cocke-Younger-Kasami or Early parsing methods. A polynomial-time algorithm for solving the second problem is known as *Viterbi* algorithm, and a polynomial-time algorithm for the third problem is known as the *inside-outside* algorithm (Lari and Young 1990).

Derivation Process

A *derivation* is a rewriting of a string in $(N \cup \Sigma)^*$ using the production rules of a CFG G. In each step of the derivation, a nonterminal from the current string is chosen and replaced with the right-hand side of a production rule for that nonterminal. This replacement process is repeated until the string consists of terminal symbols only. If a derivation begins with a nonterminal A and derives a string $\alpha \in (N \cup \Sigma)^*$, we write $A \Rightarrow \alpha$.

For example, the grammar in Fig. 1 generates an RNA sequence AGAAACUUGCUGGCCU by the following derivation: Beginning with the start symbol S, any production with S left of the arrow can be chosen to replace S. If the production $S \rightarrow \mathrm{A}X_1\mathrm{U}$ is selected (in this case, this is the only production available), the effect is to replace S with $\mathrm{A}X_1\mathrm{U}$. This one derivation step is written $S \Rightarrow \mathrm{A}X_1\mathrm{U}$, where the double arrow signifies application of a production. Next, if the production $X_1 \rightarrow \mathrm{G}X_2\mathrm{C}$ is selected, the derivation step is $\mathrm{A}X_1\mathrm{U} \Rightarrow \mathrm{AG}X_2\mathrm{CU}$. Continuing with similar derivation operations, each time choosing a nonterminal symbol and replacing it with the right-hand side of an appropriate production, we obtain the following derivation terminating with the desired sequence:

$$\begin{aligned} S &\Rightarrow \mathrm{A}X_1\mathrm{U} \Rightarrow \mathrm{AG}X_2\mathrm{CU} \Rightarrow \mathrm{AG}X_3X_4\mathrm{CU} \\ &\Rightarrow \mathrm{AGA}X_5\mathrm{U}X_4\mathrm{CU} \Rightarrow \mathrm{AGAA}X_6\mathrm{UU}X_4\mathrm{CU} \\ &\Rightarrow \mathrm{AGAAACUU}X_4\mathrm{CU} \end{aligned}$$



Probabilistic Context-Free Grammars, Fig. 1 This set of productions P generates RNA sequences with a certain restricted structure. $S, X_1, \ldots, X_{16}$ are nonterminals; A, U, G, and C are terminals representing the four nucleotides. Note that only for X_6 is there a choice of productions

$$\Rightarrow \text{AGAAACUUG}X_{15}\text{CCU}$$
$$\Rightarrow \text{AGAAACUUGC}X_{16}\text{GCCU}$$
$$\Rightarrow \text{AGAAACUUGCUGGCCU}.$$

Such a derivation can be arranged in a tree structure called a *parse tree*.

The *language generated* by a CFG G is denoted $L(G)$, that is, $L(G) = \{w | S \Rightarrow w, w \in \Sigma^*\}$. Two CFGs G and G' are said to be *equivalent* if and only if $L(G) = L(G')$.

Probability Distribution

A PCFG assigns a probability to each string which it derives and hence defines a probability distribution on the set of strings. The probability of a derivation can be calculated as the product of the probabilities of the productions used to generate the string. The probability of a string w is the sum of probabilities over all possible derivations that could generate w, written as follows:

$$\Pr(w|G) = \sum_{\text{all derivations } d} \Pr(S \overset{d}{\Rightarrow} w|G)$$
$$= \sum_{\alpha_1,\ldots,\alpha_n} \Pr(S \Rightarrow \alpha_1|G) \cdot \Pr(\alpha_1 \Rightarrow \alpha_2|G)$$
$$\ldots \Pr(\alpha_n \Rightarrow w|G).$$

Parsing Algorithm

Efficiently computing the probability of a string w, $\Pr(s|G)$, presents a problem because the number of possible derivations for w is exponential in the length of the string. However, a dynamic programming technique analogous to the Cocke-Kasami-Young or Earley methods for nonprobabilistic CFGs can accomplish this task efficiently (in time proportional to the cube of the length of w).

The CYK algorithm is a polynomial time algorithm for solving the parsing (membership) problem of CFGs using dynamic programming. The CYK algorithm assumes Chomsky normal form of CFGs, and the essence of the algorithm is the construction of a triangular *parse table T*. Given a CFG $G = (N, \Sigma, P, S)$ and an input string $w = a_1 a_2 \ldots a_n$ in Σ^* to be parsed according to G, each element of T, denoted $t_{i,j}$, for $1 \leq i \leq n$ and $1 \leq j \leq n - i + 1$, has a value which is a subset of N. The interpretation of T is that a nonterminal A is in $t_{i,j}$ if and only if $A \Rightarrow a_i a_{i+1} \ldots a_{i+j-1}$, that is, A derives the substring of w beginning at position i and of length j. To determine whether the string w is in $L(G)$, the algorithm computes the parse table T and look to see whether S is in entry $t_{1,n}$.

In the first step of constructing the parse table, the CYK algorithm sets $t_{i,1} = \{ A | A \rightarrow a_i$ is in $P\}$. In the jth step, the algorithm assumes that $t_{i,j'}$ has been computed for $1 \leq i \leq n$ and $1 \leq j' < j$, and it computes $t_{i,j}$ by examining the nonterminals in the following pairs of entries:

$$(t_{i,1}, t_{i+1,j-1}), (t_{i,2}, t_{i+2,j-2}), \ldots,$$
$$(t_{i,j-1}, t_{i+j-1,1}),$$

Probabilistic Context-Free Grammars, Fig. 2 The parse table T of G for "*abaaa*"

and if B is in $t_{i,k}$ and C is in $t_{i+k,j-k}$ for some k $(1 \leq k < j)$ and the production $A \rightarrow BC$ is in P, A is added to $t_{i,j}$.

For example, we consider a simple CFG $G = (N, \Sigma, P, S)$ of Chomsky normal form where $N = \{S, A\}$, $\Sigma = \{a, b\}$ and

$$P = \{S \rightarrow AA, S \rightarrow AS, S \rightarrow b,$$
$$A \rightarrow SA, A \rightarrow a\}.$$

This CFG generates a string "*abaaa*," that is, $S \Rightarrow abaaa$, and the parse table T for *abaaa* is shown in Fig. 2. The parse table can efficiently store all possible parse trees of G for *abaaa*.

Learning

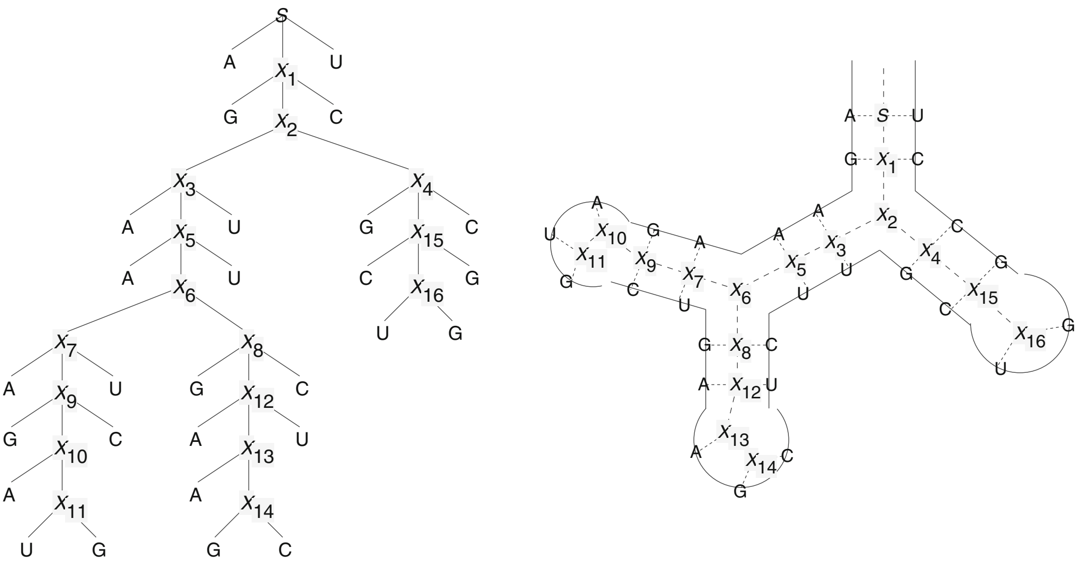
The problem of learning PCFGs from example strings has two aspects: determining a discrete structure (topology) of the target grammar and estimating probabilistic parameters in the grammar (Sakakibara 1997). Based on the maximum likelihood criterion, an efficient estimation algorithm for probabilistic parameters has been proposed: the inside-outside algorithm for PCFGs. On the other hand, finding an appropriate discrete structure of a grammar is a harder problem.

The procedure to estimate the probabilistic parameters of a PCFG is known as the *inside-outside* algorithm. Just like the forward-backward algorithm for HMMs, this procedure is an expectation-maximization (EM) method for obtaining maximum likelihood of the grammar's parameters. However, it requires the grammar to be in Chomsky normal form, which is inconvenient to handle in many practical problems (and requires more nonterminals). Further, it takes time at least proportional to n^3, whereas the forward-backward procedure for HMMs takes time proportional to n^2, where n is the length of the string w. There are also many local maxima in which the method can get caught. Therefore, the initialization of the iterative process is crucial since it affects the speed of convergence and the goodness of the results.

Application to Bioinformatics

An effective method for learning and building PCFGs has been applied to modeling a family of RNA sequences (Durbin et al. 1998; Sakakibara 2005). In RNA, the nucleotides adenine (A), cytosine (C), guanine (G), and uracil (U) interact in specific ways to form characteristic secondary-structure motifs such as helices, loops, and bulges. In general, the folding of an RNA chain into a functional molecule is largely governed by the formation of intramolecular A-U and G-C Watson–Crick pairs. Such base pairs constitute the so-called biological palindromes in a genome and can be clearly described by a CFG. In particular, productions of the forms $X \rightarrow$ A Y U, $X \rightarrow$ U Y A, $X \rightarrow$ G Y C, and $X \rightarrow$ C Y G describe a structure in RNA due to Watson–Crick base pairing. Using productions of this type, a CFG can specify a language of biological palindromes.

For example, the application of productions in the grammar shown in Fig. 1 generates the RNA sequence CAUCAGGGAAGAUCUCUUG and the derivation can be arranged in a tree structure of a *parse tree* (Fig. 3, left). A parse tree represents the syntactic structure of a sequence produced by a grammar. For the RNA sequence, this syntactic structure corresponds to the physical secondary structure (Fig. 3, right). PCFGs are applied to perform three tasks in RNA sequence analysis: to discriminate RNA-family sequences from nonfamily sequences, to produce multiple alignments, and to ascertain the secondary structure of new sequences.



Probabilistic Context-Free Grammars, Fig. 3 A parse tree (*left*) generated by a simple context-free grammar (CFG) for RNA molecules and the physical secondary structure (*right*) of the RNA sequence which is a reflection of the parse tree

Abstract

Programming by demonstration (PBD) is introduced as family of approaches to teach a computer system new behavior by demonstrating it in the context of a concrete example.

Most of the work by this author was done while on leave of absence in 2006/2007 as a Visiting Faculty Member and Erasmus Exchange Teacher at Sabancı University, Turkey.

References to classical and current PBD systems are given.

Synonyms

Programming by example (PBE)

Definition

Programming by demonstration (PBD) describes a collection of approaches for the support of end-user programming with the goal of making the power of computers fully accessible to all users. The general objective is to *teach* computer systems new behavior by demonstrating (repetitive) actions on concrete examples. A user provides examples of how a program should operate, either by demonstrating trace steps or by showing examples of the inputs and outputs, and the system infers a generalized program that achieves those examples and can be applied to new examples. Typical areas of application are macro generation (e.g., for text editing), simple arithmetic functions in spreadsheets, simple shell programs, XML transformations, or query-replace commands, as well as the generation of helper programs for web agents, geographic information systems, or computer-aided design. The most challenging approach to PBD is to obtain generalizable examples by minimal intrusion, where the user's ongoing actions are recorded without an explicit signal for the start of an example and without explicit confirmation or rejection of hypotheses. An early example of such a system is EAGER (Cypher 1993a).

Current PBD approaches incorporate some simple forms of **generalization** learning, but typically no or only highly problem-dependent methods for the induction of loops or recursion from examples or traces of repetitive commands. Introducing **inductive programming** or **trace-based programming** methods into PBD applications could significantly increase the possibilities of end-user programming support. This is demonstrated impressively with the Microsoft Excel plug-in Flash Fill (Gulwani et al. 2012).

Projective Clustering

Cecilia M. Procopiuc
AT&T Labs, NJ, USA

Synonyms

Local feature selection; Subspace clustering

Definition

Projective clustering is a class of problems in which the input consists of high-dimensional data, and the goal is to discover those subsets of the input that are strongly correlated in subspaces of the original space. Each subset of correlated points, together with its associated subspace, defines a *projective cluster*. Thus, although all cluster points are close to each other when projected on the associated subspace, they may be spread out in the full-dimensional space. This makes projective clustering algorithms particularly useful when mining or indexing datasets for which full-dimensional clustering is inadequate (as is the case for most high-dimensional inputs). Moreover, such algorithms compute projective clusters that exist in different subspaces, making them more general than global dimensionality-reduction techniques.

Motivation and Background

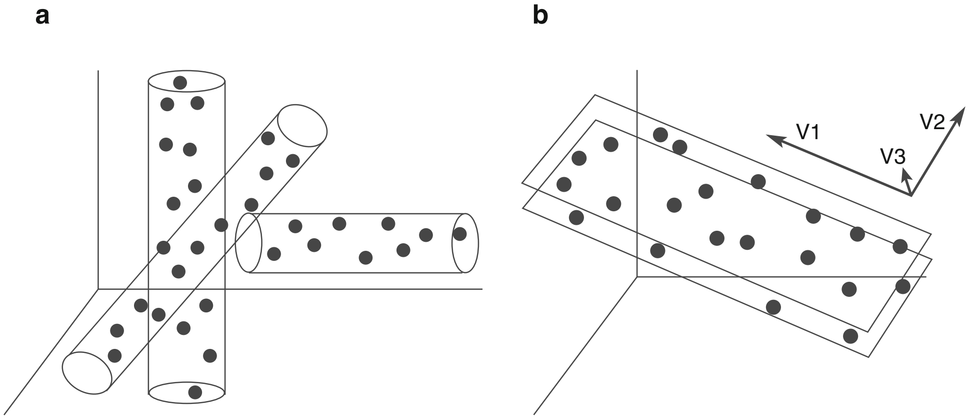
Projective clustering is a type of data mining whose main motivation is to discover correlations in the input data that exist in subspaces of the original space. This is an extension of traditional full-dimensional clustering, in which one tries to discover point subsets that are strongly correlated in all dimensions. Figure 1a shows an example of input data for which full-dimensional clustering cannot discover the three underlying patterns. Each pattern is a projective cluster.

It is well known (Beyer et al. 1999) that for a broad class of data distributions, as the dimensionality increases, the distance to the nearest neighbor of a point approaches the distance to its farthest neighbor. This implies that full-dimensional clustering will fail to discover significantly correlated subsets on such data, since the diameter of a cluster is almost the same as the diameter of the entire dataset. In practice, many applications from text and image processing generate data with hundreds or thousands of dimensions, which makes them extremely bad candidates for full-dimensional clustering methods.

One popular technique to classify high-dimensional data is to first project it onto a much lower-dimensional subspace, and then employ a full-dimensional clustering algorithm in that space. The projection subspace is the same for all points, and is computed so that it best "fits" the data. A widely used dimensionality-reduction technique, called ▸ principal component analysis (PCA), defines the best projection subspace to be the one that minimizes least-square error. While this approach has been proven successful in certain areas such as text mining, its effectiveness depends largely on the characteristics of the data. The reason is that there may be no way to choose a single projection subspace without encountering a significant error; or alternatively, setting a maximum bound on the error results in a subspace with high dimensionality. Figure 1b shows the result of PCA on a good candidate set. The points are projected on the subspace spanned by vectors V_1 and V_2, along which they have greatest variance. However, for the example in Fig. 1a, no plane or line fits the data well enough. Projective clustering can thus be viewed as a generalized dimensionality-reduction method, in which different subsets of the data are projected on different subspaces.

There are many variants of projective clustering, depending on what quality measure one tries to optimize for the clustering. Most such measures, however, are expressed as a function of the distances between points in the clusters. The distance between two cluster points is computed with respect to the subspace associated with that cluster. Alternative quality measures consider the density of cluster points inside the associated subspace.

Megiddo and Tamir (1982) showed that it is NP-Hard to decide whether a set of n points in the plane can be covered by k lines. This early result implies not only that most projective clustering problems are NP-Complete even in the planar case, but also that approximating the objective function within a constant factor is NP-Complete. Nevertheless, several approximation algorithms have been proposed, with running time polyno-



Projective Clustering, Fig. 1 Dimensionality reduction via (**a**) projective clustering and (**b**) principal component analysis

mial in the number of points n and exponential in the number of clusters k. Agrawal et al. (1998) proposed a subspace clustering method based on density measure that computes clusters in a bottom-up approach (from lower to higher dimensions). Aggarwal et al. (1999) designed a partitioning-style algorithm.

Theory

Many variants of projective clustering problems use a distance-based objective function and thus have a natural geometric interpretation. In general, the optimization problem is stated with respect to one or more parameters that constrain the kind of projective clusters one needs to investigate. Examples of such parameters are: the number of clusters, the dimensionality (or average dimensionality) of the clusters, the maximum size of the cluster in its associated subspace, the minimum density of cluster points, etc. Below we present the most frequently studied variants for this problem.

Distance-Based Projective Clustering

Given a set S of n points in $\mathbb{R}^d$ and two integers $k < n$ and $q \leq d$, find kq-dimensional flats $h_1, \ldots, h_k$ and partition S into k subsets $C_1, \ldots, C_k$ so that one of the following objective functions is minimized:

$$\max_{1 \leq i \leq k} \max_{p \in C_i} d(p, h_i) \qquad (k-\text{center})$$

$$\sum_{1 \leq i \leq k} \sum_{p \in C_i} d(p, h_i) \qquad (k-\text{median})$$

$$\sum_{1 \leq i \leq k} \sum_{p \in C_i} d(p, h_i) \qquad (k-\text{means})$$

These types of problems are also referred to as *geometric clustering problems*. They require all cluster subspaces to have the same dimensionality, i.e., $d - q$ (the subspace associated with C_i is orthogonal to h_i). The number of clusters is also fixed, and the clustering must be a partitioning of the original points.

Further variants are defined by introducing slight modifications in the above framework. For example, one can allow the existence of outliers, i.e., points that do not belong to any projective cluster. This is generally done by providing an additional parameter, which is the maximum percentage of outliers. The problems can also be changed to a dual formulation, in which a maximum value for the objective function is specified, and the goal is to minimize the number of clusters k.

Special cases for the k-center objective function are $q = d - 1$ and $q = 1$. In the first case, the problem is equivalent to finding k hyper-strips that contain S so that the maximum width of a hyper-strip is minimized. If $q = 1$, then the problem is to cover S by k congruent hyper-cylinders of smallest radius. Since this is equivalent to finding the k lines that are the axes of the hyper-cylinders, this problem is also referred to as *k-line-center*. Figure 1a is an example of 3-line-center.

In addition, k-median problems have also been studied when cluster subspaces have different dimensionalities. In that case, distances computed in each cluster are normalized by the dimensionality of the corresponding subspace.

Density-Based Projective Clustering

A convex region in a subspace is called dense if the number of data points that project inside it is larger than some user-defined threshold. For a fixed subspace, the convex regions of interest in that subspace are defined in one of several ways, as detailed below. Projective clusters are then defined to be connected unions of dense regions of interest. The different variants for defining regions of interest can be broadly classified in three classes:

(*ε-Neighborhoods*) Regions of interest are L_p-balls of radius ε centered at the data points. In general, L_p is either L_2 (hyper-spheres) or L_∞ (hyper-cubes).

(Regular Grid Cells) Regions of interest are cells defined by an axis-parallel grid in the subspace. The grid hyper-planes are equidistant along each dimension.

(Irregular Grid Cells) Regions of interest are cells defined by an irregular grid in the subspace. Parallel grid hyper-planes are not necessarily equidistant, and they may also be arbitrarily oriented.

Another variant of projective clustering defines a so-called *quality measure* for a projective cluster, which depends both on the number of cluster points and the number of dimensions in the associated subspace. The goal is to compute the clusters that maximize this measure. Projective clusters are required to be L_p-balls of fixed radius in their associated subspace, which means that clusters in higher dimensions tend to have fewer points, and vice-versa. Hence, the quality measure provides a way to compare clusters that exist in different number of dimensions. It is related to the notion of dense ε-neighborhoods.

Many other projective clustering problems are application driven and do not easily fit in the above classification. While they follow the general framework of finding correlations among data in subspaces of the original space, the notion of projective cluster is specific to the application. One such example is presented later in this section.

Algorithms

Distance-based projective clustering problems are NP-Complete when the number of clusters k is an input parameter. Moreover, k-center problems cannot be approximated within a constant factor, unless $P = NP$. This follows from the result of Meggido and Tamir (1982), who showed that it is NP-Hard to decide whether a set of n points in the plane can be covered by k lines.

Agarwal and Procopiuc (2003) first proposed approximation algorithms for k-center projective clustering in two and three dimensions. The algorithms achieve constant factor approximation by generating more clusters than required.

Subsequent work by several other authors led to the development of a general framework in which $(1 + \varepsilon)$-approximate solutions can be designed for several types of full-dimensional and projective clustering. In particular, k-center and k-means projective clustering can be approximated in any number of dimensions. The idea is to compute a so-called *coreset*, which is a small subset of the points, such that the optimal projective clusters for the coreset closely approximate the projective clusters for the original set. Computing the optimal solution for the coreset has (super) exponential dependence on the number of clusters k, but it is significantly faster than computing the optimal solution for the original set of points. The survey by Agarwal et al. (2005) gives a comprehensive overview of these results.

While the above algorithms have approximation guarantees, they are not practical even for moderate values of n, k, and d. As a result, heuristic methods have also been developed for these problems. The general approach is to iteratively refine a current set of clusters, either by re-assigning points among them, or by merging nearby clusters. When the set of points in a cluster changes, the new subspace associated with the cluster is also recomputed, in a way that tries to optimize the objective function for the new clustering. Aggarwal et al. (1999) proposed the PROCLUS algorithm for k-median projective clustering with outliers. The cluster subspaces can have different dimensionalities, but they must be orthogonal to coordinate axes. Aggarwal and Yu (2000) subsequently extended the algorithm to arbitrarily oriented clusters, but with the same number of dimensions. Agarwal and Mustafa (2004) proposed a heuristic approach for k-means projective clustering with arbitrary orientation and different dimensionalities.

The first widely used method for density-based projective clustering was proposed by Agrawal et al. (1998). The algorithm, called CLIQUE, computes projective clusters based on regular grid cells in orthogonal subspaces, starting from the lowest-dimensional subspaces (i.e., the coordinate axes) and iterating to higher dimensions. Pruning techniques are used to skip subspaces in which a large fraction of points lie outside dense regions. Subsequent strategies improved the running time and accuracy by imposing irregular grids and using different pruning criteria.

Böhm et al. (2004) designed an algorithm called 4C for computing density-connected ε-neighborhoods in arbitrarily oriented subspaces. The method is agglomerative: It computes the local dimensionality around each point p by using PCA on all points inside the (full-dimensional) ε-neighborhood of p. If the dimensionality is small enough and the neighborhood is dense, then p and its neighbors form a projective cluster. Connected projective clusters with similarly oriented subspaces are then repeatedly merged.

The OptiGrid algorithm by Hinneburg and Keim (1999) was the first method to propose irregular grid cells of arbitrary (but fixed) orientation. Along each grid direction, grid hyper-planes are defined to pass through the local minima of a probability density function. This significantly reduces the number of cells compared with a regular grid that achieves similar overall accuracy. The probability density function is defined using the kernel-density estimation framework. Input points are projected on the grid direction, and their distribution is extrapolated to the entire line by the density function

$$f(x) = \frac{1}{nh} \sum_{i=1}^{n} K\left(\frac{x - s_i}{h}\right),$$

where $s_1, \ldots, s_n$ denote the projections of the input points, and h is a parameter. The function $K(x)$, called the *kernel*, is usually the Gaussian function, although other kernels can also be used.

The DOC algorithm proposed by Procopiuc et al. (2002) approximates optimal clusters for a class of quality measures. Orthogonal projective clusters are computed iteratively via random sampling. If a sample is fully contained in a cluster then it can be used to determine the subspace of that cluster, as well as (a superset of) the other cluster points. Such a sample is called a *discriminating set*. Using the properties of the quality measure, the authors show that a discriminating set is found with high probability after a polynomial number of trials.

An overview of most of these practical methods, as well as of subsequent work expanding their results, can be found in the survey by Parsons et al. (2004).

Applications

Similar to full-dimensional clustering, projective clustering methods provide a way to efficiently organize databases for searching, as well as for pattern discovery and data compression. In a broad sense, they can be used in any application that handles high-dimensional data, and which can benefit from indexing or mining capabilities. In practice, additional domain-specific information is often necessary. We present an overview of the generic database usage first, and then discuss several domain-specific applications.

Data Indexing

An index tree is a hierarchical structure defined on top of a data set as follows. The root corresponds to the entire data set. For each internal node, the data corresponding to that node is partitioned in some pre-defined manner, and there is a child of the node corresponding to each subset in the partition. Often, the partitioning method is a distance-based clustering algorithm. In addition, each node stores the boundary of a geometric region that contains its points, to make searching the structure more efficient. For many popular indexes, the geometric region is the minimum axis-parallel bounding box. Index trees built with full-dimensional clustering methods become inefficient for dimensionality about 10 or higher, due to the large overlap in the geometric regions of sibling nodes. Chakrabarti and Mehrotra (2000) first proposed an index tree that uses projective clustering as a partitioning method. In that case, each node also stores the subspace associated with the cluster.

Pattern Discovery

A projective cluster, by definition, is a pattern in the data, so any of the above algorithms can be used in a pattern discovery application. However, most applications restrict the projective clusters to be orthogonal to coordinate axes, since the axes have special interpretations. For example, in a database of employees, one axis may represent salary, another the length of employment, and the third one the employees' age. A projective cluster in the subspace spanned by salary and employment length has the following interpretation: there is a correlation between salaries in range A and years of employment in range B, which is independent of employees' age.

Data Compression

As discussed in the introduction, projective clusters can be used as a dimensionality-reduction technique, by replacing each point with its projection on a lower dimensional subspace. The projection subspace is orthogonal to the subspace of the cluster that contains the point. In general, this method achieves smaller information loss and higher compression ratio than a global technique such as PCA.

Image Processing

A picture can be represented as a high-dimensional data point, where each pixel represents one dimension, and its value is equal to the RGB color value of the pixel. Since this representation loses pixel adjacency information, it is generally used in connection with a smoothing technique, which replaces the value of a pixel with a function that depends both on the old pixel value, and the values of its neighbors. A projective cluster groups images that share some similar features, while they differ significantly on others. The DOC algorithm has been applied to the face detection problem as follows: Projective clusters were computed on a set of (pre-labeled) human faces, then used in a classifier to determine whether a new image contained a human face.

Document Processing

Text documents are often represented as sparse high-dimensional vectors, with each dimension corresponding to a distinct word in the document collection. Several methods are used to reduce the dimensionality, e.g., by eliminating so-called stop words such as "and," "the," and "of." A non zero entry in a vector is usually a function of the corresponding word's frequency in the document. Because of the inherent sparsity of the vectors, density-based clustering, as well as k-center methods, are poor choices for such data. However, k-means projective clustering has been successfully applied to several document corpora (Li et al. 2004).

DNA Microarray Analysis

A gene-condition expression matrix, generated by a DNA microarray, is a real-valued matrix, such that each row corresponds to a gene, and each column corresponds to a different condition. An entry in a row is a function of the relative abundance of the mRNA of the gene under that specific condition. An orthogonal projective cluster thus represents several genes that have similar expression levels under a subset of conditions. Genetics researchers can infer connections between a disease and the genes in a cluster. Due to the particularities of the data, different notions of similarity are often required. For example, order preserving clusters group genes that have the same tendency on a subset of attributes, i.e., an attribute has the same rank (rather than similar value) in each projected gene. See the results of Liu and Wang (2003).

Principal Component Analysis

PCA also referred to as the Karhunen-Loève Transform, is a global ▶ dimensionality reduction technique, as opposed to projective clustering, which is a local dimensionality reduction method. PCA is defined as an orthogonal linear transformation with the property that it transforms the data into a new coordinate system, such that the projection of the data on the first coordinate has the greatest variance among all projections on a line, the projection of the data on the second coordinate has the second greatest variance, and so on. Let X denote the data matrix, with each point written as a column vector in X, and modified so that X has empirical mean zero (i.e., the mean vector is subtracted from each data point). Then the eigenvectors of the matrix XX T are the coordinates of the new system. To reduce the dimensionality, keep only the eigenvectors corresponding to the largest few eigenvalues.

Coresets

Let $P \subseteq \mathbb{R}^d$ be a set of points, and μ be a measure function defined on subsets of $\mathbb{R}^d$, such that μ is monotone (i.e., for $P_1 \subseteq P_2$, $\mu(P_1) \leq \mu(P_2)$). A subset $Q \subseteq P$ is an *ε-coreset* with respect to μ if $(1-\varepsilon)\mu(P) \leq \mu(Q)$. The objective functions for k-center, k-median, and k-means projective clustering are all examples of measure functions μ.

Prolog

Prolog is a declarative programming language based on logic. It was conceived by French and British computer scientists in the early 1970s. A considerable number of public-domain and commercial Prolog interpreters are available today. Prolog is particularly suited for applications requiring pattern matching or search. Prolog programs are also referred to as ▶ logic programs.

In machine learning, classification rules for structured individuals can be expressed using a subset of Prolog. Learning Prolog programs from examples is called ▶ inductive logic programming (ILP). ILP systems are sometimes – but not always – implemented in Prolog. This has the advantage that classification rules can be executed directly by the Prolog interpreter.

Propositionalization

Nicolas Lachiche
University of Strasbourg, Strasbourg, France

Abstract

Propositionalization is the process of explicitly transforming a ▶ relational dataset into a propositional dataset.

Definition

The input data consists of examples represented by structured terms (cf. ▶ learning from structured data), several predicates in ▶ first-order logic, or several tables in a relational database. We will jointly refer to these as *relational representations*. The output is an ▶ attribute-value representation in a single table, where each example corresponds to one row and is described by its values for a fixed set of attributes. New attributes are often called features to emphasize that they are built from the original attributes. The aim of propositionalization is to preprocess relational data for subsequent analysis by attribute-value learners. There are several reasons for doing this, the most important of which are to reduce the complexity and speed up the learning, to separate modeling the data from hypothesis construction, or to use familiar attribute-value (or propositional) learners.

Motivation and Background

Most domains are naturally modeled by several tables in a relational database or several classes in an object-oriented language, for example, customers and their transactions; molecules, their atoms, and bonds; or patients and their examinations. A proper relational dataset involves at least two tables linked together. Typically, one table of the relational representation corresponds to the individuals of interest for the machine learning task, and the other tables contain related information that could be useful. The first table is the individual or the primary table; the other tables are complementary tables.

Example 1 Let us consider a simplified medical domain as an example. This is inspired by a real medical dataset (Tomečková et al. 2002). It consists of four tables.

The patient table is the primary table. It contains data on each patient such as the patient identifier (pid), name, date of birth, height, job, the identifier of the company where the patient works, etc.

Patient

pid	Name	Birth	Height	Job	Company	…
I	Smith	15/06/1956	1.67	Manager	a	…
II	Blake	13/02/1968	1.82	Salesman	a	…
⋮	⋮	⋮	⋮	⋮	⋮	…

The company table contains its name, its location, and so on. There is a many-to-one relationship from the patient table to the company table: A patient works for a single company, but a company may have several employees.

Company

cid	Name	Location	…
a	Eiffel	Paris	…
⋮	⋮	⋮	…

The examination table contains the information on all examinations of all patients. For each examination, its identifier (eid), the patient identifier (pid), the date, the patient's weight, whether the patient smokes, his or her blood pressure, etc. are recorded. Of course, each examination corresponds to a single patient, and a given patient can have several examinations, i.e., there is a one-to-many relationship from the patient table to the examination table.

Examination

eid	pid	Date	Weight	Smokes	BP	…
1	I	10/10/1991	60	Yes	10	…
2	I	04/06/1992	64	Yes	12	…
⋮	⋮	⋮	⋮	⋮	⋮	…
23	II	20/12/1992	80	Yes	10	…
24	II	15/11/1993	78	No	11	…
⋮	⋮	⋮	⋮	⋮	⋮	…

Additional tests can be prescribed at each examination. Their identifiers (tid), corresponding examinations (eid), names, values, and interpretations are recorded in the additional_test table.

Additional_test

tid	eid	Date	Name	Value	Interpretation
t237	1	19/10/1991	Red blood cells	35	Bad
t238	1	23/10/1991	Radiography	Nothing	Good
⋮	⋮	⋮	⋮	⋮	⋮
t574	2	07/06/1992	Red blood cells	43	Good
⋮	⋮	⋮	⋮	⋮	⋮

Several approaches exist to deal directly with relational data, e.g., ▶ inductive logic programming, ▶ relational data mining (Džeroski and Lavrač 2001), or ▶ statistical relational learning. However relational hypotheses can be transformed into propositional expressions.

Generally, a richer representation language permits the description of more complex concepts; however, the cost of this representational power is that the search space for learning greatly increases. Therefore, mapping a relational representation into a propositional one generally reduces search complexity.

A second motivation of propositionalization is to focus on the construction of features before combining them into a hypothesis (Srinivasan et al. 1996). This is related to ▶ feature construction and to the use of background knowledge. One could say that propositionalization aims at building an intermediate representation of the data in order to simplify the hypothesis subsequently found by a propositional learner.

A third motivation is pragmatic. Most available machine learning systems deal with propositional data only, but tend to include a range of algorithms in a single environment, whereas relational learning systems tend to concentrate on a single algorithm. Propositional systems are therefore often more versatile and give users the possibility to work with the algorithms they are used to.

Solutions

There are various ways to propositionalize relational data consisting of at least two tables linked together through a relationship. We will first focus on a single relationship between two tables. Most approaches can then iteratively deal with several relationships as explained below.

Propositionalization mechanisms depend on whether that relationship is functional or nondeterminate. This distinction explains most common mistakes made by newcomers.

Functional Relationship (Many-to-One, One-to-One)

When the primary table has a many-to-one or one-to-one relationship to the complementary table, each row of the primary table links to one row of the complementary table. A simple join of the two tables results in a single table where each row of the primary table is completed with the information derived from the complementary table.

Example 2 In our simplified medical domain, there is a many-to-one relationship from each patient to his or her company. Let us focus on those two tables only. A join of the two tables results in a single table where each row describes a single patient and the company he or she works for.

Patient and his/her company

pid	Name	Birth	Height	Job	cid	Company	Location	...
I	Smith	15/06/1956	1.67	Manager	a	Eiffel	Paris	...
II	Blake	13/02/1968	1.82	Salesman	a	Eiffel	Paris	...
⋮	⋮	⋮	⋮	⋮	⋮	⋮	⋮	...

The resulting table is suitable for any attribute-value learner

Nondeterminate Relationship (One-to-Many, Many-to-Many)

Propositionalization is less trivial in a nondeterminate context, when there is a one-to-many or many-to-many relationship from the primary table to the complementary table, i.e., when one individual of the primary table is associated with a set of rows of the complementary table.

A propositional attribute is built by applying an aggregation function to a column of the complementary table over a selection of rows. Of course a lot of conditions can be used to select the rows. Those conditions can involve other columns than the aggregated column. Any aggregation function can be used, e.g., to check whether the set is not empty, to count how many elements there are, to find the mean (for numerical) or the mode (for categorical) values, etc.

Example 3 In our simplified medical domain, there is a one-to-many relationship from the patient to his or her examinations. Let us focus on those two tables only. Many features can be constructed. Simple features are aggregation functions applied to a scalar (numerical or categorical) column. The number of occurrences of the different values of every categorical attributes can be counted. For instance, the f60 feature in the table below counts in how many examinations the patient stated he or she smoked. The maximum, minimum, average, and standard deviation of every numerical column can be estimated, e.g., the f84 and f85 features in the table below, respectively, estimate the average and the maximum blood pressure of the patient over his or her examinations. The aggregation functions can be applied to any selection of rows, e.g., the f135 feature in the table below estimates the average blood pressure over the examinations when the patient smoked.

Patient and his/her examinations

pid	Name	…	f60	…	f84	f85	…	f135	…
I	Smith	…	2	…	11	12	…	11	…
II	Blake	…	1	…	10.5	11	…	10	…
⋮	⋮	…	⋮	…	⋮	⋮	…	⋮	…

From this example it is clear that nondeterminate relationships can easily lead to a combinatorial explosion of the number of features.

Common Mistakes and Key Rules to Avoid Them

Two mistakes are frequent when machine learning practitioners face a propositionalization problem, i.e., when they want to apply a propositional learner to an existing relational dataset (Lachiche 2005).

The first mistake is to misuse the (universal) join. Join is valid in a functional context, as explained earlier. When applied to a nondeterminate relationship, it produces a table where several rows correspond to a single individual, leading to a multiple-instance problem (Dietterich et al. 1997) (cf. ▶ multi-instance learning).

Example 4 In our simplified medical domain, there is a one-to-many relationship from the patient table to the examination table. If a join is performed, each row of the examination table is completed with the information on the examined patient, i.e., there are as many rows as examinations.

Examination and its patient

eid	Date	Weight	Smokes	BP	…	pid	Name	…
1	10/10/1991	60	Yes	10	…	I	Smith	…
2	04/06/1992	64	Yes	12	…	I	Smith	…
⋮	⋮	⋮	⋮	⋮	…	⋮	⋮	…
23	20/12/1992	80	Yes	10	…	II	Blake	…
24	15/11/1993	78	No	11	…	II	Blake	…
⋮	⋮	⋮	⋮	⋮	…	⋮	⋮	…

In this example, the joined table deals with the examinations rather than with the patients. An attribute-value learner could be used to learn hypotheses about the examinations, not about the patients

This example reinforces a key representation rule in attribute-value learning: "Each row corresponds to a single individual, and vice-versa."

The second mistake is a meaningless column concatenation. This is more likely when a one-to-many relationship can be misinterpreted as several one-to-one relationships, i.e., when the practitioner is led to think that a nondeterminate relationship is actually functional.

Example 5 In our simplified medical domain, let us assume that the physician numbered the successive examinations (1, 2, 3, and so on) of each patient. Then given that each patient has a first examination, it is tempting to consider that there is a functional relationship from the patient to his or her "first" examination, "second" examination, and so on. This would result in a new patient table with concatenated columns: weight at the first examination, whether he or she smoked at the first examination, . . . , weight at the second examination, etc. This could easily lead

Patient and his/her examinations (incorrect representation!)

pid	Name	…	"First" examination			"Second" examination			…
			Weight	Smokes	…	Weight	Smokes	…	…
I	Smith	…	60	Yes	…	64	Yes	…	…
II	Blake	…	80	Yes	…	78	No	…	…
⋮	⋮	…	⋮	…	⋮	⋮	⋮	…	…

to an attribute-value learner generalizing over a patient's weight at their *i*th examination, which is very unlikely to be meaningful

Two aspects should warn the user of such a representation problem: first, the number of columns depends on the dataset, and as a consequence, lots of columns are not defined for all individuals. Moreover, when the absolute numbering does not make sense, there is no functional relationship. Such a misunderstanding can be avoided by remembering that in an attribute-value representation, "each column is uniquely defined for each row."

Further Relationships

The first complementary table can itself have a nondeterminate relationship with another complementary table and so on. Two approaches are available.

A first approach is to consider the first complementary table, the one having a one-to-many relationship, as a new primary table in a recursive propositionalization.

Example 6 In our simplified medical domain, the examination table has a one-to-many relationship with the additional_test table. The propositionalization of the examination and additional test tables will lead to a new examination table completed with new features, such as a count of how many tests were bad.

Examination and its additional_tests

eid	pid	Date	Weight	Smokes	BP	…	Bad tests	…
1	I	10/10/1991	60	Yes	10	…	1	…
2	I	04/06/1992	64	Yes	12	…	0	…
⋮	⋮	⋮	⋮	⋮	⋮	…	⋮	…

Then the propositionalization of the patient table and the already propositionalized examination tables is performed, producing a new patient table completed with new features such as the mean value for each patient of the number of bad tests among all his or her examinations (f248)

Patient, his/her examinations and additional_tests

pid	name	…	f60	…	f248	…
I	Smith	…	2	…	1	…
⋮	⋮	…	⋮	…	⋮	…

It is not necessarily meaningful to aggregate at an intermediate level. An alternative is to join complementary tables first and apply the aggregation at the individual level only. A variant consists in replacing the join by a propagation of the identifier, i.e., adding the identifier of the individual into all related tables. Both lead to a kind of "star schema" where the individual is directly linked to all complementary tables.

Example 7 In our simplified medical domain, it is perhaps more interesting to first relate all additional tests to their patients, then aggregate on similar tests. First the complementary tables are joined

Additional_test and its examination

tid	Name	Value	Interpretation	eid	pid	Weight	…
t237	Red blood cells	35	Bad	1	I	60	…
t238	Radiography	Nothing	Good	1	I	60	…
⋮	⋮	⋮	⋮	⋮	⋮	⋮	…
t574	Red blood cells	43	Good	2	I	64	…
⋮	⋮	⋮	⋮	⋮	⋮	⋮	…

Let us emphasize the difference with the propositionalized examination and its additional_tests table of Example 6

There is a one-to-many relationship from the patient table to that new additional_test and its examination table. Aggregation functions can be used to build features such as the minimum percentage of red blood cells (f352)

Patient, his/her additional_tests and examinations

pid	Name	…	f60	…	f352	…
I	Smith	…	2	…	35	…
⋮	⋮	…	⋮	…	⋮	…

Finally, different propositionalization approaches can be combined, by a simple join.

Future Directions

Propositionalization explicitly aims at leaving attribute selection to the propositional learner applied afterward. The number of potential features is large. No existing propositionalization system is able to enumerate all imaginable features. Historically existing approaches have focused on a subset of potential features, e.g., numerical aggregation functions without selection (Knobbe et al. 2001) and selection based on a single elementary condition and existential aggregation (Flach and Lachiche 1999; Kramer et al. 2001). Most approaches can be combined to provide more features. The propositionalization should be guided by the user.

Propositionalization is closely related to knowledge representation. Specific representational issues require appropriate propositionalization techniques, e.g., Perlich and Provost (2006) introduce new propositionalization operators to deal with high-cardinality categorical attributes. New data sources, such as geographical or multimedia data, will need an appropriate representation and perhaps appropriate propositionalization operators to apply off-the-shelf attribute-value learners.

Propositionalization raises three fundamental questions. The first question is related to knowledge representation. That question is whether the user should adapt to existing representations, and accept a need to propositionalize, or whether data can be mined from the data sources, requiring the algorithms to be adapted or invented. The second question is whether propositionalization is needed. Propositionalization explicitly allows the user to contribute to the feature elaboration and invites him or her to guide the search, thanks to that language bias. It separates feature elaboration from model extraction. Conversely, relational data mining techniques automate the elaboration of the relevant attributes during the model extraction, but at the same time leave less opportunity to select the features by hand.

The third issue is one of efficiency. A more expressive representation necessitates a more complex search. Relational learning algorithms face the same dilemma as attribute-value learning in the form of a choice between an intractable search in the complete search space and an ad hoc heuristic/search bias (cf. ▶ search bias). They only differ in the size of the search space (cf. ▶ hypothesis space). Propositionalization is concerned with generating the search space. Generating all potential features is usually impossible. So practitioners have to constrain the propositionalization, e.g., by choosing the aggregation functions, the complexity of the selections, etc.; by restricting the numbers of operations; and so on. Different operators fit different problems and might lead to differences in performance (Krogel et al. 2003).

University of Leoben, Leoben, Austria

Abstract

Pruning describes the idea of avoiding ▶ Overfitting by simplifying a learned concept, typically after the actual induction phase.

Method

The term originates from decision tree learning, where the idea of improving the decision tree by cutting some of its branches may be viewed as an analogy to the concept of pruning in gardening.

Commonly, one distinguishes two types of pruning:

Pre-pruning monitors the learning process and prevents further refinements if the current hypothesis becomes too complex.

Post-pruning first learns a possibly overfitting hypothesis and then tries to simplify it in a separate learning phase.

Pruning techniques are particularly important for state-of-the-art ▶ Decision Tree and ▶ Rule Learning algorithms (see there for more details).

The key idea of pruning is essentially the same as ▶ Regularization in statistical learning, with the key difference that regularization incorporates a complexity penalty directly into the learning heuristic, whereas pruning uses a separate pruning criterion or pruning algorithm.

DOI 10.1007/978-1-4899-7687-1

Definition

Quality Threshold (QT) clustering (Heyer et al. 1999) is a partitioning clustering algorithm originally proposed for gene clustering. The focus of the algorithm is to find clusters with guaranteed quality. Instead of specifying K, the number of clusters, QT uses the maximum cluster diameter as the parameter.

The basic idea of QT is as follows: form a candidate cluster by starting with a random point and iteratively add other points, with each iteration adding the point that minimizes the increase in cluster diameter. The process continues until no point can be added without surpassing the diameter threshold. If surpassing the threshold, a second candidate cluster is formed by starting with a point and repeating the procedure. In order to achieve reasonable clustering quality, already assigned points are available for forming another candidate cluster.

For data partition, QT selects the largest candidate cluster and removes the points which belong to the cluster from consideration and repeats the procedure on the remaining set of data.

The advantage of QT clustering is that it can guarantee cluster quality and does not require the prior knowledge of the cluster number. The disadvantage is that the algorithm is computationally expensive as much as $O(N^3)$.

Softwares

The following softwares have implementations of the Quality Threshold (QT) clustering algorithm:

Quantum Machine Learning

Maria Schuld[1] and Francesco Petruccione[2]
[1]Quantum Research Group, School of Chemistry & Physics, University of KwaZulu-Natal, Durban, South Africa
[2]National Institute of Theoretical Physics (NITheP), KwaZulu-Natal, South Africa

Abstract

Quantum machine learning is a young research area investigating which consequences the emerging technology of quantum computing has for machine learning. This article introduces into basic concepts of quantum information and summarises some major strategies of implementing machine learning algorithms on a quantum computer.

Definition

Quantum machine learning (QML) is a subdiscipline of quantum information processing research, with the goal of developing *quantum algorithms* that learn from data in order to improve existing methods in machine learning. A quantum algorithm is a routine that can be implemented on a *quantum computer*, a device that exploits the laws of quantum theory in order to process information.

A number of quantum algorithms have been proposed for various machine learning models such as neural networks, support vector machines, and graphical models, some of which claim runtimes that under certain conditions grow only logarithmic with the size of the input space and/or dataset compared to conventional methods. A crucial point for runtime considerations is to find a procedure that efficiently encodes classical data into the properties of a quantum system. QML algorithms are often based on well-known quantum subroutines (such as *quantum phase estimation* or *Grover search*) or exploit fast annealing techniques through quantum tunneling and can make use of an exponentially compact representation of data through the probabilistic description of quantum systems.

Besides finding quantum algorithms for pattern recognition and data mining, QML also investigates more fundamental questions about the concept of learning from the perspective of quantum theory. Sometimes the definition of QML is extended by research that applies machine learning *to* quantum information, such as is frequently done when the full evolution or state of a quantum system has to be reconstructed from limited experimental data.

Motivation and Background

The accurate solution of many learning problems is known to be NP-hard, such as the training of Boltzmann machines or inference in graphical models. But also methods for which tractable algorithms are known suffer from the increasing size of datasets available in today's applications. The idea behind QML is to approach these problems from the perspective of quantum information and harvest the power of quantum computers for applications in artificial intelligence and data mining.

The motivation to find quantum analogues for "classical" machine learning algorithms derives from the success of the dynamic research field of quantum information. Some speedups compared to the best or best-known classical algorithms have already been shown, the most prominent being Shor's factorization algorithm (Shor 1997) (providing an exponential speedup compared to the best classical algorithm known) and Grover's search algorithm for unsorted databases (Grover 1996) (providing a quadratic speedup to the best possible classical algorithm). Although it is still an open question whether "true" exponential speedups are possible, the number of quantum algorithms is constantly growing. Also the technological implementation of large-scale universal quantum computers makes steady progress, and many proof-of-principle experiments have confirmed the theoretical predictions (The reader can get a first impression of the current progress in Wikipedia's "timeline of quantum computing" https://en.wikipedia.org/wiki/Timeline_of_quantum_computing.) The first realizations of quantum annealing devices, which solve a very specific type of optimization problem and are thus not universal, are already commercially available (e.g., http://www.dwavesys.com/).

Proposals that apply quantum computing to data mining in general and learning tasks in particular have been sporadically put forward since quantum computing became a well-established research area in the 1990s. A specifically large share of attention has been devoted to so-called *quantum neural network* models which simulate the behavior of artificial neural networks based on quantum information. They were initially motivated by questions of whether quantum mechanics can help to explain the functioning of our brain (Kak 1995) and vary in the degree of a rigorous application of quantum theory (Schuld et al. 2015). Since around 2012, there has been a rapid increase in other contributions to QML, consisting of proposals for quantum versions of hidden Markov models (Barry et al. 2014), Boltzmann machines (Wiebe et al. 2014; Adachi and Henderson 2015), belief nets (Low et al. 2014), support vector machines (Rebentrost et al. 2014), linear regression (Schuld et al. 2016), Gaussian processes (Zhao et al. 2015) and many more. Several collaborations between IT companies and academic institutions have been created and promise to advance the field of QML in future. For example, Google and NASA founded the *Quantum Artificial Intelligence Lab* in 2013, the University of

Oxford and Nokia set up a *Quantum Optimisation and Machine Learning* program in 2015, and the University of Southern California collaborates with Lockheed Martin on machine learning applications through the *Quantum Computation Center*.

Quantum Computing

In order to present the major approaches to QML research below, it is necessary to introduce some basic concepts of quantum information. The interested reader shall be referred to the excellent introduction by Nielsen and Chuang (2010).

In conventional computers, the state of a physical system represents bits of information and is manipulated by the Newtonian laws of physics (e.g., the presence of a current in a circuit represents 0 and 1 and is manipulated by the laws of electrodynamics). A quantum computer follows a very similar concept, only that the underlying physical system is governed by the laws of quantum theory and is therefore called a *quantum system*.

Quantum theory is a mathematical apparatus describing physical objects on very small scales (i.e., electrons, atoms, photons). More precisely, it is a probabilistic description of the results of physical measurements on quantum systems, and although confirmed in many experiments, it shows a number of features distinct to classical or Newtonian mechanics. Quantum computers exploit these features through information processing based on the rules of quantum theory. Although a number of exciting results have been achieved, it is still unknown whether BQP, the class of decision problems solvable by a quantum computer in polynomial time, is larger than BPP, its classical analogue. In short, quantum computing is a very dynamic research area with many promising results and open questions.

The quantum information community uses a variety of computational models that have been shown to be equivalent, but which constitute different building blocks of universal quantum computation. The following will give a short introduction to the most influential model, the *circuit model*, to clarify important concepts on which QML algorithms are based.

The Concept of a Qubit

A central concept in the major quantum computational models is the *qubit*, an abstraction of a quantum system that has two possible configurations or states. As long as certain properties are fulfilled (DiVincenzo 2000), such a *two-level system* can have many possible physical realizations (just like bits may be encoded in currents of circuits or the pits and lands of CDs), for example, a hydrogen atom in the energetic ground or first excited state, the current in a superconducting circuit or the path a light photon chooses through a semitransparent mirror.

Qubits are often introduced as "bits that can be in states 0 and 1 at the same time," which mystifies rather than explains the concept. In fact, qubits can be compared to a probabilistic description of a *classical* physical system with two different states, say a coin with the states "heads" and "tails." As illustrated in Table 1, the probabilities p_{00}, p_{01}, p_{10}, and p_{11} with $\sum_i p_i = 1$ describe our expectation to get the respective result "head and head," "head and tail," "tail and head," and "tail and tail" after tossing two coins. Note that the coin tosses do not necessarily need to be statistically independent events.

The probabilistic description of a qubit shows a significant difference (see Table 2). The four configurations "00," "01," "10," and "11" of a two-qubit system such as two simplified atoms

Quantum Machine Learning, Table 1 Probabilistic description of a classical system of two coins. Each of the four possible outcomes or configurations after tossing both coins is associated with a probability.

example	config.	probability
① ①	'00'	p_{00}
● ①	'01'	p_{01}
● ①	'10'	p_{10}
● ●	'11'	p_{11}

Quantum Machine Learning, Table 2 Important elements in the description of a two-qubit system. An example is two atoms that can each be in the ground and first excited state, so that the system has four possible abstract configurations. Quantum theory associates each configuration (or potential measurement outcome) with an *amplitude*, and the absolute square of the amplitude is the probability of measuring this state. In the mathematical notation, each configuration corresponds to a unit basis vector or, in Dirac notation, a Dirac basis state

example	config.	probability	amplitude	unit basis	Dirac basis
	00	$\|a_{00}\|^2$	a_{00}	$(1,0,0,0)^T$	$\|00\rangle$
	01	$\|a_{01}\|^2$	a_{01}	$(0,1,0,0)^T$	$\|01\rangle$
	10	$\|a_{10}\|^2$	a_{10}	$(0,0,1,0)^T$	$\|10\rangle$
	11	$\|a_{11}\|^2$	a_{11}	$(0,0,0,1)^T$	$\|11\rangle$

are each associated with a complex number called *amplitude*, and the probability of observing the two qubits in one of the four possible joint states is given by the absolute square of the amplitude. The sum of absolute squares of the amplitudes $a_i, i = 1, \ldots, 2^n$ of an n-qubit system consequently has to add up to one, $\sum_i |a_i|^2 = 1$. In both the classical and the quantum case, once the coins or atoms are observed in one of the joint configurations, their state is fully determined, and repeated observations will only confirm the result. As will be explained below, this concept of complex amplitudes is central to quantum information and has up to the present – 100 years after the beginning of quantum theory – still not found a satisfying interpretation for our everyday intuition.

Algorithmic Manipulations of Qubits

Information processing is about the manipulation of bits by elementary logic gates such as AND or XOR, and quantum information processing likewise needs to define elementary operations on qubit systems (of course derived from the laws of quantum theory), from which algorithms with a well-defined output can be constructed.

In a probabilistic description, manipulating information corresponds to a transformation of the system's probability distribution. For example, in the case of the two coins, this could mean drawing a "heads" over the "tails" symbol, causing the coin to only toss "heads." Using the mathematical language of Markov chains, changes of a *classical* probability distribution can be expressed by a linear transformation applied to the vector of probabilities, written as a stochastic matrix $S = (s_{ij})$ multiplied from the left. The stochastic matrix has the properties that its entries are nonnegative and all columns sum up to one, in order to guarantee that the resulting vector on the right side is again a probability distribution. In our two-coin example, this reads

$$S \begin{pmatrix} p_{00} \\ p_{01} \\ p_{10} \\ p_{11} \end{pmatrix} = \begin{pmatrix} p'_{00} \\ p'_{01} \\ p'_{10} \\ p'_{11} \end{pmatrix}, \qquad \begin{array}{c} s_{ij} \geq 0, \\ \sum_i s_{ij} = 1. \end{array} \tag{1}$$

For *quantum* systems, any physically possible evolution can be mathematically represented by a unitary matrix $U = (u_{ij})$ applied to the vector of amplitudes, which in the two-qubit example reads

$$U \begin{pmatrix} a_{00} \\ a_{01} \\ a_{10} \\ a_{11} \end{pmatrix} = \begin{pmatrix} a'_{00} \\ a'_{01} \\ a'_{10} \\ a'_{11} \end{pmatrix}, \qquad \begin{array}{c} u_{ij} \in \mathbb{C}, \\ S^\dagger S = 1. \end{array} \tag{2}$$

A unitary matrix has orthogonal column vectors, guaranteeing that the resulting vector on the right side is again a quantum amplitude vector. Equation (2) describes in fact any possible closed evolution of a two-qubit system in quantum theory.

Quantum algorithms (as well as QML algorithms) are usually formulated using the Dirac notation, in which one decomposes the amplitude vector into a linear combination of unit vectors and rewrites the unit vectors as Dirac vectors:

$$\mathbf{a} = a_1 \begin{pmatrix} 1 \\ 0 \\ \vdots \\ 0 \end{pmatrix} + \ldots + a_{2^n} \begin{pmatrix} 0 \\ 0 \\ \vdots \\ 1 \end{pmatrix} \tag{3}$$

$$\Updownarrow \tag{4}$$

$$|\psi\rangle = a_1 \, |0 \ldots 0\rangle + \ldots + a_{2^n} \, |1 \ldots 1\rangle \, . \tag{5}$$

Dirac notation is very handy as it visualizes the actual measurement result of the n qubits corresponding to an amplitude.

Similarly to elementary gates, the circuit model defines elementary unitary transformations as building blocks to manipulate the quantum state of a qubit system. For example, consider a single qubit described by the complex amplitude vector $(a_1, a_2)^T$. If the quantum system is in state $(1, 0)^T$, we know with certainty that a measurement will produce the state 0 (since the probability of measuring the 0 state is given by $p_0 = |a_1|^2 = 1.0$, while $p_1 = |a_2|^2 = 0.0$). The unitary transformation

$$U_x = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$$

then transforms this state into $(0, 1)^T$, which will certainly result in a measurement of state 1. U_x hence effectively performs a bit flip or NOT gate on the state of the qubits. In a similar fashion, other quantum gates can be defined that together form a set of universal gates for quantum computation.

Why Is Quantum Computing Different?

Returning to the question why complex amplitudes change the rules of classical information processing, consider another elementary quantum gate that has no classical equivalent since it cannot be expressed as a stochastic matrix with positive entries. The Hadamard gate

$$U_H = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix} ,$$

will, applied to a state $(1, 0)^T$, produce $(\frac{1}{\sqrt{2}}, \frac{1}{\sqrt{2}})^T$, which is called a *superposition* of states 0 and 1. A classical equivalent would be a state of maximum uncertainty, as the probability of measuring the qubit in state 0 or 1 is $|\frac{1}{\sqrt{2}}|^2 = \frac{1}{2}$ each. However, the difference of a superposition becomes apparent when applying U_H once more, which transforms the state back into $(1, 0)^T$ as the minus in U_H cancels the two amplitudes with each other when calculating the second entry of the resulting amplitude vector. In other words, amplitudes can annihilate each other, a phenomenon called *interference* which is often mentioned as the crucial resource of quantum computing. Beyond this illustration, the elegant theory of quantum Turing machines allows a more sophisticated comparison between quantum and classical computing (Deutsch 1985), but goes beyond our scope here.

Quantum Machine Learning Algorithms

Most existing QML algorithms solve problems of supervised or unsupervised pattern classification and regression, although first advancements to reinforcement learning have been made (e.g., Paparo et al. 2014). Given a (classical) dataset $\mathcal{D}$ and a new instance $\tilde{x}$ for which we would make a prediction, a QML algorithm usually consists of three parts: First, the input has to be encoded into a quantum system through a *state preparation* routine. Second, the quantum algorithm is executed by unitary transformations (Note that nonunitary evolutions are possible in so-called *open quantum systems*, but correspond to a unitary evolution of a larger system.) Third, the result is read out by measuring the quantum system (see Fig. 1). The encoding and readout steps are often the bottlenecks of a QML algorithm; for example, reading out an amplitude in a quantum state that is in a uniform superposition of all possibilities will on average take a number of measurements that is exponential in the number of qubits. In particular, claims of quantum algorithms that run in time logarithmic in the size of the dataset and input vectors often ignore the resources it takes for the crucial step of encoding the information carried by a dataset into

Quantum Machine Learning, Fig. 1 Comparison of the basic scheme of classical (*left*) and quantum (*center*) machine learning algorithms for pattern classification, together with the operations on the quantum system (*right*). In order to solve machine learning tasks based on classical datasets, the quantum algorithm requires an information encoding and readout step that are in general highly nontrivial procedures, and it is important to consider them in the runtime

a quantum system. Such algorithms can still be valuable for pure quantum information processing, i.e., if the "quantum data" is generated by previous routines or experiments.

The QML algorithm and readout step depend heavily on the way information is encoded into the quantum system; one can distinguish three ways of information encoding into an n-qubit system:

1. Interpreting the possible measurement outcomes of a qubit system as a bit sequence.
2. Interpreting the amplitude vector as (i) a 2^n-dimensional classical real vector or (ii) a probability distribution over n binary variables.
3. Encoding the result to an optimization problem into the ground state (state of the lowest energy) of a quantum system.

These strategies help to distinguish different approaches to develop QML algorithms.

Associating Qubits with Bits

The most straightforward method of information encoding into quantum systems is to associate bits with qubits. For example, the two-qubit state $(1, 0, 0, 0)^T$ in the example in Table 2 represents the bit string [00], since the system has unit probability of being measured in the '00' state.

To encode a full dataset in this fashion, it needs to be given in binary form, meaning that every feature vector (and, if applicable, its label) has been translated into an n-bit binary sequence. For example, the dataset $\mathcal{D}$ [$\mathcal{D} = \left\{ \begin{pmatrix} 0 \\ 0 \\ 1 \end{pmatrix}, \begin{pmatrix} 0 \\ 1 \\ 1 \end{pmatrix}, \begin{pmatrix} 1 \\ 1 \\ 0 \end{pmatrix} \right\}$] can be encoded into the quantum state $\mathbf{a}_{\mathcal{D}} = \frac{1}{\sqrt{3}}(01010010)^T$:

In this case, the Dirac notation introduced above is helpful as it explicitly contains the encoded feature vectors:

$$|\mathcal{D}\rangle = \frac{1}{\sqrt{3}}(|001\rangle + |011\rangle + |110\rangle).$$

An early example of a QML algorithm based on such a "quantum dataset" has been developed for pattern completion (finding feature vectors containing a given bit sequence) by an associative memory mechanism as known from Hopfield models (Ventura and Martinez 2000). The authors suggest a routine to construct the state $\mathbf{a}_{\mathcal{D}}$ efficiently and use a modified Grover search algorithm, in which the amplitudes corresponding to the desired measurement outcomes are marked in one single step, after which the amplitudes of the marked states are amplified. The resulting quantum state has a high probability of being measured in one of the basis states containing the desired bit sequence.

An example of a QML algorithm for supervised pattern classification is a quantum version of k-nearest neighbor (Schuld et al. 2014b). Beginning with a superposition as in Eq. (6) where some selected qubits encode the class label, the idea is to weigh the amplitudes by the Hamming distance between each corresponding training vector and the new input. Only the "class-label qubits" get measured, so that close inputs contribute more to the probability of measuring their class label than distant ones. An alternative is presented by Wiebe et al. (2015), who also prepare a quantum state with distance-weighted amplitudes and then performed a subroutine based on the Grover search to find the basis state representing the closest neighbor.

Encoding Information into Amplitudes

Another way to encode information is to associate the quantum amplitude vector with a real classical vector:

$$\begin{pmatrix} a_1 \\ \vdots \\ a_{2^n} \end{pmatrix} \leftrightarrow \begin{pmatrix} x_1 \\ \vdots \\ x_{2^n} \end{pmatrix}, \sum_i |x_i|^2 = 1, x_i \in \mathbb{R}.$$

Note that since amplitude vectors are normalized, the classical vector has to be preprocessed accordingly. A quantum system of n qubits can therefore in principle encode 2^n real numbers, which is an exponentially compact representation. There are some vectors for which state preparation can be done in time that grows only linear with the number of qubits, and if the QML algorithm and readout step have the same property, an algorithm which is logarithmic in the input dimension is found.

Two different strategies to use this encoding for QML can be distinguished, one that associates the amplitude vector with one or all feature vectors in order to use the power of eigenvalue decomposition inherent in the formalism of quantum theory, and the other in which amplitudes are used to encode classical probability distributions.

Quantum Eigenvalue Decompositions

An important branch of QML research is based on the intrinsic feature of quantum theory to evaluate eigenvalues of operators, which has been exploited in an important quantum algorithm for the solution of systems of linear equations (Harrow et al. 2009). The routine takes a quantum state described by the amplitude vector $\mathbf{b}$ which corresponds to the (normalized) right side of a classical linear system of equations $\mathbf{A}\mathbf{x} = \mathbf{b}$. Through a set of involved operations (including the Hamiltonian simulation of an operator corresponding to $\mathbf{A}$, a quantum phase estimation algorithm and a selective measurement that has to be repeated until a certain result was obtained), the quantum state is transformed into $\sum_j \lambda_j^{-1} \mathbf{u}_j^T \mathbf{b}\, \mathbf{u}_j$ with eigenvalues λ_j and eigenvectors $\mathbf{u}_j$ of $\mathbf{A}$, which equals the correct solution $\mathbf{x}$. Due to the exponentially compact representation of information, the complexity of the algorithm depends only logarithmically on the size of $\mathbf{b}$ when we ignore the encoding and readout step. However, its running time depends sensibly on other parameters such as the condition number and sparsity of $\mathbf{A}$, as well as the desired accuracy in the result. This makes the linear systems algorithm only applicable to very special problems (Aaronson 2015). QML researchers have tried to find such applications in different areas of machine learning that rely on matrix inversion.

The first full QML example exploiting the ideas of the linear systems algorithm was the quantum support vector machine (Rebentrost et al. 2014). The main idea is to take the dual formulation of support vector machines written as a least squares problem, in which a linear system of equations with the kernel matrix $K_{ij} = \mathbf{x}_i \mathbf{x}_j$ and $\mathbf{x}_i, \mathbf{x}_j \in \mathcal{D}$ has to be solved, and apply the above quantum routine. By making use of a trick, the linear systems algorithm can take a quantum state encoding K_{ij} (instead of a quantum operator as in the original version). Creating a quantum version of K_{ij} is surprisingly elegant if one can prepare a quantum state:

$$(x_1^1, \ldots, x_N^1, \ldots, x_1^M, \ldots, x_N^M) \qquad (6)$$

whose amplitudes encode the MN features of all training vectors $\mathbf{x}^m = (x_1^m, \ldots, x_N^m)^T$ $m = 1, \ldots, M$. The statistics of a specific subset of the qubits in state Eq. (6) include a covariance matrix (in quantum theory known as density matrix) that is entrywise equivalent to the kernel and which can be accessed by further processing.

Data fitting by linear regression has been approached by means of the quantum linear systems algorithm by Wiebe et al. (2012) to obtain the well-known least squares solution:

$$\mathbf{w} = \mathbf{X}^{+}\mathbf{y}$$

for the linear regression parameters $\mathbf{w}$ with the pseudoinverse $\mathbf{X}^{+} = (\mathbf{X}^{+}\mathbf{X})^{-1}\mathbf{X}^{+}$ where the columns of X are the training inputs. Schuld et al. (2016), propose another version of the quantum algorithm that is suited for prediction. The algorithm is based on a quantum computation of the singular value decomposition of $\mathbf{X}^{+}$ which in the end encodes the result of the prediction of a new input into the measurement result of a single qubit.

Other QML algorithms based on the principle of matrix inversion and eigenvalue estimation on a quantum computer have been proposed for Gaussian processes (Zhao et al. 2015) as well as to find topological and geometric features of data (Lloyd et al. 2016). The routines discussed here specify the core algorithm as well as the readout step in the scheme of Fig. 1 and are logarithmic in the dimension of the feature vectors. However, they leave the crucial encoding step open, which might merely "hide" the complexity for all but some selected problems as has been critically remarked by Aaronson (2015).

Quantum Probability Distributions

Since quantum theory defines probability distributions over measurement results, it is immediately apparent that probability distributions over binary variables can very genuinely be represented by the amplitudes of a qubit system.

More precisely, given n random binary variables, an amplitude vector can be used to encode the square roots of 2^n probabilities of the different realizations of these variables. For example, the probability distribution over the possible results of the two-coin toss in Table 1 could be encoded into an amplitude vector $\left(\sqrt{p_{00}}, \sqrt{p_{01}}, \sqrt{p_{10}}, \sqrt{p_{11}}\right)$ of the two-qubit system in Table 2. Despite the efficient representation of probability distributions, also the marginalization of variables, which is intractable in classical models, corresponds to the simple step of excluding the qubits corresponding to these variables from measurements and considering the resulting statistics.

While these advantages sound impressive, it turns out that the problem of statistical inference remains prohibitive: Conditioning the qubit probability distribution on the state of all but one qubit, $p(x_1, \ldots, x_N) \rightarrow p(x_N|x_1, \ldots, x_{N-1})$, requires measuring these qubits in exactly the desired state, which has in general an exponentially small probability. Measuring the state can be understood as sampling from the probability distribution, and one has to do an unfeasibly large number of measurements to obtain the conditional statistics, while after each measurement a new quantum state has to be prepared. It has in fact been shown that the related problem of Bayesian updating through quantum distribution is intractable (Wiebe and Granade 2015), as it corresponds to a Grover search which can only be quadratically faster than classically possible.

Even without the ability for efficient inference, quantum systems can still be interesting for probabilistic machine learning models. Low et al. (2014) exploit the quadratic speedup for a problem of inference with "quantum Bayesian nets." Hidden Markov models have been shown to have an elegant formal generalization in the language of open quantum systems (Barry et al. 2014). Wiebe et al. (2014) show how quantum states that approximate Boltzmann distributions can be prepared to get samples for the training of Boltzmann machines through contrastive divergence. The same authors propose a semi-classical routine for Bayesian updating (Wiebe and Granade 2015). These contributions suggest that a lot of potential lies in approaches that exploit the genuinely stochastic structure of quantum theory for probabilistic machine learning methods.

Optimization and Quantum Annealing

Another branch of QML research is based on techniques of *quantum annealing*, which can be understood as an analogue version of quantum computing (Das and Chakrabarti 2008). Similar to the metaheuristic of simulated annealing, the idea is to drive a physical system into its energetic ground state which encodes the desired result of an optimization problem. To associate each basis state of a qubit with an energy, one has to introduce externally controllable physical interactions between the qubits.

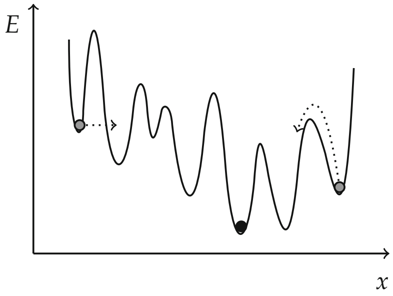
The main difference between classical and quantum annealing is that "thermal fluctuations" are replaced by quantum fluctuations which enable the system to *tunnel* through high and thin energy barriers (the probability of quantum tunneling decreases exponentially with the barrier width, but is independent of its height). That makes quantum annealing especially fit for problems with a "sharply ragged" objective function (see Fig. 2). Quantum annealing can be understood as a heuristic version of the famous computational model of quantum adiabatic computation, which is why some authors speak of *adiabatic quantum machine learning*.

The significance of quantum annealing lies in its relatively simple technological implementation, and quantum annealing devices are available commercially. Current machines are limited to solving quadratic unconstrained binary optimization (QUBO) problems:

$$\underset{(x_1,\ldots,x_N)}{\text{argmin}} \sum_{ij} w_{ij}\, x_i x_j \quad \text{with} \quad x_i, x_j \in [0,1]. \tag{7}$$

An important step is therefore to translate the problem into QUBO form, which has been done for simple binary classifiers or perceptrons (Pudenz and Lidar 2013; Denchev et al. 2012), image matching problems (Neven et al. 2008) and Bayesian network structure learning (O'Gorman et al. 2015). Other machine learning models naturally relate to the form of Eq. (7). For example, a number of contributions investigate quantum annealing for the sampling step required in the training of Boltzmann machines via contrastive divergence (Adachi and Henderson 2015; Amin et al. 2016). Another example is the Hopfield model for pattern recognition via associative memory, which has been investigated from the perspective of adiabatic quantum computation with nuclear magnetic resonance systems (Neigovzen et al. 2009).

Measuring the performance of quantum annealing compared to classical annealing schemes is a non-trivial problem, and although advantages of the quantum schemes have been demonstrated in the literature mentioned above, general statements about speedups are still controversial.



Quantum Machine Learning, Fig. 2 Illustration of quantum annealing in an energy landscape over (here continuous) states or configurations x. The ground state is the configuration of the lowest energy (*black dot*). Quantum tunneling allows the system state to transgress high and thin energy barriers (*gray dot* on the *left*), while in classical annealing technique stochastic fluctuations have to be large enough to allow for jumps over peaks (*gray dot* on the *right*)

Experimental Realizations

The reason why one rarely finds classical computer simulations of quantum machine learning algorithms in the literature is that the description of quantum systems is classically intractable due to the exponential size of the amplitude vectors. Until a large-scale universal quantum computer is built, only QML algorithms based on quantum annealing can be tested on real devices and benchmarked against classical machine learning algorithms. Some proof-of-principle experiments have nevertheless implemented few-qubit examples of proposed QML algorithms in the lab. Among those are experimental realizations of the quantum support vector machine (Cai et al. 2015) as well as quantum clustering algorithms (Li et al. 2015; Neigovzen et al. 2009).

Query-Based Learning

Sanjay Jain[1] and Frank Stephan[2]
[1]School of Computing, National University of Singapore, Singapore, Singapore
[2]Department of Mathematics, National University of Singapore, Singapore, Singapore

Abstract

Query learning models the learning process as a dialogue between a pupil (learner) and a teacher; the learner has to figure out the target concept by asking questions of certain types and whenever the teacher answers these questions correctly, the learner has to learn within the given complexity bounds. Complexity can be measured by both, the number of queries as well as the computational complexity of the learner. Query learning has close connections to statistical models like PAC learning.

Definition

Most learning scenarios consider learning as a relatively passive process where the learner observes more and more data and eventually formulates a hypothesis that explains the data observed. Query-based learning is an ▶ active learning process where the learner has a dialogue with a teacher, which provides on request useful information about the concept to be learned.

Detail

This article will mainly focus on query-based learning of finite classes and of parameterized families of finite classes. In some cases, an infinite class has to be learned where then the behavior of the learner is measured in terms of a parameter belonging to the concept. For example, when learning the class of all singletons $\{x\}$ with $x \in \{0,1\}^*$, the parameter would be the length n of x, and an algorithm based on membership queries would need up to $2^n - 1$ queries of the form "Is y in L?" to learn an unknown set $L = \{x\}$ with $x \in \{0,1\}^n$. In Query-based learning, the questions asked are similar to the following: Which classes can be learned using queries of this or that type? If queries of a given type are used to learn a parameterized class $\bigcup C_n$, is it possible to make a learner which (with or without knowledge of n) succeeds to learn every $L \in C_n$ with a number of queries that is polynomial in n? What is the exact bound on queries needed to learn a finite class C in dependence of the topology of C and the cardinality of C? If a query-based learner using polynomially many queries exists for a parameterized class $\bigcup C_n$, can this learner also be implemented such that it is computable in polynomial time?

In the following, let C be the class of concepts to be learned and the concepts $L \in C$ are subsets of some basic set X. Now the learning process is a dialogue between a learner and a teacher in order to identify a language $L \in C$, which is known to the teacher but not to the learner. The dialogue goes in turns and follows a specific protocol that goes over a finite number of rounds. Each round consists of a query placed by the learner to the teacher and the answer of the teacher to this query. The query and the answer have to follow a specific format (see Table 1) and there are the following common types, where $a \in X$ and $H \in C$ are data items and concepts chosen by the learner and $b \in X$ is a counterexample chosen by the teacher:

While for subset queries and superset queries it is not required by all authors that the teacher provides a counterexample in the case that the answer is "no," this requirement is quite standard for the case of equivalence queries. Without counterexamples, a learner would not have any real benefit from these queries in settings where faster convergence is required, than by just checking "Is $H_0 = L$?," "Is $H_1 = L$?," "Is $H_2 = L$?," . . ., which would be some trivial kind of algorithm.

Here is an example: Given the class C of all finite subsets of $\{0,1\}^*$, a learner using superset queries could just work as given in Table 2 to learn each set of the form $L = \{x_1, x_2, \ldots, x_n\}$ with $n + 1$ queries.

Query-Based Learning, Table 1 Types of Queries

Query name	Precise Query	Answer if true	Answer if false
Membership query	Is $a \in L$?	"Yes"	"No"
Equivalence query	Is $H = L$?	"Yes"	"No" plus b (where $b \in H - L \cup L - H$)
Subset query	Is $H \subseteq L$?	"Yes"	"No" plus b (where $b \in H - L$)
Superset query	Is $H \supseteq L$?	"Yes"	"No" plus b (where $b \in L - H$)
Disjointness query	Is $H \cap L = \emptyset$?	"Yes"	"No" plus b (where $b \in H \cap L$)

Query-Based Learning, Table 2 Learning finite sets using superset queries

Round	Query	Answer	Counterexample
1	Is $L \subseteq \emptyset$?	"No"	x_1
2	Is $L \subseteq \{x_1\}$?	"No"	x_2
3	Is $L \subseteq \{x_1, x_2\}$?	"No"	x_3
$\vdots$	$\vdots$	$\vdots$	$\vdots$
n	Is $L \subseteq \{x_1, x_2, \ldots, x_{n-1}\}$?	"No"	x_n
$n+1$	Is $L \subseteq \{x_1, x_2, \ldots, x_{n-1}, x_n\}$?	"Yes"	—

Here, of course, the order on how the counterexamples come up does not matter; the given order was just preserved for the reader's convenience. Note that the same algorithm works also with equivalence queries in place of superset queries. In both cases, the algorithm stops with outputting "$L = \{x_1, x_2, \ldots, x_n\}$" after the last query. However, the given class is not learnable using membership and subset queries which can be seen as follows: Assume that such a learner learns $\emptyset$ using the subset queries "Is $H_0 \subseteq L$?," "Is $H_1 \subseteq L$?," "Is $H_2 \subseteq L$?," ..., "Is $H_m \subseteq L$?" and the membership queries "Is $y_0 \in L$?," "Is $y_1 \in L$?," "Is $y_2 \in L$?," ..., "Is $y_k \in L$?" Furthermore, let D be the set of all counterexamples provided by the learner to subset queries. Now let $E = D \cup H_0 \cup H_1 \cup \ldots \cup H_m \cup \{y_0, y_1, \ldots, y_k\}$. Note that E is a finite set and let x be an element of $\{0,1\}^* - E$. If $L = \{x\}$, then the answers to these queries are the same to the case that $L = \emptyset$. Hence, the learner cannot distinguish between the sets $\emptyset$ and $\{x\}$; therefore, the learner is incorrect on at least one of these sets.

In the case that C is finite, one could just ask what is the number of queries needed to determine the target L in the worst case. This depends on the types of queries permitted and also on the topology of the class C. For example, if C is the power set of $\{x_1, x_2, \ldots, x_n\}$, then n membership queries are enough; but if C is the set of all singleton sets $\{x\}$ with $x \in \{0,1\}^n$, then $2^n - 1$ membership queries are needed to learn the concept, although in both cases the cardinality of C is 2^n. One can do with $\log(|C|)$ many equivalence queries with counterexamples in the case that a class-comprising hypothesis space is permitted. For this, each conjecture H has that for all x, $H(x)$ follows the majority of those $L \in C$ which are consistent with all previous counterexamples. Then each counterexample would invalidate the majority of the still valid/consistent members of C and thus give the logarithmic bound.

Angluin (2004) provides a survey of the prior results on questions like how many queries are needed to learn a given finite class. Maass and Turán (1992) showed that usage of membership queries in addition to equivalence queries does not speed up learning too much compared to the case of using equivalence queries alone. If EQ is the number of queries needed to learn C from equivalence queries alone (with counterexamples) and EMQ is the number of queries needed to learn C with equivalence queries and membership queries, then

$$\frac{EQ}{\log(EQ+1)} \leq EMQ \leq EQ;$$

here the logarithm is base 2. This result is based on a result of Littlestone (1988) who characterized the number of queries needed to learn from equivalence queries alone and provided a "standard optimal algorithm" for this task. Note that these two results used class-comprising hypothesis spaces, where one can make an equivalence query with a hypothesis which is not in the class to be learned – this technique permits to get meaningful counterexample.

Angluin (1987) showed that the class of all regular languages can be learned in polynomial time using queries and counterexamples. Here the learning time is measured in terms of two parameters: the number n of states that the smallest deterministic finite automaton generating the language has and the number m of symbols in the longest counterexample provided by the teacher. Ibarra and Jiang (1988) showed that the algorithm can be improved to need at most dn^3 equivalence queries when the teacher always returns the shortest counterexample; Birkendorf et al. (2000) improved the bound to dn^2. In these bounds, d is the size of the alphabet used for defining the regular languages to be learned.

Much attention has been paid to the following question: Which classes of Boolean formulas over n variables can be learned with polynomially many queries, uniformly in n (see, e.g., Aizenstein et al. 1992; Aizenstein and Pitt 1995; Angluin et al. 1993; Hellerstein et al. 1996)? Angluin et al. (1993) showed that read-once formulas, in which every variable occurs only once, are learnable in polynomial time using membership and equivalence queries. On the other hand, read-thrice DNF (disjunctive normal form) formulas cannot be learned in polynomial time using the same queries (Aizenstein et al. 1992) unless $P = NP$. In other words, such a learner would not succeed because of the limited computational power of a polynomial time learner; hence, equipping the learner with an additional oracle that can provide this power would permit to build such a learner. Here an oracle – in contrast to a teacher – does not know the task to be learned but gives information which is difficult or impossible to compute. Such an oracle could, for example, be the set SAT of all satisfiable formulas, and thus the learner could gain additional power by asking the oracle whether certain formulas are satisfiable. A special class of Boolean formulas is that of Horn clauses (see, e.g., Angluin et al. 1992; Arias 2004; Arias and Balcázar 2009; Arias and Khardon 2002).

There are links to other fields. Angluin (1988, 1990) investigated the relation between query learning and ▶ PAC Learning. She found that every class which is learnable using membership queries and equivalence queries is also PAC learnable (Angluin 1988); the PAC learner also works in polynomial time and needs at most polynomially many examples. More recent research on learning Boolean formulas also combines queries with probabilistic aspects (Jackson 1997). Furthermore, query learning has also been applied to ▶ Inductive Inference (see, e.g., Gasarch and Lee 2008; Gasarch and Smith 1992; Jain et al. 2007; Lange and Zilles 2005). Here the power of the learner depends not only on the type of queries permitted but also on whether queries of the corresponding type can be asked finitely often or infinitely often; the latter applies of course only to learning models where the learner converges in the limit and may revise the hypothesis from time to time. Furthermore, queries to oracles have been studied widely; see the entry on ▶ Complexity of Inductive Inference.

Definition

Radial basis function networks are a means of approximation by algorithms using linear combinations of translates of a rotationally invariant function, called the radial basis function. The coefficients of these approximations usually solve a minimization problem and can also be computed by interpolation processes. Sometimes the very useful approach of quasi-interpolation is also applied where approximations are computed that do not necessarily match the target functions pointwise but satisfy certain smoothness and decay conditions. The radial basis functions constitute so-called reproducing kernels on certain Hilbert spaces or – in a slightly more general setting – semi-Hilbert spaces. In the latter case, the aforementioned approximation also contains an element from the null-space of the seminorm of the semi-Hilbert space. That is usually a polynomial space.

Motivation and Background

Radial basis function networks are a method to approximate functions and data in a way which is related to the idea of neural networks and learning with kernels. More specifically, approximations of functions or data via algorithms that make use of networks (or neural networks) can be interpreted as either interpolation or minimization problems using kernels of certain shapes, called radial basis functions in the form in which we wish to consider them in this entry. In all cases, they are usually *high-dimensional approximations*, that is, the number of unknowns n in the argument of the kernel may be very large. On the other hand, the number of learning examples ("data") may be quite small. The name neural networks comes from the idea that this learning process simulates the natural functioning of neurons.

At any rate, the purpose of this approach will be the modelization of the learning process by mathematical methods. In most practical cases of

C. Sammut, G.I. Webb (eds.), *Encyclopedia of Machine Learning and Data Mining*,
DOI 10.1007/978-1-4899-7687-1

networks, the data from which we will learn in the method are rare, i.e., we have few data "points." We will consider this learning approach as an approximation problem in this description; essentially it is a minimizing (regression) problem.

Structure of the Network/Learning System

To begin with, let $\varphi : \mathbb{R}_+ \to \mathbb{R}$ be a univariate continuous function and $\|\cdot\|$ be the Euclidean norm on $\mathbb{R}^n$ for some $n \in \mathbb{N}$, as used for approximation in the seminal paper by Schoenberg (1938). Here, $\mathbb{R}_+$ denotes the set of nonnegative reals. Therefore

$$\varphi(\|\cdot\|) : \mathbb{R}^n \to \mathbb{R},$$
$$(x_1, x_2, \ldots, x_n)^T \mapsto \varphi\left(\sqrt{x_1^2 + x_2^2 + \cdots + x_n^2}\right),$$

is a multivariate function and here the number n of unknowns may be very large in practice. This function is rotationally invariant. Incidentally, much of what is going to be said here will work if we replace this function by a general, n-variate function which needs no longer be rotationally invariant, but then, strictly speaking, we are no longer talking about radial basis functions. Then other conditions may replace the restriction to radiality. Nonetheless we stick to the simple case (which is entirely sufficient for many practical applications) when the function really is radially symmetric.

We also require for the time being that this n-variate function be positive definite, that is, for all finite sets Ξ of pairwise different so-called *centers* or data sites $\xi \in \Xi \subset \mathbb{R}^n$, the symmetric matrix

$$A = \{\varphi(\|\xi - \zeta\|)\}_{\xi,\zeta\in\Xi}$$

is a positive definite matrix. The condition of pairwise different data in Ξ may of course in practice not be necessarily met. For quasi-interpolation, no linear systems need to be solved that depend on the target data, but other conditions that guarantee localness and polynomial accuracy of the approximants are required.

This property is usually obtained by requiring that $\varphi(\|\cdot\|)$ be absolutely integrable, and its Fourier transform – which thereby exists and is continuous – is positive everywhere ("Bochner's theorem"). An example for such a useful function is the exponential (the "Gauß-kernel") $\varphi(r) = \exp(-c^2r^2)$, $r \geq 0$, where c is a positive parameter. For this the above positive definiteness is guaranteed for all positive c and all n. Another example is the Poisson-kernel $\varphi(r) = \exp(-cr)$. However, we may also take the non-integrable "inverse multiquadrics" $\varphi(r) = 1/\sqrt{r^2+c^2}$ which has a Fourier transform in the generalized or distributional sense that is also positive everywhere except at zero. There it has a singularity. Nonetheless, the aforementioned matrices of the form A are still always positive definite for these exponentials and the inverse multiquadrics so long as $c > 0$ and $n = 1, 2, \ldots$. Still further examples come from the so-called Dagum class of radial basis functions $\varphi(r) = 1-(r^\beta/(1+r^\beta))^\gamma$ which give positive definiteness for a variety of choices of parameters β and γ.

This requirement of positive definiteness guarantees that for all given finite sets Ξ and "data" $f_\xi \in \mathbb{R}$, $\xi \in \Xi$, there is a unique linear combination:

$$s(x) = \sum_{\xi\in\Xi} \lambda_\xi \varphi(\|x - \xi\|), \qquad x \in \mathbb{R}^n,$$

which satisfies the linear interpolation conditions:

$$s(\xi) = f_\xi, \qquad \forall\ \xi \in \Xi.$$

This is because the interpolation matrix which is used to compute the coefficients λ_ξ is just the matrix A above which is positive definite, thus regular. The expression in the penultimate display is the network that approximates the data given by the user. Of course the interpolation conditions are just what is meant by learning from examples, the data being the $|\Xi|$ examples. Here as always, $|\Xi|$ denotes the cardinality of the set Ξ. In the learning theory, the linear space spanned by the above translates of $\varphi(\|\cdot\|)$ by $\xi \in \Xi$ is called the feature space with φ as activation function.

Incidentally, it is straightforward to generalize the approximation method to an approximation to data in $\mathbb{R}^m$, $m \in \mathbb{N}$, by approximating the data $f_\xi \in \mathbb{R}^m$ componentwise by m such expressions as the above, call them $s_1, s_2, \ldots, s_m$.

Applications

Applications include classification of data, pattern recognition, time series analysis, picture smoothing similar to diffusion methods, and optimization.

Theory/Solution

Returning to interpolation, the problem may also be reinterpreted as a minimization problem. If we define the weighted L^2-integral

$$\|g\|_\varphi := \frac{1}{(2\pi)^{n/2}} \sqrt{\int_{\mathbb{R}^n} \frac{1}{\hat{\varphi}(\|x\|)} |\hat{g}(x)|^2 \, dx}$$

with $\hat{\varphi}$ still being the above positive Fourier transform, for all $g : \mathbb{R}^n \to \mathbb{R}$ for which the Fourier transform in the sense of $L^2(\mathbb{R}^n)$ is well defined and for which the above integral is finite, we may ask for the approximant to the above data – which still must satisfy the aforementioned interpolation conditions – that minimizes $\|\cdot\|_\varphi$. As Duchon noted, for example, for the thin-plate spline case $\varphi(r) = r^2 \log r$ in this seminal paper, this is just the above interpolant, i.e., that linear combination s of translates of radial basis functions, albeit in the thin-plate spline case with a linear polynomial added as we shall see below.

This works immediately both for the two examples of exponential functions and the inverse multiquadrics. Note that the fact that the latter has a Fourier transform with a singularity at the origin does not matter since its reciprocal appears as a weight function in the integral above. The important requirement is that the Fourier transform has no zero. It also works for the positive definite radial basis functions of compact support, for instance, in Buhmann (1998).

Regularization and Generalizations

Since, generally, the interpolation problem to data may be ill conditioned or unsuitable in the face of data errors, smoothing or regularization is appropriate as an alternative. Indeed, the interpolation problem may be replaced by a smoothing problem which is of the form

$$\frac{1}{|\Xi|} \sum_{\xi \in \Xi} \Big(s(\xi) - f_\xi \Big)^2 + \mu \|s\|_\varphi^2 = \min_s !.$$

Here the L^2-integral is still the one used in the description above and μ is a positive smoothing parameter.

However, when there is only a trivial nullspace of the $\|\cdot\|_\varphi$, i.e., $g = 0$ is the only g with $\|g\|_\varphi = 0$, then it is a norm, and the solution of this problem will have the form

$$s(x) = \sum_{\xi \in \Xi} \lambda_\xi \varphi(\|x - \xi\|), \qquad x \in \mathbb{R}^n.$$

This is where the name regularization network comes from, regularization and smoothing being used synonymously. The form used in the penultimate display is a classical regularizing network problem or in the spline terminology a smoothing spline problem. For so-called support vector machines, the square of the residual term $s(\xi) - f_\xi$ should be replaced by another expression, for example, the one by Vapnik (1996):

$$|s(\xi) - f_\xi|_\varepsilon := \begin{cases} f_\xi - s(\xi) - \varepsilon & if\, |f_\xi - s(\xi)| \geq \varepsilon, \\ 0 & \text{otherwise,} \end{cases}$$

and for the support vector machines classification by the truncated power function $(\cdot)_+^\nu$ which is a positive power for positive argument and otherwise zero.

In the case of a classical regularizing network, the coefficients of the solution may be found by solving a similar linear system to the standard interpolation linear system mentioned above, namely,

$$(A + \mu I)\lambda = f,$$

where f is the vector $(f_\xi)_{\xi\in\Xi}$ in $\mathbb{R}^\Xi$ of the data given and $\lambda = (\lambda_\xi)_{\xi\in\Xi}$. The I denotes the $|\Xi| \times |\Xi|$ identity matrix and A is still the same matrix as above. Incidentally, also scaling mechanisms may be introduced into the radial basis function by replacing the simple translate $\varphi(\|x - \xi\|)$ by $\varphi(\|x - \xi\|/\delta)$ for a positive δ which may even depend on ξ.

The ideas of regularization and smoothing are of course not new; for instance, regularization goes back to Tichonov and Arsenin (1977) ("Tichonov regularization") and spline smoothing to Wahba (1985), especially when the smoothing parameter is adjusted via cross-validation or GCV (generalized cross-validation).

Now to the case of semi-norms $\|\cdot\|_\varphi$ with nontrivial null-spaces: indeed, the same idea can be carried through for other radial basis functions as well. In particular we are thinking here of those ones that do not provide positive definite radial basis interpolation matrices but strictly conditionally positive definite ones. We have strictly positive definite radial basis functions of order $k + 1$, $k \geq -1$, if the above interpolation matrices A are still positive definite but only on the subspace of those nonzero vectors $\lambda = (\lambda_\xi)$ in $\mathbb{R}^\Xi$ which satisfy

$$\sum_{\xi\in\Xi} \lambda_\xi p(\xi) = 0 \qquad \forall\ p \in \mathbb{P}_n^k,$$

where $\mathbb{P}_n^k$ denotes the linear space of polynomials in n variables with total degree at most k. In other words, the quadratic form $\lambda^T A\lambda$ need only be positive for such $\lambda \neq 0$. For simplicity of the presentation, we shall let $\mathbb{P}_n^{-1}$ denote $\{0\}$. In particular, if the radial basis function is conditionally positive definite of order 0, its interpolation matrices A are always positive definite, that is, without condition. Also, we have the minimal requirement that the sets of centers Ξ are unisolvent for this polynomial space, i.e., the only polynomial $p \in \mathbb{P}_n^k$ that vanishes identically on Ξ is the zero polynomial.

The connection of this with a layered neural network is that the approximation above is a weighted sum (weighted by the coefficients λ_ξ) over usually nonlinear activation functions φ. The entries in the sum are the radial basis function neurons and there are usually many of them. The number of nodes in the model is n. The hidden layer of "radial basis function units" consists of $|\Xi|$ nodes, i.e., the number of centers in our radial basis function approximation. The output layer has m responses if the radial basis function approximation above is generalized to m-variate data, i.e., then we get $s_1, s_2, \ldots, s_m$ instead of just s, as already described. This network here is of the type of a nonlinear, layered, feedforward network. More than one hidden layer is unusual. The choice of the radial basis functions (its smoothness, for instance) and the flexibility in the positioning of the centers in clusters, grids (e.g., Buhmann 1990), or otherwise provide much of the required freedom for good approximations.

The properties of conditional positive definiteness are fulfilled now for a much larger realm of radial basis functions which have still nowhere vanishing generalized Fourier transforms but with higher-order singularities at the origin. (Remember that this creates no problem for the well definedness of $\|\cdot\|_\varphi$.) For instance, the above properties are true for the thin-plate spline function $\varphi(r) = r^2 \log r$, for the shifted logarithm $\varphi(r) = (r^2 + c^2)\log(r^2 + c^2)$, and for the multiquadric $\varphi(r) = -\sqrt{r^2 + c^2}$. Here we still have a parameter c which may now be arbitrary real. The order of the above is one for the multiquadric and two for the thin-plate spline. Another commonly used radial basis function which gives rise to conditional positive definiteness is the $\varphi(r) = r^3$.

Hence the norm becomes a semi-norm with null-space $\mathbb{P}_n^k$, but it still has the same form as a square integral with the reciprocal of the Fourier transform of the radial basis function as a weight.

Therefore we have to include a polynomial from the null-space of the semi-norm to the approximant which becomes

$$s(x) = \sum_{\xi \in \Xi} \lambda_\xi \varphi(\|x - \xi\|) + q(x), \qquad x \in \mathbb{R}^n,$$

where $q \in \mathbb{P}_n^k$ and the side conditions on the coefficients

$$\sum_{\xi \in \Xi} \lambda_\xi p(\xi) = 0, \qquad \forall\ p \in \mathbb{P}_n^k.$$

When quasi-interpolation is used, this inclusion of polynomials is not because they are not formed by interpolation condition, and the reproduction of polynomials (thus their presence in the linear space) is directly guaranteed by their construction.

If we consider the regularization network problem with the smoothing parameter μ again, then we have to solve the linear system with a smoothing parameter μ:

$$(A + \mu I)\lambda + P^T b = f, \quad P\lambda = 0,$$

where $P = (p_i(\xi))_{i=1,\ldots,L,\xi \in \Xi}$ and p_i form a basis of $\mathbb{P}_n^k$, b_i being the components of b, and $q(x) = \sum_{i=1}^{L} b_i p_i(x)$ is the expression of the polynomial added to the radial basis function sum. So in particular P is a matrix with as many rows as the dimension $L = \binom{n+k}{n}$ of $\mathbb{P}_n^k$ is and $|\Xi|$ columns.

In all cases, the radial basis functions composed of the Euclidean norm can be regarded as reproducing kernels in the semi-Hilbert spaces defined by the set X of distributions f for which $\|g\|_\varphi$ is finite and the semi-inner product

$$(h, g) = \frac{1}{(2\pi)^n} \int_{\mathbb{R}^n} \frac{1}{\hat{\varphi}(\|x\|)} \hat{h}(x)\overline{\hat{g}(x)}\, dx,$$
$$h, g, \in X.$$

In particular, $\|g\|_\varphi^2 = (g, g)$. If the evaluation functional is continuous (bounded) on that space X, there exists a reproducing kernel, i.e., there is a $K : X \times X \to \mathbb{R}$ such that

$$g(x) = (g, K(\cdot, x)), \quad \forall\ x \in \mathbb{R}^n,\ g \in X,$$

See, for example, Wahba (1990). If the semi-inner product is actually an inner product, then the reproducing kernel is unique. The kernel gives rise to positive definite matrices $\{K(\xi, \zeta)\}_{\xi,\zeta \in \Xi}$ if and only if it is a positive operator. For the spaces X defined by our radial basis functions, it turns out that $K(x, y) := \varphi(\|x - y\|)$; see, e.g., the overview in Buhmann (2003). Then the matrices A are positive definite if $\hat{\varphi}(\|\cdot\|)$ is well defined and positive, but if it has a singularity at zero, the A may be only conditionally positive definite. Note here that $\hat{\varphi}(\|\cdot\|)$ denotes the n-variate Fourier transform of $\varphi(\|\cdot\|)$, both being radially symmetric.

Advantages of the Approach

Why are we interested in using radial basis functions for networks? The radial basis functions have many excellent approximation properties which make them useful as general tools for approximation. Among them are the variety of more or less smoothness as required (e.g., multiquadrics is C^∞ for positive c and just continuous for $c = 0$), the fast evaluation and computation methods available (see, e.g., Beatson and Powell 1994), the aforementioned nonsingularity properties and their connection with the theory of reproducing kernel Hilbert spaces, and finally their excellent convergence properties (see, e.g., Buhmann 2003). Generally, neural networks are a tried and tested approach to approximation, modeling, and smoothing by methods from learning theory.

Limitations

The number of applications where the radial basis function approach has been used is vast. Also, the solutions may be computed efficiently by far-field expansions, approximated Lagrange functions, and multipole methods. However, there are still some limitations with these important computational methods when the dimension n is large. So far, most of the multipole and far-field methods have been implemented only for medium-sized dimensions.

Random Decision Forests

▶ Random Forests

Random Forests

Synonyms

Random decision forests

Definition

Random Forests is an ▶ ensemble learning technique. It is a hybrid of the ▶ Bagging algorithm and the ▶ random subspace method, and uses ▶ decision trees as the base classifier. Each tree is constructed from a bootstrap sample from the original dataset. An important point is that the trees are not subjected to pruning after construction, enabling them to be partially overfitted to their own sample of the data. To further diversify the classifiers, at each branch in the tree, the decision of which feature to split on is restricted to a *random subset* of size n, from the full feature set. The random subset is chosen anew for each branching point. n is suggested to be $\log_2(N+1)$, where N is the size of the whole feature set.

Random Subspace Method

Synonyms

Random subspaces; RSM

Definition

The random subspace method is an ▶ ensemble learning technique. The principle is to increase diversity between members of the ensemble by restricting classifiers to work on different random subsets of the full feature space. Each classifier learns with a subset of size n, chosen uniformly at random from the full set of size N. Empirical studies have suggested good results can be obtained with the rule-of-thumb to choose $n = N/2$ features. The method is generally found to perform best when there are a large number of features (large N), and the discriminative information is spread across them. The method can underperform in the converse situation, when there are few informative features, and a large number of noisy/irrelevant features. ▶ Random Forests is an algorithm combining RSM with the ▶ Bagging algorithm, which can provide significant gains over each used separately.

Rank Correlation

Johannes Fürnkranz[1,2] and Eyke Hüllermeier[3]
[1] Knowledge Engineering Group, TU Darmstadt, Darmstadt, Deutschland
[2] Department of Information Technology, University of Leoben, Leoben, Austria
[3] Department of Computer Science, Paderborn University, Paderborn, Germany

Abstract

Rank correlation measures the correspondence between two rankings, τ and τ', of a set of m objects.

Method

Various proposals for such measures have been made, especially in the field of statistics. Two of the best-known measures are Spearman's rank correlation and Kendall's tau.

Spearman's rank correlation (Spearman 1904) calculates the sum of squared rank distances and is normalized such that it evaluates to -1 for reversed and to $+1$ for identical rankings. Formally, it is defined as follows:

$$(\tau, \tau') \mapsto 1 - \frac{6 \sum_{i=1}^{m} (\tau(i) - \tau'(i))^2}{m(m^2 - 1)} \qquad (1)$$

Kendall's tau (Kendall 1938) is the number of pairwise rank inversions between τ and τ', again normalized to the range $[-1, +1]$:

$$(\tau, \tau') \mapsto 1 - \frac{4 \left| \{(i, j) \mid i < j, \tau(i) < \tau(j) \wedge \tau'(i) > \tau'(j)\} \right|}{m(m-1)} \qquad (2)$$

Spearman's rank correlation and Kendall's tau give equal weight to all ranking positions, which is not desirable for all applications. For example, ranking problems in information retrieval are often evaluated with the (normalized) discounted cumulative gain (NDCG), which assigns more weight to the lower-ranking positions (cf. ▶ learning to rank).

Recommender Systems

Prem Melville and Vikas Sindhwani
IBM T. J. Watson Research Center, Yorktown Heights, NY, USA

Definition

The goal of a recommender system is to generate meaningful recommendations to a collection of users for items or products that might interest them. Suggestions for books on Amazon, or movies on Netflix, are real-world examples of the operation of industry-strength recommender systems. The design of such recommendation engines depends on the domain and the particular characteristics of the data available. For example, movie watchers on Netflix frequently provide ratings on a scale of 1 (disliked) to 5 (liked). Such a data source records the quality of interactions between users and items. Additionally, the system may have access to user-specific and item-specific profile attributes such as demographics and product descriptions, respectively. Recommender systems differ in the way they analyze these data sources to develop notions of affinity between users and items, which can be used to identify well-matched pairs. ► Collaborative Filtering systems analyze historical interactions alone, while ► Content-based Filtering systems are based on profile attributes; and hybrid techniques attempt to combine both of these designs. The architecture of recommender systems and their evaluation on real-world problems is an active area of research.

Motivation and Background

Obtaining recommendations from trusted sources is a critical component of the natural process of human decision making. With burgeoning consumerism buo-yed by the emergence of the web, buyers are being presented with an increasing range of choices while sellers are being faced with the challenge of personalizing their advertising efforts. In parallel, it has become common for enterprises to collect large volumes of transactional data that allows for deeper analysis of how a customer base interacts with the space of product offerings. Recommender systems have evolved to fulfill the natural dual need of buyers and sellers by automating the generation of recommendations based on data analysis.

The term "collaborative filtering" was introduced in the context of the first commercial recommender system, called Tapestry (Goldberg et al. 1992), which was designed to recommend documents drawn from newsgroups to a collection of users. The motivation was to leverage social collaboration in order to prevent users from getting inundated by a large volume of streaming documents. Collaborative filtering, which analyzes usage data across users to find well-matched user-item pairs, has since been juxtaposed against the older methodology of content filtering, which had its original roots in information retrieval. In content filtering, recommendations are not "collaborative" in the sense that suggestions made to a user do not explicitly utilize information across the entire user-base. Some early successes of collaborative filtering on related domains included the GroupLens system (Resnick et al. 1994b).

As noted in Billsus and Pazzani (1998), initial formulations for recommender systems were based on straightforward correlation statistics and predictive modeling, not engaging the wider range of practices in statistics and machine learning literature. The collaborative filtering problem was mapped to classification, which allowed dimensionality reduction techniques to be brought into play to improve the quality of the solutions. Concurrently, several efforts attempted to combine content-based methods with collaborative filtering, and to incorporate additional domain knowledge in the architecture of recommender systems.

Further research was spurred by the public availability of datasets on the web, and the interest generated due to direct relevance to e-commerce. Netflix, an online streaming video and DVD rental service, released a large-scale dataset containing 100 million ratings given by about half-a-million users to thousands of movie titles, and announced an open competition for the best collaborative filtering algorithm in this domain. Matrix Factorization (Bell et al. 2009) techniques rooted in numerical linear algebra and statistical matrix analysis emerged as a state-of-the-art technique.

Currently, recommender systems remain an active area of research, with a dedicated ACM conference, intersecting several subdisciplines of statistics, machine learning, data mining, and information retrievals. App-lications have been pursued in diverse domains ranging from recommending webpages to music, books, movies, and other consumer products.

Structure of Learning System

The most general setting in which recommender systems are studied is presented in Fig. 1. Known user preferences are represented as a matrix of n users and m items, where each cell $r_{u,i}$ corresponds to the rating given to item i by the user u. This *user ratings matrix* is typically sparse, as most users do not rate most items. The *recommendation task* is to predict what rating a user would give to a previously unrated item. Typically, ratings are predicted for all items that have not been observed by a user, and the highest rated items are presented as recommendations. The user under current consideration for recommendations is referred to as the *active user*.

The myriad approaches to recommender systems can be broadly categorized as:

- *Collaborative Filtering (CF)*: In CF systems, a user is recommended items based on the past ratings of all users collectively.
- *Content-based recommending*: These approaches recommend items that are similar in content to items the user has liked in the past, or matched to pre-defined attributes of the user.
- *Hybrid approaches*: These methods combine both collaborative and content-based approaches.

		Items					
		1	*2*	...	*i*	...	*m*
Users	*1*	5	3		1	2	
	2		2				4
	:			5			
	u	3	4		2	1	
	:					4	
	n			3	2		
	a	3	5		?	1	

Recommender Systems, Fig. 1 User ratings matrix, where each cell $r_{u,i}$ corresponds to the rating of user u for item i. The task is to predict the missing rating $r_{a,i}$ for the active user a

Collaborative Filtering

Collaborative filtering (CF) systems work by collecting user feedback in the form of ratings for items in a given domain and exploiting similarities in rat-ing behavior amongst several users in determining how to recommend an item. CF methods can be further subdivided into *neighborhood-based* and *model-based* approaches. Neighborhood-based methods are also commonly referred to as *memory-based* approaches (Breese et al. 1998).

Neighborhood-Based Collaborative Filtering

In neighborhood-based techniques, a subset of users are chosen based on their similarity to the active user, and a weighted combination of their ratings is used to produce predictions for this user. Most of these approaches can be generalized by the algorithm summarized in the following steps:

1. Assign a weight to all users with respect to similarity with the active user.
2. Select k users that have the highest similarity with the active user – commonly called the *neighborhood*.
3. Compute a prediction from a weighted combination of the selected neighbors' ratings.

In step 1, the weight $w_{a,u}$ is a measure of similarity between the user u and the active user a. The most commonly used measure of similarity is the Pearson correlation coefficient between the ratings of the two users (Resnick et al. 1994a), defined below:

$$w_{a,u} = \frac{\sum_{i \in I}(r_{a,i} - \bar{r}_a)(r_{u,i} - \bar{r}_u)}{\sqrt{\sum_{i \in I}(r_{a,i} - \bar{r}_a)^2 \sum_{i \in I}(r_{u,i} - \bar{r}_u)^2}} \qquad (1)$$

where I is the set of items rated by both users, $r_{u,i}$ is the rating given to item i by user u, and $\bar{r}_u$ is the mean rating given by user u.

In step 3, predictions are generally computed as the weighted average of deviations from the neighbor's mean, as in:

$$p_{a,i} = \bar{r}_a + \frac{\sum_{u \in K}(r_{u,i} - \bar{r}_u) \times w_{a,u}}{\sum_{u \in K} w_{a,u}} \qquad (2)$$

where $p_{a,i}$ is the prediction for the active user a for item i, $w_{a,u}$ is the similarity between users a and u, and K is the neighborhood or set of most similar users.

Similarity based on Pearson correlation measures the extent to which there is a linear dependence between two variables. Alternatively, one can treat the ratings of two users as a vector in an m-dimensional space, and compute similarity based on the cosine of the angle between them, given by:

$$W_{a,u} = \cos(\mathbf{r}_a, \mathbf{r}_u) = \frac{\mathbf{r}_a \cdot \mathbf{r}_u}{\|\mathbf{r}_a\|_2 \times \|r_u\|_2} \\ = \frac{\sum_{i=1}^{m} r_{a,i} r_{u,i}}{\sqrt{\sum_{i=1}^{m} r_{a,i}^2}\sqrt{\sum_{i=1}^{m} r_{u,i}^2}} \qquad (3)$$

When computing cosine similarity, one cannot have negative ratings, and unrated items are treated as having a rating of zero. Empirical studies (Breese et al. 1998) have found that Pearson correlation generally performs better. There have been several other similarity measures used in the literature, including *Spearman rank correlation*, *Kendall's* τ *correlation*, *mean squared differences*, *entropy*, and *adjusted cosine similarity* (Herlocker et al. 1999; Su and Khoshgoftaar 2009).

Several extensions to neighborhood-based CF, which have led to improved performance are discussed below.

Item-based Collaborative Filtering: When applied to millions of users and items, conventional neighborhood-based CF algorithms do not scale well, because of the computational complexity of the search for similar users. As a alternative, Linden et al. (2003) proposed *item-to-item* collaborative filtering where rather than matching similar users, they match a user's rated items to similar items. In practice, this approach leads to faster online systems, and often results in improved recommendations (Linden et al. 2003; Sarwar et al. 2001).

In this approach, similarities between pairs of items i and j are computed off-line using Pearson correlation, given by:

$$w_{i,j} = \frac{\sum_{u \in U}(r_{u,i} - \bar{r}_i)(r_{u,j} - \bar{r}_j)}{\sqrt{\sum_{u \in U}(r_{u,i} - \bar{r}_i)^2}\sqrt{\sum_{u \in U}(r_{u,j} - \bar{r}_j)^2}} \qquad (4)$$

where U is the set of all users who have rated both items i and j, $r_{u,i}$ is the rating of user u on item i, and $j, r_{u,i}$ is the average rating of the ith item across users.

Now, the rating for item i for user a can be predicted using a simple weighted average, as in:

$$p_{a,i} = \frac{\sum_{j \in K} r_{a,j} w_{i,j}}{\sum_{j \in K} |w_{i,j}|} \qquad (5)$$

where K is the neighborhood set of the k items rated by a that are most similar to i.

For item-based collaborative filtering too, one may use alternative similarity metrics such as *adjusted cosine similarity*. A good empirical comparison of variations of item-based methods can be found in Sarwar et al. (2001).

Significance Weighting: It is common for the active user to have highly correlated neighbors that are based on very few co-rated (overlapping) items. These neighbors based on a small number of overlapping items tend to be bad predictors. One approach to tackle this problem is to multiply the similarity weight by a *significance weighting* factor, which devalues the correlations based on few co-rated items (Herlocker et al. 1999).

Default Voting: An alternative approach to dealing with correlations based on very few co-rated items is to assume a default value for the rating for items that have not been explicitly rated. In this way one can now compute correlation (Eq. 1) using the union of items rated by users being matched as opposed to the intersection. Such a *default voting* strategy has been shown to improve collaborative filtering by Breese et al. (1998).

Inverse User Frequency: When measuring the similarity between users, items that have been rated by all (and universally liked or disliked) are not as useful as less common items. To account for this Breese et al. (1998) introduced the notion of *inverse user frequency*, which is computed as $f_i = \log n/n_i$, where n_i is the number of users who have rated item i out of the total number of n users. To apply inverse user frequency while using similarity-based CF, the original rating is transformed for i by multiplying it by the factor f_i. The underlying assumption of this approach is that items that are universally loved or hated are rated more frequently than others.

Case Amplification: In order to favor users with high similarity to the active user, Breese et al. (1998) introduced *case amplification* which transforms the original weights in Eq. (2) to

$$w'_{a,u} = w_{a,u} \cdot |w_{a,u}|^{\rho-1}$$

where ρ is the amplification factor, and $\rho \geq 1$.

Other notable extensions to similarity-based collaborative filtering include *weighted majority prediction* (Nakamura and Abe 1998) and *imputation-boosted CF* (Su et al. 2008).

Model-based Collaborative Filtering: Model-based techniques provide recommendations by estimating parameters of statistical models for user ratings. For example, Billsus and Pazzani (1998) describe an early approach to map CF to a classification problem, and build a classifier for each active user representing items as features over users and available ratings as labels, possibly in conjunction with dimensionality reduction techniques to overcome data sparsity issues. Other predictive modeling techniques have also been applied in closely related ways.

More recently, ▶ latent factor and matrix factorization models have emerged as a state-of-the-art methodology in this class of techniques (Bell et al. 2009). Unlike neighborhood based methods that generate recommendations based on statistical notions of similarity between users, or between items, latent factor models assume that the similarity between users and items is simultaneously induced by some hidden lower-dimensional structure in the data. For example, the rating that a user gives to a movie might be assumed to depend on few implicit factors such as the user's taste across various movie genres. Matrix factorization techniques are a class of widely successful latent factor models where users and items are simultaneously represented as unknown feature vectors (column vectors) w_u, $h_i \in \mathbb{R}^k$ along k latent dimensions. These feature vectors are learnt so that inner products $w_u^T h_i$ approximate the known preference ratings $r_{u,i}$ with respect to some loss measure. The squared loss is a standard choice for the loss function, in which case the following objective function is minimized,

$$j(W, H) = \sum_{(u,i)\in L} (r_{u,i} - w_u^T h_i)^2 \qquad (6)$$

where $W = [w_1 \ldots w_n]^T$ is an $n \times k$ matrix, $H = [h_1 \ldots h_m]$ is a $k \times m$ matrix, and L is the set of user-item pairs for which the ratings are known. In the impractical limit where all user-item ratings are known, the above objective function is $J(W, H) = \|R - WH\|^2_{fro}$ where R denotes the $n \times m$ fully known user-item matrix. The solution to this problem is given by taking the truncated SVD of R, $R = UDV^T$ and setting $W = U_K D_k^{\frac{1}{2}}$, $H = D_k^{\frac{1}{2}} V_k^T$ where U_k, D_k, V_k contain the k largest singular triplets of R. However, in the realistic setting where the majority of user-item ratings are unknown and insufficient number of matrix entries are observed, such a nice globally optimal solution cannot in general be directly obtained, and one has to explicitly optimize the non-convex objective function $J(W, H)$. Note that in this case, the objective function is a particular form of weighted loss, that is, $J(W, H) = \|S \odot (R - WH)\|^2_{fro}$ where $\odot$ denotes elementwise products, and S is a binary matrix that equals one over known user-item pairs L, and 0 otherwise. Therefore, weighted low-rank approximations are pertinent to this discussion (Srebro and Jaakkola 2003). Standard optimization procedures include gradient-based techniques, or procedures like alternating least squares where H is solved keeping W fixed and vice versa until a convergence criterion is satisfied. Note that fixing either W or H turns the problem of estimating the other into a weighted ▶ linear regression task. In order to avoid learning a model that overfits, it is common to minimize the objective function in the presence of ▸ regularization terms, $J(W, H) + \gamma\|W\|^2 + \lambda\|H\|^2$, where γ, λ are regularization parameters that can be determined by cross-validation. Once W, H are learnt, the product WH provides an approximate reconstruction of the rating matrix from where recommendations can be directly read off.

Different choices of loss functions, regularizers, and additional model constraints have generated a large body of literature on matrix factorization techniques. Arguably, for discrete ratings, the squared loss is not the most natural loss function. The maximum margin matrix factorization (Rennie and Srebro 2005) approach uses margin-based loss functions such as the hinge loss used in ▸ SVM classification, and its ordinal extensions for handling multiple ordered rating categories. For ratings that span over K values, this reduces to finding $K - 1$ thresholds that divide the real line into consecutive intervals specifying rating bins to which the output is mapped, with a penalty for insufficient margin of separation. Rennie and Srebro (2005) suggest a nonlinear conjugate gradient algorithm to minimize a smoothed version of this objective function.

Another class of techniques is the nonnegative matrix factorization popularized by the work of Lee and Seung (1999) where nonnegativity constraints are imposed on W, H. There are weighted extensions of NMF that can be applied to recommendation problems. The rating behavior of each user may be viewed as being a manifestation of different roles, for example, a composition of prototypical behavior in clusters of users bound by interests or community. Thus, the ratings of each user are an additive sum of basis vectors of ratings in the item space. By disallowing subtractive basis, nonnegativity constraints lend a part-based interpretation to the model. NMF can be solved with a variety of loss functions, but with the generalized KL-divergence loss defined as follows,

$$J(W, H) = \sum_{u,i \in L} r_{u,i} \log \frac{r_{u,i}}{w_u^T h_i} - r_{u,i} + w_u^T h_i$$

NMF is in fact essentially equivalent to probabilistic latent semantic analysis (pLSA) which has also previously been used for collaborative filtering tasks (Hofmann 2004).

The recently concluded million-dollar Netflix competition has catapulted matrix factorization techniques to the forefront of recommender technologies in collaborative filtering settings (Bell et al. 2009). While the final winning solution was a complex ensemble of different models, several enhancements to basic matrix factorization models were found to lead to improvements. These included:

1. The use of additional user-specific and item-specific parameters to account for systematic biases in the ratings such as popular movies receiving higher ratings on average.
2. Incorporating temporal dynamics of rating behavior by introducing time-dependent variables.

In many settings, only implicit preferences are available, as opposed to explicit like–dislike ratings. For example, large business organizations, typically, meticulously record transactional details of products purchased by their clients. This is a one-class setting since the business domain knowledge for negative examples that a client has no interest in buying a product ever in the future is typically not available explicitly in corporate databases. Moreover, such knowledge is difficult to gather and maintain in the first place, given the rapidly changing business environment. Another example is recommending TV shows based on watching habits of users, where preferences are implicit in what the users chose to see without any source of explicit ratings. Recently, matrix factorization techniques have been advanced to handle such problems (Pan and Scholz 2009) by formulating confidence weighted objective function, $J(W, H) = \Sigma_{(u,i)} c_{u,i}(r_{u,i} - w_u^T h_i)^2$, under the assumption that unobserved user-item pairs may be taken as negative examples with a certain degree of confidence specified via $c_{u,i}$.

The problem of recovering missing values in a matrix from a small fraction of observed entries is also known as the Matrix Completion problem. Recent work by Candès and Tao (2009) and Recht (2009) has shown that under certain assumptions on the singular vectors of the matrix, the matrix completion problem can be solved exactly by a convex optimization problem provided with a sufficient number of observed entries. This problem involves finding among all matrices consistent with the observed entries, the one with the minimum nuclear norm (sum of singular values).

Content-Based Recommending

Pure collaborative filtering recommenders only utilize the user ratings matrix, either directly, or to induce a collaborative model. These approaches treat all users and items as atomic units, where predictions are made without regard to the specifics of individual users or items. However, one can make a better personalized recommendation by knowing more about a user, such as demographic information (Pazzani 1999), or about an item, such as the director and genre of a movie (Melville et al. 2002). For instance, given movie genre information, and knowing that a user liked "Star Wars" and "Blade Runner," one may infer a predilection for science fiction and could hence recommend "Twelve Monkeys." Content-based recommenders refer to such approaches, that provide recommendations by comparing representations of content describing an item to representations of content that interests the user. These approaches are sometimes also referred to as *content-based filtering*.

Much research in this area has focused on recommending items with associated *textual* content, such as web pages, books, and movies; where the web pages themselves or associated content like descriptions and user reviews are available. As such, several approaches have treated this problem as an information retrieval (IR) task, where the content associated with the user's preferences is treated as a query, and the unrated documents are scored with relevance/similarity to this query (Balabanovic and Shoham 1997). In NewsWeeder (Lang 1995), documents in each rating category are converted into *tf-idf* word vectors, and then averaged to get a prototype vector of each category for a user. To classify a new document, it is compared with each prototype vector and given a predicted rating based on the cosine similarity to each category.

An alternative to IR approaches, is to treat recommending as a classification task, where each example represents the content of an item, and a user's past ratings are used as labels for these examples. In the domain of book recommending, Mooney and Roy (2000) use text from fields such as the title, author, synopses, reviews, and subject terms, to train a multinomial naive Bayes classifier. Ratings on a scale of 1 to k can be directly mapped to k classes (Melville et al. 2002), or alternatively, the numeric rating can be used to weight the training example in a probabilistic binary classification setting (Mooney and Roy 2000). Other classification algorithms have also been used for purely content-based recommending, including k-nearest neighbor, ▶ decision trees, and ▶ neural networks (Pazzani and Billsus 1997).

Hybrid Approaches

In order to leverage the strengths of content-based and collaborative recommenders, there have been several hybrid approaches proposed that combine the two. One simple approach is to allow both content-based and collaborative filtering methods to produce separate ranked lists of recommendations, and then merge their results to produce a final list (Cotter and Smyth 2000). Claypool et al. (1999) combine the two predictions using an adaptive weighted average, where the weight of the collaborative component increases as the number of users accessing an item increases.

Melville et al. (2002) proposed a general framework for *content-boosted collaborative filtering*, where content-based predictions are applied to convert a sparse user ratings matrix into a full ratings matrix, and then a CF method is used to provide recommendations. In particular, they use a Naïve Bayes classifier trained on documents describing the rated items of each user, and replace the unrated items by predictions from this classifier. They use the resulting *pseudo ratings matrix* to find neighbors similar to the active user, and produce predictions using Pearson correlation, appropriately weighted to account for the overlap of actually rated items, and for the active user's content predictions. This approach has been shown to perform better than pure collaborative filtering, pure content-based systems, and a linear combination of the two. Within this content-boosted CF framework, Su et al. (2007) demonstrated improved results using a stronger content-predictor, TAN-ELR, and unweighted Pearson collaborative filtering.

Several other hybrid approaches are based on traditional collaborative filtering, but also maintain a content-based profile for each user. These content-based profiles, rather than co-rated items, are used to find similar users. In Pazzani's approach (Pazzani 1999), each user-profile is represented by a vector of weighted words derived from positive training examples using the Winnow algorithm. Predictions are made by applying CF directly to the matrix of user-profiles (as opposed to the user-ratings matrix). An alternative approach, Fab (Balabanovic and Shoham 1997), uses ▶ relevance feedback to simultaneously mold a personal filter along with a communal "topic" filter. Documents are initially ranked by the topic filter and then sent to a user's personal filter. The user's relevance feedback is used to modify both the personal filter and the originating topic filter. Good et al. (1999) use collaborative filtering along with a number of personalized information filtering agents. Predictions for a user are made by applying CF on the set of other users and the active user's personalized agents.

Several hybrid approaches treat recommending as a classification task, and incorporate collaborative elements in this task. Basu et al. (1998) use *Ripper*, a ▶ rule induction system, to learn a function that takes a user and movie and predicts whether the movie will be liked or disliked. They combine collaborative and content information, by creating features such as *comedies liked by user* and *users who liked movies of genre X*. In other work, Soboroff and Nicholas (1999) multiply a *term-document matrix* representing all item content with the user-ratings matrix to produce a *content-profile matrix*. Using latent semantic Indexing, a rank-k approximation of the content-profile matrix is computed. Term vectors of the user's relevant documents are averaged to produce a user's profile. Then, new documents are ranked against each user's profile in the LSI space. Some hybrid approaches attempt to directly combine content and collaborative data under a single probabilistic framework. Popescul et al. (2001) extended Hofmann's *aspect model* (Hofmann 1999) to incorporate a three-way co-occurrence data among users, items, and item content. Their generative model assumes that users select latent topics, and documents and their content words are generated from these topics. Schein et al. (2002) extend this approach, and focus on making recommendations for items that have not been rated by any user.

Evaluation Metrics

The quality of a recommender system can be evaluated by comparing recommendations to a test set of known user ratings. These systems are typical measured using *predictive accuracy metrics* (Herlocker et al. 2004), where the predicted ratings are directly compared to actual user ratings. The most commonly used metric in the literature is ▶ Mean Absolute Error (MAE) – defined as the average absolute difference between predicted ratings and actual ratings, given by:

$$\text{MAE} = \frac{\sum_{\{u,i\}} |P_{u,i} - r_{u,i}|}{N} \tag{7}$$

Where $p_{u,i}$ is the predicted rating for user u on item i, $r_{u,i}$ is the actual rating, and N is the total number of ratings in the test set.

A related commonly used metric, Root Mean Squared Error (RMSE), puts more emphasis on larger absolute errors, and is given by:

$$\text{RMSE} = \sqrt{\frac{\sum_{\{u,i\}} (p_{u,i} - r_{u,i})^2}{N}} \tag{8}$$

Predictive accuracy metrics treat all items equally. However, for most recommender systems the primary concern is accurately predict the items a user will like. As such, researchers often view recommending as predicting *good*, that is, items with high ratings versus *bad* or poorly rated items. In the context of information retrieval (IR), identifying the good from the background of bad items can be viewed as discriminating between "relevant" and "irrelevant" items; and as such, standard IR measures, like ▶ Precision, ▶ Recall and ▶ Area Under the ROC Curve (AUC) can be utilized. These, and several other measures, such as *F1-measure*, *Pearson's product-moment correlation*, *Kendall's* τ, *mean average precision*, *half-life utility*, and *normalized distance-based performance measure* are discussed in more detail by Herlocker et al. (2004).

Challenges and Limitations

This section, presents some of the common hurdles in deploying recommender systems, as well as some research directions that address them.

Sparsity: Stated simply, most users do not rate most items and, hence, the user ratings matrix is typically very sparse. This is a problem for collaborative filtering systems, since it decreases the probability of finding a set of users with similar ratings. This problem often occurs when a system has a very high item-to-user ratio, or the system is in the initial stages of use. This issue can be mitigated by using additional domain information (Melville et al. 2002; Su et al. 2007) or making assumptions about the data generation process that allows for high-quality imputation (Su et al. 2008).

The Cold-Start Problem: New items and new users pose a significant challenge to recommender systems. Collectively these problems are referred to as the *cold-start problem* (Schein et al. 2002). The first of these problems arises in collaborative filtering systems, where an item cannot be recommended unless some user has rated it before. This issue applies not only to new items, but also to obscure items, which is particularly detrimental to users with eclectic tastes. As such the *new-item problem* is also often referred to as the *first-rater problem.* Since content-based approaches (Mooney and Roy 2000; Pazzani and Billsus 1997) do not rely on ratings from other users, they can be used to produce recommendations for *all* items, provided attributes of the items are available. In fact, the content-based predictions of similar users can also be used to further improve predictions for the active user (Melville et al. 2002).

The *new-user problem* is difficult to tackle, since without previous preferences of a user it is not possible to find similar users or to build a content-based profile. As such, research in this area has primarily focused on effectively selecting items to be rated by a user so as to rapidly improve recommendation performance with the least user feedback. In this setting, classical techniques from ▶ active learning can be leveraged to address the task of item selection (Harpale and Yang 2008; Jin and Si 2004).

Fraud: As recommender systems are being increasingly adopted by commercial websites, they have started to play a significant role in affecting the profitability of sellers. This has led to many unscrupulous vendors engaging in different forms of fraud to game recommender systems for their benefit. Typically, they attempt to inflate the perceived desirability of their own products (*push attacks*) or lower the ratings of their competitors (*nuke attacks*). These types of attack have been broadly studied as *shilling attacks* (Lam and Riedl 2004) or *profile injection attacks* (Burke et al. 2005). Such attacks usually involve setting up dummy profiles, and assume different amounts of knowledge about the system. For instance, the *average attack* (Lam and Riedl 2004) assumes knowledge of the average rating for each item; and the attacker assigns values randomly distributed around this average, along with a high rating for the item being *pushed.* Studies have shown that such attacks can be quite detrimental to predicted ratings, though *item-based* collaborative filtering tends to be more robust to these attacks (Lam and Riedl 2004). Obviously, content-based methods, which only rely on a users past ratings, are unaffected by profile injection attacks.

While pure content-based methods avoid some of the pitfalls discussed above, collaborative filtering still has some key advantages over them. Firstly, CF can perform in domains where there is not much content associated with items, or where the content is difficult for a computer to analyze, such as ideas, opinions, etc. Secondly, a CF system has the ability to provide serendipitous recommendations, that is, it can recommend items that are relevant to the user, but do not contain content from the user's profile.

Record Linkage

Abstract

Many data mining and machine learning projects require information from various data sources to be integrated and linked before they can be used for further analysis. A crucial task of such data integration is to identify which records refer to the same real-world entities across databases when no common entity identifiers are available and when records can contain errors and variations. This process of record linkage therefore has to rely upon the attributes that are available in the databases to be linked. For databases that contain personal information, for example, of customers, taxpayers, or patients, these are commonly their names, addresses, phone numbers, and dates of birth.

To improve the scalability of the linkage process, blocking or indexing techniques are commonly applied to limit the comparison of records to pairs or groups that likely correspond to the same entity. Records are compared using a variety of comparison functions, most commonly approximate string comparators that account for typographical errors and variations in textual attributes.

The compared records are then classified into matches, non-matches, and potential matches, depending upon the decision model used. If training data in the form of true matches and non-matches are available, supervised classification techniques can be employed. However, in many practical record linkage applications, no ground truth data are available, and therefore unsupervised approaches are required. An approach known as probabilistic record linkage is commonly employed. In this article we provide an overview of record linkage with an emphasis on the classification aspects of this process.

Synonyms

Authority control; Citation or reference matching (when applied to bibliographic data); Co-reference resolution; Data linkage; Data matching; Data reconciliation; Deduplication or duplicate detection (when applied to one database only); Entity resolution; Field scrubbing; Identity uncertainty; List washing; Merge-purge; Object identification; Object matching; Reference reconciliation

Definition

Identifying and linking records that correspond to the same real-world entity in one or more databases is an increasingly important task in many data mining and machine learning projects. The aim of record linkage is to compare records within one (known as *deduplication*) or across two databases and classify the compared pairs of records as *matches* (pairs where both records are assumed to refer to the same real-world entity) and *non-matches* (pairs where the two records are assumed to refer to different entities).

Formally, let us consider two databases (or files), $\mathbf{A}$ and $\mathbf{B}$, and record pairs in the product space $\mathbf{A} \times \mathbf{B}$ (for the deduplication of a single database $\mathbf{A}$, the product space is $\mathbf{A} \times \mathbf{A}$). The aim of record linkage is to classify these record pairs into the classes of *matches* (links) and *non-matches* (non-links) (Christen 2012). Depending upon the decision model used (Fellegi and Sunter 1969; Herzog et al. 2007), a third class of *potential matches* (potential links) might be used. These are difficult to classify record pairs that will need to be manually assessed and classified as matches or non-matches in a manual clerical review process.

Each record pair in $\mathbf{A} \times \mathbf{B}$ is assumed to correspond to either a *true match* or a *true non-match*. The space $\mathbf{A} \times \mathbf{B}$ is therefore partitioned into the set M of true matches and the set U of true non-matches. The objective of record linkage is to correctly classify record pairs from M into the class of matches and pairs from U into the class of non-matches.

Motivation and Background

Increasingly, information systems and data mining projects require data from multiple sources to be integrated and linked in order to improve data quality, enrich existing data sources, or facilitate data analysis that is not feasible on an individual database. Compared to analyzing databases in isolation, the analysis of data linked across disparate sources, either within a single or between different organizations, can lead to much improved benefits. Integrated data can also allow types of analyses that are not feasible on individual databases, for example, the detection of fraud or terrorism suspects through the analysis of certain suspicious patterns of activities or the identification of adverse drug reactions in particular patient groups (Christen 2012). Record linkage has been employed in a wide range of domains as we discuss in section "Applications" below.

In most cases the databases to be linked (or deduplicated) do not contain unique entity identifiers or keys. Therefore, attributes (fields) that are common across the databases need to be used to identify similar records that likely correspond to the same entity. If the databases contain information about people, then these common attributes can be names, addresses, dates of birth, and other partially identifying personal details.

However, often the quality of such information is low, as personal details can be entered or recorded wrongly, be incomplete, or be out of date. Record linkage based on "dirty data" is challenging as ambiguities, errors, variations, and value changes can lead to both false matches (record pairs wrongly classified as referring to the same entity) and false non-matches (missed true matching pairs of records classified as non-matches).

The term record linkage was used in 1946 by Halbert Dunn to describe the idea of assembling a *book of life* for all individuals in the world (Dunn 1946). Each such book would begin with a birth record and end with a death record and in between would contain marriage and divorce records, as well as records about a person's contacts with the health and social security systems. Dunn realized that having such books of life for a full population would provide a wealth of information that would allow governments to improve national statistics, better plan services, and also help to identify individuals.

The first computer-based linkage techniques were proposed in the 1950s and early 1960s by Howard Newcombe et al. (1959), who also developed the basic ideas of the successful *probabilistic record linkage* approach described in the following section. Based on Newcombe's ideas, Fellegi and Sunter in 1969 published their seminal paper on a theory for probabilistic record linkage (Fellegi and Sunter 1969). They proved that an optimal probabilistic decision rule can be found under the assumption of independence of the attributes used in the comparison of records. This influential work has been the basis for many record linkage systems and software products, and it is still widely used today.

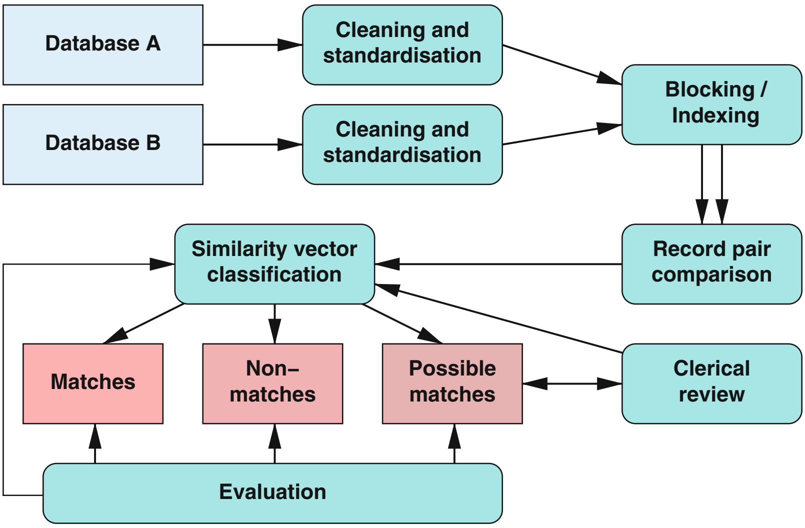
Theory/Solution

We now describe the steps involved in the record linkage process, followed by a more detailed discussion of techniques used to classify record pairs into matches and non-matches. Note that for the deduplication of a single database, all steps of the record linkage process are still applicable.

The Record Linkage Process

Figure 1 provides an overview of the steps involved in the general record linkage process. We assume two databases that contain details about the same types of entities (such as people, businesses, scientific publications, and so on). The first step of *data cleaning and standardization* is important to convert the input data into the same format so they are more suitable for comparison. This step involves, for example, converting all letters into lower or upper case, removing

Record Linkage, Fig. 1 The general process of linking two databases (As adapted from Christen 2012)



certain punctuations and words, and splitting attributes into specific fields (such as title, first name, middle name, and last name for personal names).

The second step of *blocking* or *indexing* is aimed at reducing the number of record pairs that need to be compared from the full pairwise comparison space of $|\mathbf{A}| \times |\mathbf{B}|$, where $|\cdot|$ is the number of records in a database. The idea is to only compare records in detail that likely refer to matches. This is accomplished by splitting the databases into blocks according to some criteria and then only comparing records in the same block across the two databases. An example criteria can, for example, be a post- or zip code attribute, resulting in only records being compared that have the same post- or zip code value. Various such blocking or indexing techniques have been developed in the past few decades (Christen 2012).

In the *comparison* step, candidate record pairs generated in the blocking/indexing step are then compared in detail using a variety of attribute and record comparison functions. As many attributes used in record linkage to compare records contain textual values (like names and addresses), approximate string comparison functions such as Jaro-Winkler or edit distance are commonly used (Christen 2012). Specific comparison functions have also been developed for values such as ages, dates, or phone numbers (Christen 2012). Generally all these comparison functions return a numerical similarity, s, that is normalized in $0 \leq s \leq 1$, with $s = 1$ if two attribute values are the same (like "geoff" and "geoff"), $s = 0$ if they are completely different (like "claude" and "geoff"), and $0 < s < 1$ if they are somehow similar (like "geoff" and "jeff"). For each compared record pair, a similarity vector (also known as weight vector) is formed that contains the similarities of all compared attributes of that pair.

In the *classification* step (as we discuss in more details below), each compared candidate record pair is classified into one of the classes of matches, non-matches, and possibly also potential matches, depending upon the decision model used (Fellegi and Sunter 1969; Herzog et al. 2007). Various classification techniques (both supervised and unsupervised) have been developed in the past nearly five decades.

If candidate record pairs have been classified into potential matches, a manual *clerical review* process is required to decide their final match status (match or non-match). These manual classifications can flow back into the classification model when an active learning approach is employed. Several active learning approaches have been developed for record linkage (Christen 2012).

In the final *evaluation* step, the complexity, completeness, and quality of the linked records are evaluated using a variety of measures (Christen 2012). The complexity of a linkage can be measured by the number of candidate record pairs generated by an indexing or blocking technique. Measuring completeness and linkage quality requires truth data in the form of known true matching and non-matching record pairs. Linkage quality is generally measured using precision and recall, while completeness is similar to recall but measures how many of all known true matches are included in the set of candidate record pairs (i.e., how many true matches are not removed in the indexing/blocking step).

Record Linkage Model of Fellegi and Sunter

Fellegi and Sunter (1969) provided a formal mathematical model for ideas that had been introduced by Newcombe et al. (1959). Fellegi and Sunter (1969) also provided ways of estimating key parameters without training data. Generally, training data have not been available for most record linkage applications.

Following the notation used in section "Definition" above, Fellegi and Sunter, making rigorous concepts introduced by Newcombe et al. (1959), considered ratios of probabilities of the form:

$$R = \frac{P(\gamma \in \Gamma|M)}{P(\gamma \in \Gamma|U)}, \tag{1}$$

where γ is an arbitrary agreement pattern in a comparison space Γ. For instance, Γ might consist of eight patterns representing simple agreement or not on the largest name component, street name, and street number (Herzog et al. 2007). Alternatively, each $\gamma \in \Gamma$ might additionally account for the relative frequency with which specific values of name components such as "Smith", "Zabrinsky", "AAA", and "Capitol" occur. The ratio R or any monotonically increasing function of it (such as the natural log) is referred to as a *matching weight* (or score). The decision rule is given by:

$$\begin{aligned} &\text{If } R \geq T_\mu, && \text{then designate pair as a match.} \\ &\text{If } T_\lambda < R < T_\mu, && \text{then designate pair as a possible match} \\ & && \text{and hold for clerical review.} \\ &\text{If } R \leq T_\lambda, && \text{then designate pair as a non-match.} \end{aligned} \tag{2}$$

The cutoff thresholds T_λ and T_μ are determined by a priori error bounds on false matches and false non-matches. The thresholds are often called lower and upper cutoffs. Rule (2) agrees with intuition. If $\gamma \in \Gamma$ consists primarily of agreements, then it is intuitive that $\gamma \in \Gamma$ would be more likely to occur among matches than non-matches, and the ratio (1) would be large. On the other hand, if $\gamma \in \Gamma$ consists primarily of disagreements, then the ratio (1) would be small. Rule (2) partitions the set $\gamma \in \Gamma$ into three disjoint subregions. The region $\{T_\lambda < R < T_\mu\}$ is referred to as the no-decision region or clerical review region (Herzog et al. 2007). In some situations, resources are available to review pairs clerically.

Figure 2 provides an illustration of the curves of log frequency versus log weight for matches and non-matches, respectively. The data used in Fig. 2 are based on information obtained while matching name and address files from one of the sites for the 1988 US Dress Rehearsal Census. The clerical review region consists of individuals within the same household that are missing both name and age. Figure 2 shows hypothetical cutoff thresholds that we denote with the symbols L (lower) and U (upper) in this figure, respectively.

Learning Parameters via the Methods of Fellegi and Sunter

Fellegi and Sunter (1969) were the first to provide very general methods for computing the probabilities in the ratio (1). As the methods are useful, we describe what they introduced and then show how the ideas led into more general methods that can be used for unsupervised learning (i.e., without training data) in a large number of situations.

Fellegi and Sunter observed several things. Firstly,

$$P(S) = P(S|M)P(M) + P(S|U)P(U) \tag{3}$$

for any set S of pairs in $\mathbf{A} \times \mathbf{B}$. The probability on the left can be computed directly from the set of pairs. In Equation (3), M and U are restricted to S. Secondly, if sets A^x represent simple agreement/disagreement, under the conditional independence assumption (**CI**) (i.e., naive Bayes), we obtain

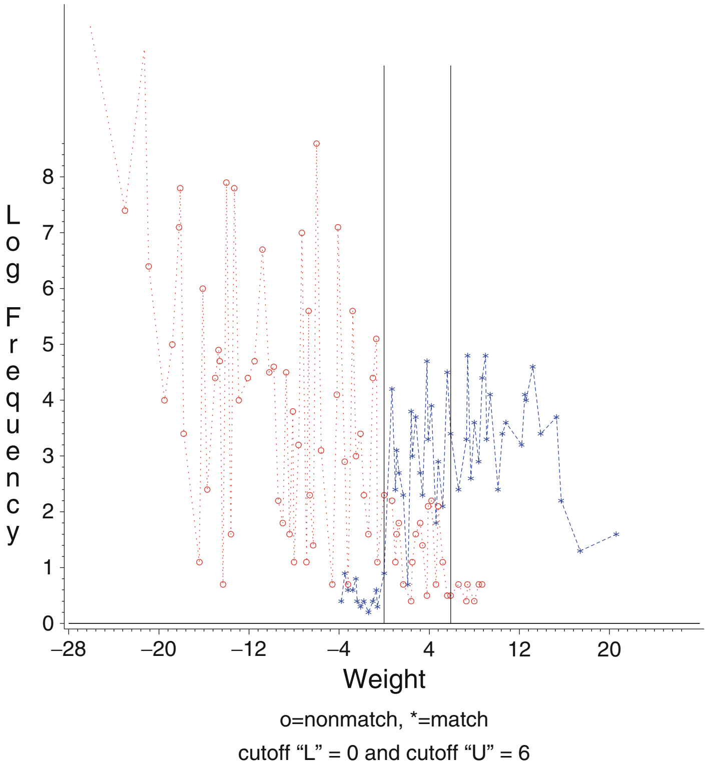
$$\begin{aligned} &P(A_1^x \cap A_2^x \cap A_3^x|D) \\ &\quad = P(A_1^x|D)P(A_2^x|D)P(A_3^x|D). \end{aligned} \tag{4}$$

Here D is either M or U. Then (3) and (4) provide seven equations and seven unknowns (as x represents agree or disagree) that yield quadratic equations that they solved. Equation (or set of equations) (4) can be expanded to K fields.

The expectation-maximization (EM) algorithm (Dempster et al. 1977) can be used to estimate the probabilities in Eqs. (3) and (4) when there are more than K fields or when condition (**CI**) may not hold.

For the 1990 US Decennial Census, Winkler (1988) introduced an EM algorithm that found the best naive Bayes approximation of a general Bayes net model where interactions between fields were accounted for. This type of EM was necessary because "optimal" parameters were used for each of the ~500 regions into which the

Record Linkage, Fig. 2 Log frequency versus weight, matches and non-matches combined



USA was divided, the entire matching operations needed to be completed in less than 6 weeks to provide estimates required under the US law, and it was impossible to obtain training data.

Herzog et al. (2010) provide many of the details of the EM procedures used in the 1990 US Decennial Census production matching systems that we do not cover here. We provide two highlights that were in Herzog et al. (2010). Firstly, the EM algorithm in this particular application was able to adapt automatically to increasing missing data. During 1 week in one of seven processing offices, it was discovered that the clerical review region increased significantly. Upon follow-up, it was determined that two clerks had managed to bypass keypunch edits on the year-of-birth field, and all records keyed by them disagreed on the computed age. Age and first name were the only fields that would allow distinguishing true matches within households.

Secondly, the probabilities from the unsupervised learning yielded better matching results than results from an iterative refinement procedure (a type of *active learning*) that was in widespread use for matching. In the iterative refinement procedure, a subset of clerical pairs were followed up to determine matches and nonmatches, the matching probabilities were reestimated, an additional set of clerical pairs were followed up, and parameters were reestimated, with the entire interactive learning procedure being repeated on the order of five cycles until the matching probabilities stabilized.

Superficially, the EM algorithm (Winkler 1988) considers different orderings of the form

$$P(A^x_{\rho,1} \cap \cdots \cap A^x_{\rho,k} | D) \\ = \Pi^K_{i=1} P(A^x_{\rho,i} | A^x_{\rho,i-1}, \cdots, A^x_{\rho,1}, D), \quad (5)$$

where ρ, i represents the ith entry in a permutation ρ of the integers 1 thru K. The greater generality of (5) in comparison to (4) can yield better fits to the data. It can be reasonably assumed that the EM algorithm under the conditional independence assumption (as the actual computational methods work) simultaneously chooses the best permutation and the best parameters.

Because training data are seldom available and can be exceptionally expensive to obtain, some authors (Larsen and Rubin 2001) recommend *semi-supervised learning* where a small amount of judiciously chosen training data are combined with a large amount of unlabeled data for which true matching status is unknown. The semi-supervised methods generally outperform the unsupervised methods.

Some commercial record linkage software uses *rule-based* methods, which employ strategies such as if these three fields are the same in a pair of records, call the pair a designated match, designated link, or possible same entity. Ferrante and Boyd (2012), in a large comparison, showed that one rule-based commercial package was outperformed by one commercial package and several shareware packages that each applied variants of the Fellegi-Sunter model.

Applications

Record linkage has been used in a wide range of domains (Christen 2012; Herzog et al. 2007). In the following we briefly describe some example applications:

- **Linking personal data**: Traditionally the most common use of record linkage is to identify and link records about the same person across two databases. Examples of such linkages occur in national censuses (linking people between two census collections), in the health domain (linking patient records between different hospital and healthcare providers or over time with the aim to compile patient-oriented longitudinal data sets for public health studies), or between government agencies to, for example, identify people who commit welfare fraud.

  In the health domain, population informatics (Kum et al. 2014), the study of populations by linking and analyzing large databases that contain detailed information about a large proportion of individuals in a population (such as their health, education, financial, census, location, shopping, employment, or social networking records), has recently attracted increasing interest.
- **Deduplication of customer databases**: A common data quality problem for many businesses is that a customer might be recorded in their databases more than once due to address or name changes and variations. Such duplicates can incur significant costs for a business, for example, when sending out advertisement mail. The task of deduplicating a single database is in principle the same as when linking two databases. Each record in the database potentially needs to be compared with all others (indexing or blocking is generally also applied to speed up the deduplication process).
- **Linking historical population data**: The quantitative social sciences are currently seeing a shift toward the use of large-scale data collections for studying a diverse range of aspects of the human society. Often these are historical data such as census, birth, death, and marriage registries that span several decades (or even centuries) and that need to be linked to reconstruct historical populations (Bloothooft et al. 2015). The major challenges when linking such data include data quality (as such data have to be transcribed from hand-written forms, a process that is error-prone and labor-intensive), the dynamics of people's characteristics over time, and the complexity of roles and relationships for each individual as they change over time.
- **Consumer product comparison shopping**: With the increasing popularity of online comparison shopping Web sites, the challenging task of identifying which descriptions of products across diverse shopping sites correspond to the same real-world product has attracted interest from various domains. Compared to personal data, such as names and addresses, different consumer products might only be distinguishable by a single digit (such as the *Canon 600D* and *Canon 650D* digital cameras). To improve linkage quality in this domain, novel similarity calculation functions and machine learning approaches

that learn the characteristic features that distinguish consumer products have been developed (Christen 2012).

- **Linking bibliographic data**: Research is increasingly being published through online databases such as *Springer Link* or the *ACM Digital Library*. These databases facilitate a much faster dissemination of knowledge, and they allow government funding agencies to calculate numerical metrics to assess the impact of researchers, research groups, and even institutions. This requires to link all records of an individual researcher with high accuracy. A major challenge with bibliographic data is that there can be several researchers with the same name details in a database, some even working in the same research domain. Even if full given names are provided, it can be unclear if two publications were written by the same individual or not. Journal and conference names are also often abbreviated and do not follow standardized formats.

Future Directions

Most research in record linkage in the past decade has concentrated on improving either the scalability of the linkage process through the development of advanced indexing or blocking techniques (Christen 2012) or linkage quality by employing sophisticated classification techniques. Most of these techniques assume the databases to be linked are static and the linkage can be done off-line and in batch mode. In the following we summarize areas of ongoing research that aim to address various practical problems in record linkage.

- **Collective classification**: Traditional record linkage techniques classify each compared record pair individually (Herzog et al. 2007). This can lead to violations of transitivity (if record A is classified as a match with record B, and record B as a match with record C, then records A and C must also be a match). With traditional approaches, transitivity is often addressed in a post-linkage process (Christen 2012).

  Recently developed graph-based and collective *entity resolution* techniques (Bhattacharya and Getoor 2007) instead aim to find an overall optimal assignment of records to entities. These techniques take both attribute similarities and relationship information into account. They generally build a graph where nodes are records and edges connect records that have a similarity above a certain minimum threshold. The task then becomes one of splitting such a graph into individual subgraphs such that each subgraph contains the records of one entity only, and each entity is represented by one subgraph.

  While such techniques have been shown to achieve high linkage quality (mainly on bibliographic data), their computational complexity (quadratic or larger in the number of records to be linked) makes the application of these techniques to large-scale record linkage problems challenging. Furthermore, how to employ such collective linkage techniques in domains where only limited relational information is available (such as for data about people) is an open question.

- **Group linkage**: Related to the previous topic is the challenge of linking groups of records instead of individual pairs. Groups can, for example, represent the people in a household or family or the coauthors of a scientific publication. Group linkage (On et al. 2007) is generally a two-step process, where in the first step, individual record pairs are linked, followed by the linkage of groups using some form of bipartite graph matching. The challenges in group linkage occur when groups do not have the same number of members, when group membership changes over time, and when groups can split or merge, such as does happen in families and households.
- **Linking temporal data**: Most personal details of people change over time, such as their addresses, names, employments, and relationships. If records with such details have time stamps attached (such as the dates when the information was recorded), then considering such temporal information might help improve linkage quality (Li et al. 2011). For ex-

ample, if it is known that a certain proportion of people in a population move their address between two census collections 5 years apart, then less weight should be assigned to address similarities when the overall similarities between records are calculated. Some initial work has investigated how such adjustment of similarity weights can help improve overall linkage quality for bibliographic data (assuming authors change their institutions); however more research is needed to investigate if and how such techniques can be employed when, for example, linking census or health data.

- **Statistical analysis across multiple files**: Economists and demographers want to analyze $(\mathbf{X}, \mathbf{Y})$ – data where multivariate $\mathbf{X}$ is taken from one file **A** and multivariate $\mathbf{Y}$ is taken from another file **B**. The common data for linking the files are typically nonunique identifiers such as name, address, and date of birth. Lahiri and Larsen (2005) provide such a model that can adjust certain statistical analyses such as regression under modest assumptions for linkage error. Others have considered $(\mathbf{X}, \mathbf{Y})$ – data where $\mathbf{X}$ and $\mathbf{Y}$ are each composed of discrete or continuous data but under very strong assumptions.
- **Real-time linkage**: As services in the public and private sectors move online, organizations increasingly require real-time linkage in applications such as online identity verification based on personal details or web and document search where duplicates in the set of retrieved records or documents need to be identified. Compared to the batch linkage of two databases, real-time linkage considers a stream of query records that need to be linked in sub-second time with a potentially large database that contains entity records. Often these databases are also dynamic, where new records are added and existing records are modified.

  Novel indexing techniques are required that allow the efficient and effective retrieval of candidate records that are likely to be matching with a query record (Ramadan et al. 2015), as well as fast classification and ranking techniques that are adaptive to changes in the underlying entity database.
- **Privacy-preserving record linkage**: In many application domains, record linkage relies on personal details, such as names and addresses, to conduct the linkage. Privacy and confidentiality issues can be of great concern, especially when databases are linked between organizations. Many countries have privacy legislation that limits the sharing and use of personal information. Linking records, for example, between a private hospital and a government health department might therefore be limited or even prohibited.

  The past decade has seen the emergence of research that aims to develop techniques that allow the linking of databases across organizations while ensuring that no sensitive private or confidential information is being revealed (Vatsalan et al. 2013). Using encoding techniques such as one-way hashing and Bloom filters, and cryptographic approaches such as secure multiparty computation, privacy-preserving record linkage techniques encode records at the data sources in such ways that similarity calculations and approximate matching of string values are feasible, while still allowing the linkage of large databases in efficient and effective ways.

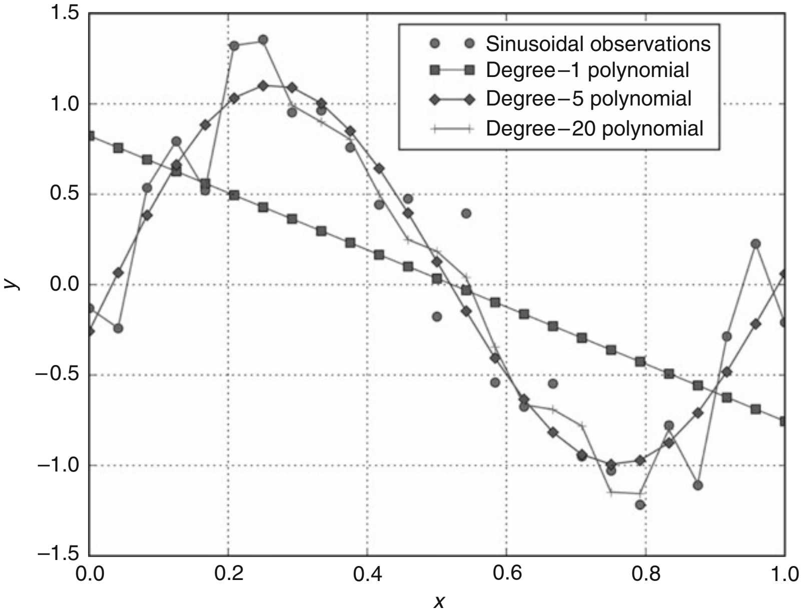
Definition

Regression is a fundamental problem in statistics and machine learning. In regression studies, we are typically interested in inferring a real-valued function (called a regression function) whose values correspond to the mean of a dependent (or response or output) variable conditioned on one or more independent (or input) variables. Many different techniques for estimating this regression function have been developed, including parametric, semi-parametric, and nonparametric methods.



Regression, Fig. 1 Twentyfive data points (one-dimensional input x and output y variables) with a Gaussian-corrupted sinusoidal input–output relationship, $y = \sin(2\pi x) + \epsilon$ where ϵ is the normally distributed noise. The task is to learn the functional relationship between x and y. Various lines show the inferred relationship based on a linear regression model with polynomial basis functions having various degrees

Motivation and Background

Assume that we are given a set of data points sampled from an underlying but unknown distribution, each of which includes input x and output y. An example is given in Fig. 1. The task of regression is to learn a hidden functional relationship between x and y from observed and possibly noisy data points. In Fig. 1, the input–output relationship is a Gaussian-corrupted sinusoidal relationship, that is, $y = \sin(2\pi x) + \epsilon$ where ϵ is the normally distributed noise. Various lines show the inferred relationship based on a linear parametric regression model with polynomial basis functions. The higher the degree of the polynomial, the more complex is the inferred relationship, as shown in Fig. 1, as the function tries to better fit the observed data points.

While the most complex polynomial here is an almost perfect reconstruction of observed data points (it has "low bias"), it gives a very poor representation of the true underlying function $\sin(2\pi x)$ that can change significantly with the change of a few data points (it has "high variance"). This phenomenon is called the ▶ *bias-variance dilemma*, and selecting a complex model with too high a variance is called ▶ *overfitting*. Complex parametric models (like polynomial regression) lead to low bias estimators with a high variance, while simple models lead to low variance estimators with high bias. To sidestep the problem of trying to estimate or select the model complexity represented, for instance, by the degree of the polynomial, so-called nonparametric methods allow a rich variety of functions from the outset (i.e., a function class not finitely parameterizable) and usually provide a hyperparameter that tunes the regularity, curvature, or complexity of the function.

Theory/Solution

Formally, in a regression problem, we are interested in recovering a functional dependency $y_i = f(x_i) + \epsilon_i$ from N-observed training data points $\{(x_i, y_i)\}_{i=1}^N$, where $y_i \in \mathbb{R}$ is the noisy observed output at input location $x_i \in \mathbb{R}^d$. For ▶ linear regression, we represent the regression function $f()$ by a parameter $w \in \mathbb{R}^H$ in the form $f(x_i) := \langle \phi(x_i), w \rangle$ for H fixed basis functions $\{\phi_h(x_i)\}_{h=1}^H$. With general basis functions such as polynomials, exponentials, sigmoids, or even more sophisticated Fourier or wavelets bases, we can obtain a regression function which is nonlinear with regard to the input variables although still linear with regard to the parameters.

In regression, many more methods are possible. Some variations on these standard linear models are piecewise linear models, trees, and splines (roughly, piecewise polynomial models joined up smoothly) (Hastie et al. 2003). These are called semi-parametric models, because they have a linear parametric component as well as a nonparametric component.

Fitting

In general, regression fits a model to data using an objective function or quality criterion in a form such as

$$E(f) = \sum_{i=1}^{N} \epsilon(y_i, f(x_i)) \,,$$

where smaller $E(f)$ implies better quality. This might be derived as an error/loss function or as a negative log likelihood or log probability. The squared error function is the most convenient (leading to a least squares calculation), but many possibilities exist. In general, methods are distinguished by three aspects: (1) the representation of the function $f()$, (2) the form of the term $\epsilon(y_i, f(x_i))$, and (3) the penalty term discussed next.

Regularized/Penalized Fitting

The issue of overfitting, as mentioned already in the section Motivation and Background, is usually addressed by introducing a regularization or penalty term to the objective function. The regularized objective function is now in the form of:

$$E_{\text{reg}} = E(f) + \lambda R(f). \tag{1}$$

Here, $E(f)$ measures the quality of the solution for $f()$ on the observed data points, $R(f)$ penalizes complexity of $f()$, and λ is called the regularization parameter which controls the relative importance between the two. Measures of function curvature, for instance, can be used for $R(f)$. In standard ▶ support vector machines, the term $E(f)$ measures the hinge loss, and penalty $R(f)$ is the sum of squares of the parameters, also used in ridge regression (Hastie et al. 2003).

Bias-Variance Dilemma

As we have seen in the previous section, the introduction of the regularization term can help avoid overfitting. However, this raises the question of determining an optimal value for the regularization parameter λ. The specific choice of λ controls the bias-variance tradeoff (Geman et al. 1992).

Recall that we try to infer a latent regression function $f(x)$ based on N-observed training data points $\mathcal{D} = \{(x_i, y_i)\}_{i=1}^N$. The notation $f(x; \mathcal{D})$ explicitly shows the dependence of f on the data $\mathcal{D}$. The mean squared error (MSE) which measures the effectiveness of f as a predictor of y is

$$\begin{aligned}&\mathbf{E}[(y - f(x;\mathcal{D}))^2 | x, \mathcal{D}]\\ &= \mathbf{E}[(y - \mathbf{E}[y|x])^2 | x, \mathcal{D}] + (f(x;\mathcal{D}) - \mathbf{E}[y|x])^2\end{aligned} \tag{2}$$

where $\mathbf{E}[.]$ means expectation with respect to a conditional distribution $p(y|x)$. The first term of (2) does not depend on $f(x; \mathcal{D})$, and it represents the intrinsic noise on the data. The MSE of f as an estimator of the regression $\mathbf{E}[y|x]$ is

$$\mathbf{E}_{\mathcal{D}}[(f(x;\mathcal{D}) - \mathbf{E}[y|x])^2] \tag{3}$$

where $\mathbf{E}_{\mathcal{D}}$ means expectation with respect to the training set $\mathcal{D}$. The estimation error in (3) can be decomposed into a bias and a variance terms, that is,

$$
\begin{aligned}
\mathbf{E}_{\mathcal{D}}[(f(x;\mathcal{D})-\mathbf{E}[y|x])^2] &= \mathbf{E}_{\mathcal{D}}[(f(x;\mathcal{D})\\
&\quad -\mathbf{E}_{\mathcal{D}}[f(x;\mathcal{D})]+\mathbf{E}_{\mathcal{D}}[f(x;\mathcal{D})]-\mathbf{E}[y|x])^2]\\
&= \mathbf{E}_{\mathcal{D}}[(f(x;\mathcal{D})-\mathbf{E}_{\mathcal{D}}[f(x;\mathcal{D})])^2]\\
&\quad +(\mathbf{E}_{\mathcal{D}}[f(x;\mathcal{D})]-\mathbf{E}[y|x])^2+2\mathbf{E}_{\mathcal{D}}[(f(x;\mathcal{D})\\
&\quad -\mathbf{E}_{\mathcal{D}}[f(x;\mathcal{D})])](\mathbf{E}_{\mathcal{D}}[f(x;\mathcal{D})]-\mathbf{E}[y|x])\\
&= \mathbf{E}_{\mathcal{D}}[(f(x;\mathcal{D})-\mathbf{E}_{\mathcal{D}}[f(x;\mathcal{D})])^2]\\
&\quad +(\mathbf{E}_{\mathcal{D}}[f(x;\mathcal{D})]-\mathbf{E}[y|x])^2\\
&= \text{variance}+\text{bias}^2.
\end{aligned}
$$

The bias term measures the difference between the average predictor over all datasets and the desired regression function. The variance term measures the adaptability of the predictor to a particular dataset. There is a tradeoff between the bias and variance contributions to the estimation error, with very flexible models having low bias but high variance (overfitting) and relatively rigid models having low variance but high bias (underfitting). Typically, variance is reduced through "smoothing," that is, an introduction of the regularization term. This, however, will introduce bias as peaks and valleys of the regression function will be blurred. To achieve an optimal predictive capability, an estimator with the best balance between bias and variance is chosen by varying the regularization parameter λ. It is crucial to note that bias-variance decomposition albeit powerful is based on averages of datasets; however, in practice only a single dataset is observed. In this regard, a Bayesian treatment of regression, such as Gaussian process regression which will avoid overfitting problem of maximum likelihood and which will also lead to automatic methods of determining model complexity using the training data alone, could be an attractive alternative.

Nonparametric Regression

In the parametric approach, an assumption on the mathematical form of the functional relationship between input x and output y such as linear, polynomial, exponential, or combination of them needs to be chosen a priori. Subsequently, parameters are placed on each of the chosen forms and the optimal values learned from the observed data. This is restrictive both in the fixed functional form and in the ability to vary the model complexity. Nonparametric approaches try to derive the functional relationship directly from the data, that is, they do not parameterize the regression function.

▶ Gaussian Processes for regression, for instance, are well developed. Another approach is the *kernel method*, of which a rich variety exists (Hastie et al. 2003). These can be viewed as a regression variant of nearest neighbor classification where the function is made up of a local element for each data point:

$$f(x) = \frac{\sum_i y_i K_\lambda(x_i,x)}{\sum_i K_\lambda(x_i,x)},$$

where the function $K_\lambda(x_i,)$ is a nonnegative "bump" in x space centered at its first argument with diameter approximately given by λ. Thus, the function has a variable contribution from each data point and λ controls the bias-variance tradeoff.

Generalized Linear Models

The previous discussion about regression focuses on continuous output/dependent variables. While this type of regression problem is ubiquitous, there are however some interests in cases of *restricted* output variables:

1. The output variable consists of two categories (called *binomial* regression).
2. The output variable consists of more than two categories (called *multinomial* regression).
3. The output variable consists of more than two categories which can be ordered in a meaningful way (called *ordinal* regression). and
4. The output variable is a count of the repetition of the occurrence of an event (called *poisson* regression).

Nelder and Wedderburn (1972) introduced the generalized linear model (GLM) by allowing the linear model to be related to the output variables via a link function. This is a way to unify different cases of response variables under one

Regression, Table 1 A table of various link functions associated with the assumed distribution on the output variable

Distribution of dependent variable	Name	Link function
Gaussian	Identity link	$g(\mu) = \mu$
Poisson	Log link	$g(\mu) = \log(\mu)$
Binomial multinomial	Logit link	$g(\mu) = \log\left(\frac{\mu}{1-\mu}\right)$
Exponential gamma	Inverse link	$g(\mu) = \mu^{-1}$
Inverse Gaussian	Inverse squared link	$g(\mu) = \mu^{-2}$

framework, each only differs in the choice of the link function. Specifically, in GLM, each output variable is assumed to be generated from the exponential family of distributions. The mean of this distribution depends on the input variables through

$$\mathbf{E}[y] = g(\mu) = w_0 + w_1\phi_1(x_i) + \ldots + w_D\phi_D(x_i), \tag{4}$$

where $g(\mu)$ is the link function (Table 1). The parameters of the generalized linear model can then be estimated by the maximum likelihood method, which can be found by iterative reweighted least squares (IRLS), an instance of the expectation maximization (EM) algorithm.

Other Variants of Regression

So far, we have focused on the problem of predicting a single output variable y from an input variable x. Some studies look at predicting multiple output variables simultaneously. The simplest approach for the *multiple outputs* problem would be to model each output variable with a different set of basis functions. The more common approach uses the same set of basis functions to model all of the output variables. Not surprisingly, the solution to the multiple outputs problem decouples into independent regression problems with shared basis functions.

For some other studies, the focus of regression is on computing several regression functions corresponding to various percentage points or quantiles (instead of the mean) of the conditional distribution of the dependent variable given the independent variables. This type of regression is called *quantile* regression (Koenker 2005). The sum of tilted absolute loss (called pinball loss) is being optimized for this type of regression. Quantile regression has many important applications within econometrics, data mining, social sciences, and ecology, among other domains.

Instead of inferring one regression function corresponding to the mean of a response variable, k regression functions can be computed with the assumption that the response variable is generated by a mixture of k components. This is called the *mixture of regressions* problem (Gaffney and Smyth 1999). Applications include trajectory clustering, robot planning, and motion segmentation.

Another important variant is the *heteroscedastic* regression model where the noise variance on the data is a function of the input variable x. The Gaussian process framework can be used conveniently to model this noise-dependent case by introducing a second Gaussian process to model the dependency of noise variance on the input variable (Goldberg et al. 1998). There are also attempts to make the regression model more robust to the presence of a few problematic data points called outliers. The sum of absolute loss (instead of the sum of squared loss) or student's t-distribution (instead of Gaussian distribution) can be used for *robust* regression.

Regression Trees

Luís Torgo
University of Porto, Porto, Portugal

Synonyms

Decision trees for regression; Piecewise constant models; Tree-based regression

Definition

Regression trees are supervised learning methods that address multiple regression problems. They provide a tree-based approximation $\hat{f}$, of an unknown regression function $Y = f(\mathbf{x}) + \varepsilon$ with $Y \in \Re$ and $\varepsilon \approx N(0, \sigma^2)$, based on a given sample of data $D = \{\langle x_i^1, \cdots, x_i^p, y_i \rangle\}_{i=1}^n$. The obtained models consist of a hierarchy of logical tests on the values of any of the p predictor variables. The terminal nodes of these trees, known as the leaves, contain the numerical predictions of the model for the target variable Y.

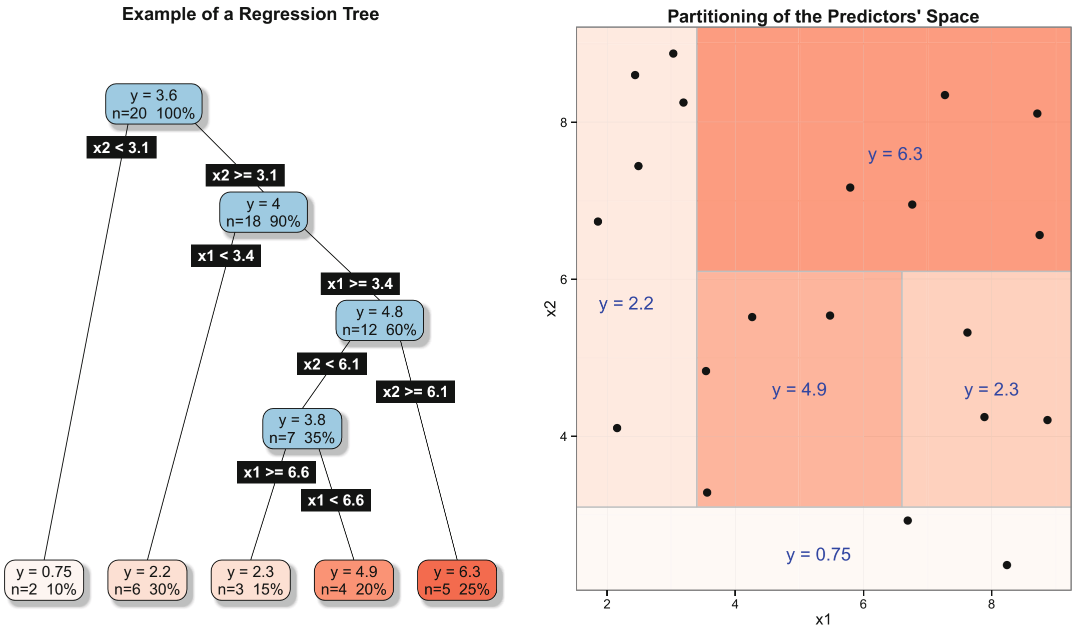
Motivation and Background

Work on regression trees goes back to the AID system by Morgan and Sonquist (1963). Nonetheless, the seminal work is the book *Classification and Regression Trees* by Breiman and colleagues (1984). This book has established several standards in many theoretical aspects of tree-based regression, including over-fitting avoidance by post-pruning, the notion of surrogate splits for handling unknown variable, and estimating variable importance.

Regression trees have several features that make them a very interesting approach to several multiple regression problems. Namely, regression trees provide (i) automatic variable selection making them highly insensitive to irrelevant variables, (ii) computational efficiency that allows addressing large problems, (iii) handling of unknown variable values, (iv) handling of both numerical and nominal predictor variables, (v) insensitivity to predictors' scales, and (vi) interpretable models for most domains. In spite of all these advantages, regression trees have poor prediction accuracy in several domains because of the piecewise constant approximation they provide, and they are also unstable with respect to small changes on the training data.

Structure of Learning System

The most common regression trees are binary with logical tests in each node (an example is given on the left graph of Fig. 1). Tests on numerical variables usually take the form $x_i < \alpha$, with $\alpha \in \Re$, while tests on nominal variables have the form $x_j \in \{v_1, \cdots, v_m\}$. Each path from the root (top) node to a leaf can be seen as a logical assertion defining a region on the predictors' space. Any regression tree provides a full mutually exclusive partition of the predictor space into L regions with boundaries that are



Regression Trees, Fig. 1 A regression tree and the partitioning it provides

parallel to the predictors' axes due to the form of the tests. Figure 1 illustrates these ideas with a tree and the respective partitioning on the right side of the graph.

Using a regression tree for obtaining predictions for new observations is straightforward. For each new observation, we follow a path from the root node to a leaf selecting the branches according to the variable values of the observation. All observations falling in a partition are predicted with the same constant value, and that is the reason for regression trees sometimes being referred to as piecewise constant models. In effect, the approximation provided by a regression tree is given by

$$Y = \sum_{l \in \mathcal{L}} k_l \cdot I(P_l) \qquad (1)$$

where $\mathcal{L}$ is the set of L leaves, the ks are the constants at each leaf, $I()$ is an indicator function, and P_i is a logical assertion formed by the conjunction of conditions from the root node till the leaf i. For instance, the rightmost leaf of the tree in Fig. 1 is described by the logical assertion $x_2 \geq 3.1 \wedge x_1 \geq 3.4 \wedge x_2 \geq 6.1$, which is equivalent to $x_1 \geq 3.4 \wedge x_2 \geq 6.1$.

Learning a Regression Tree

A binary regression tree is obtained by a very efficient algorithm known as recursive partitioning (Algorithm 1).

If the termination criterion is not met by the input sample D, the algorithm selects the best logical test on one of the predictor variables according to some criterion. This test divides the current sample in two partitions: the one with the cases satisfying the test and the remaining. The algorithm proceeds by recursively applying the same method to these two partitions to obtain the left and right branches of the node. Algorithm 1 has three main components that characterize the type of regression tree we are obtaining: (i) the *termination criterion*, (ii) the *constant* k, and (iii) the method to find the *best test on one of the predictors*. The choices for these components are related to the preference criteria that are used to build the trees. The most common criterion is the minimization of the sum of the square errors, known as the least squares (LS) criterion. Using this criterion it can be easily proven (e.g., Breiman et al. 1984) that the constant k should be the average target variable value of the cases in the leaf. With respect to

Algorithm 1 Recursive partitioning

```
function RECURSIVEPARTITIONING($D$)
  $Input$ :    $D$, a sample of cases, $\{\langle x_i^1, \cdots, x_i^p, y_i \rangle\}$
  $Output$ :    $t$, a tree node

    if <TERMINATION CRITERION> then
        Return a leaf node with <CONSTANT K>
    else
        $t \leftarrow$ new tree node
        $t.split \leftarrow$ <FIND THE BEST TEST ON ONE OF THE VARIABLES>
        $t.leftNode \leftarrow$ RecursivePartitioning($\{\mathbf{x} \in D : \mathbf{x} \vDash t.split\}$)
        $t.rightNode \leftarrow$ RecursivePartitioning($\{\mathbf{x} \in D : \mathbf{x} \nvDash t.split\}$)
        Return the node $t$
    end if
end function
```

the *termination criterion*, usually very relaxed settings are selected so that an overly large tree is grown. The reasoning is that the trees will be pruned afterward with the goal of overcoming the problem of over-fitting of the training data.

According to the LS criterion, the error in a given node is given by

$$Err(t) = \frac{1}{n_t} \sum_{\langle \mathbf{x}_i, y_i \rangle \in D_t} (y_i - k_t)^2 \qquad (2)$$

where D_t is the sample of cases in node t, n_t is the cardinality of this set, and k_t is the average target variable value of the cases in D_t.

Any logical test s divides the cases in D_t in two partitions, D_{t_L} and D_{t_R}. The resulting pooled error is given by

$$Err(t,s) = \frac{n_{t_L}}{n_t} \times Err(t_L) + \frac{n_{t_R}}{n_t} \times Err(t_R) \qquad (3)$$

where n_{t_L}/n_t (n_{t_R}/n_t) is the proportion of cases going to the left (right) branch of t.

In this context, we can estimate the value of the split s by the respective error reduction, and this can be used to evaluate all candidate splits test for a node:

$$\Delta(s,t) = Err(t) - Err(t,s) \qquad (4)$$

Finding the best split test for a node t involves evaluating all possible tests for this node using Eq. 4. For each predictor of the problem, one needs to evaluate all possible splits in that variable. For continuous variables, this requires a sorting operation on the values of this variable occurring in the node. After this sorting, a fast incremental algorithm can be used to find the best cut point value for the test (e.g., Torgo 1999). With respect to nominal variables, Breiman and colleagues (1984) have proved a theorem that avoids trying all possible combinations of values, reducing the computational complexity of this task from $O(2^{v-1} - 1)$ to $O(v - 1)$, where v is the number of values of the nominal variable.

Departures from the standard learning procedure described above include, among others, the use of multivariate split nodes (e.g., Breiman et al. 1984, Li et al. 2000, and Gama 2004) to overcome the axis parallel representation limitation of partitions, the use of different criteria to find the best split node (e.g., Robnik-Sikonja and Kononenko 1996, Buja and Lee 2001, and Loh 2002), the use of different preference criteria to guide the tree growth (e.g., Breiman et al. 1984, Torgo 1999, Buja and Lee 2001, and Torgo and Ribeiro 2003), and the use of both regression and split nodes (e.g., Lubinsky 1995 and Malerba et al. 2004).

Pruning Regression Trees

As most nonparametric modeling techniques, regression trees may over-fit the training data which will inevitably lead to poor out of the sample predictive performance. The standard procedure to fight this undesirable effect is to grow an overly large tree and then to use some reliable error estimation procedure to find the "best" sub-tree of this large model. This procedure is known as post-pruning a tree (Breiman et al. 1984). An alternative is to stop tree growth sooner in a process known as pre-pruning which again needs to be guided by reliable error estimation to known when over-fitting is starting to occur. Although more efficient in computational terms, this latter alternative may lead to stop tree growth too soon even with look-ahead mechanisms.

Post-pruning is usually carried out in a three-stage procedure: (i) a set of sub-trees of the initial tree is generated, (ii) some reliable error estimation procedure is used to obtain estimates for each member of this set, and (iii) some method based on these estimates is used to select one of these trees as the final tree model. Different methods exist for each of these steps. A common setup (e.g., Breiman et al. 1984) is to use error-complexity pruning to generate a sequence of nested sub-trees, whose error is then estimated by cross validation. The final tree is selected using the x-SE rule which starts with the lowest estimated error sub-tree and then selects the smallest tree within the interval of x standard errors of the lowest estimated error tree (a frequent setting is to use 1 standard error).

Variations on the subject of pruning regression trees include, among others, pre-pruning alternatives (e.g., Breiman and Meisel 1976 and Friedman 1979), the use of different tree error estimators (see Torgo (1998) for a comparative study and references to different alternatives), and the use of the MDL principle to guide the pruning (Robnik-Sikonja and Kononenko 1998).

Abstract

Regularization plays a key role in many machine learning algorithms. Exactly fitting a model to the training data is generally undesirable, because it will fit the noise in the training examples (▸ overfitting), and is doomed to predict (generalize) poorly on unseen data. In contrast, a simple model that fits the training data well is more likely to capture the regularities in it and generalize well. A number of regularizers have been proposed for various applications, and theoretical tools that characterize their complexity are also available.

Definition

In general, a regularizer a quantifier of the complexity of a model, and many successful machine learning algorithms fall in the framework of regularized risk minimization:

$$\text{(How well the model fits the training data)} \tag{1}$$

$$+\lambda \cdot \text{(complexity/regularization of the model)}, \tag{2}$$

where the positive real number λ controls the trade-off.

There is a variety of regularizers, which yield different statistical and computational properties. In general, there is no universally best regularizer, and a regularization approach must be chosen depending on the dataset.

Motivation and Background

The main goal of machine learning is to induce a model from the observed data and use this model to make predictions and decisions. This is also largely the goal of general natural science and is commonly called inverse problems ("forward problem" means using the model to generate observations). Therefore, it is no surprise that regularization had been well studied before the emergence of machine learning.

Inverse problems are typically ill posed, e.g., having only a finite number of samples drawn from an uncountable space or having a finite number of measurements in an infinite dimensional space. In machine learning, we often need to induce a classifier for the whole feature-label space, while only a finite number of feature-label pairs are available for training. In practice, the set of candidate models is often flexible enough to precisely fit all the training examples. However, this can lead to significant overfitting when the training data is noisy, and the real challenge is how to generalize well on the unseen data in the whole feature-label space.

Many techniques have been proposed to tackle ill-posed inverse problems. Almost all of them introduce an additional measure on how much a model is preferred a priori (i.e., without observing the training data). This extra belief on the desirable form of the model reflects the external knowledge of the model designer. It cannot be replaced by the data itself according to the "no free lunch theorem," which states that if there is no assumption on the mechanism of labeling, then it is impossible to generalize, and any model can be inferior to another on some distribution of the feature-label pair (Devroye et al. 1996).

A commonly used prior is the so-called ▸ Occam's razor, which prefers "simple" models. It asserts that among all the models which fit the training data well, the simplest one is more likely to capture the "regularities" in it and hence has a larger chance to generalize well to the unseen data. Then an immediate question is how to quantify the complexity of a model, which is often called a regularizer. Intuitively, a regularizer can encode preference for a sparse model (few features are relevant for prediction), a large margin model (two classes have a wide margin), or a smooth model with weak high-frequency components. A general framework of regularization was given by Tikhonov (1943).

Theory

Suppose n feature-label pairs $\{(\mathbf{x}_i, y_i)\}_{i=1}^n$ are drawn *iid* from a certain joint distribution P on $\mathcal{X} \times \mathcal{Y}$, where $\mathcal{X}$ and $\mathcal{Y}$ are the spaces of feature and label, respectively. Let the marginal distribution on $\mathcal{X}$ and $\mathcal{Y}$ be P_x and P_y respectively. For convenience, let $\mathcal{X}$ be $\mathbb{R}^p$ (Euclidean space). Denote $X := (\mathbf{x}_1, \ldots, \mathbf{x}_n)$ and $\mathbf{y} := (y_1, \ldots, y_n)^\top$.

An Illustrative Example: Ridge Regression

Ridge regression is illustrative of the use of regularization. It tries to fit the label y by a linear model $\langle \mathbf{w}, \mathbf{x} \rangle$ (inner product). So we need to solve a system of linear equations in $\mathbf{w}$: $(\mathbf{x}_1, \ldots, \mathbf{x}_n)^\top \mathbf{w} = \mathbf{y}$, which is equivalent to a linear least square problem: $\min_{\mathbf{w} \in \mathbb{R}^p} \left\| X^\top \mathbf{w} - \mathbf{y} \right\|^2$. If the rank of X is less than the dimension of $\mathbf{w}$, then it is overdetermined and the solution is not unique.

To approach this ill-posed problem, one needs to introduce additional assumptions on what models are preferred, i.e., the regularizer. One choice is to pick a matrix Γ and regularize $\mathbf{w}$ by $\|\Gamma \mathbf{w}\|^2$. As a result we solve $\min_{\mathbf{w} \in \mathbb{R}^p} \left\| X^\top \mathbf{w} - \mathbf{y} \right\|^2 + \lambda \left\| \Gamma^\top \mathbf{w} \right\|^2$, and the solution has a closed form $\mathbf{w}^* = (XX^\top + \lambda \Gamma \Gamma^\top) X \mathbf{y}$. Γ can be simply the identity matrix which encodes our preference for small norm models.

The use of regularization can also be justified from a Bayesian point of view. Treating $\mathbf{w}$ as a multivariate random variable and the likelihood as $\exp\left(-\left\| X^\top \mathbf{w} - \mathbf{y} \right\|^2\right)$, then the minimizer of $\left\| X^\top \mathbf{w} - \mathbf{y} \right\|^2$ is just a maximum likelihood estimate of $\mathbf{w}$. However, we may also assume a prior distribution over $\mathbf{w}$, e.g., a Gaussian prior $p(\mathbf{w}) \sim \exp\left(-\lambda \left\| \Gamma^\top \mathbf{w} \right\|^2\right)$. Then the solution of the ridge regression is simply the maximum a posterior estimate of $\mathbf{w}$.

Examples of Regularization

A common approach to regularization is to penalize a model by its complexity measured by some real-valued function, e.g., a certain "norm" of $\mathbf{w}$. We list some examples below.

***L_1* regularization** L_1 regularizer, $\|\mathbf{w}\|_1 := \sum_i |w_i|$, is a popular approach to finding sparse models, i.e., only a few components of $\mathbf{w}$ are nonzero, and only a corresponding small number of features are relevant to the prediction. A well-known example is the LASSO algorithm (Tibshirani 1996), which uses a L_1-regularized least square:

$$\min_{\mathbf{w} \in \mathbb{R}^p} \left\| X^\top \mathbf{w} - \mathbf{y} \right\|^2 + \lambda \|\mathbf{w}\|_1 .$$

***L_2* regularization** The L_2 regularizer, $\|\mathbf{w}\|_2 := \sqrt{\sum_i |w_i|^2}$, is popular due to its self-dual properties. In all L_p spaces, only the L_2 space is Hilbertian and self-adjoint, so it affords much convenience in studying and exploiting the dual properties of the L_2-regularized models. A well-known example is the support vector machines (SVMs), which minimize the L_2-regularized hinge loss:

$$\frac{1}{n} \sum_{i=1}^{n} \max\{0, 1 - \langle \mathbf{w}, \mathbf{x}_i \rangle\} + \lambda \|\mathbf{w}\|_2^2 .$$

***L_p* regularization** In general, all L_p norms $\|\mathbf{w}\|_p := \left(\sum_i |w_i|^p\right)^{1/p}$ $(p \geq 1)$ can be used for regularization. When $p < 1$, $\left(\sum_i |w_i|^p\right)^{1/p}$ is no longer convex. A specially interesting case is when $p = 0$, and $\|\mathbf{w}\|_0$ is defined as the number of nonzero elements in $\mathbf{w}$ (the sparseness of $\mathbf{w}$). But explicitly optimizing the L_0 norm leads to a combinatorial problem which is hard to solve. In some cases, the L_1 regularizer can approximately recover the solution of L_0 regularization (Candes and Tao 2005).

***$L_{p,q}$* regularizer** The $L_{p,q}$ regularizer is popular in the context of multitask learning (Tropp 2006). Suppose there are T tasks, and each training example $\mathbf{x}_i$ has a label vector $\mathbf{y}_i \in \mathbb{R}^T$ with each component corresponding to a task.

For each task t, we seek for a linear regressor $\langle \mathbf{w}_t, \mathbf{x} \rangle$ such that for each training example $\mathbf{x}_i$, $\langle \mathbf{w}_t, \mathbf{x}_i \rangle$ fits the t-th component of $\mathbf{y}_i$. Of course, the $\mathbf{w}_t$ could be determined independently from each other. But in many applications, the T tasks are somehow related, and it will be advantageous to learn them as a whole. Stack $\mathbf{w}_t$'s into a matrix $W := (\mathbf{w}_1, \ldots, \mathbf{w}_T)$ where each column corresponds to a task and each row corresponds to a feature. Then the intuition of multitask learning can be concretized by regularizing W with the $L_{p,q}$ compositional norm ($p, q \geq 1$):

$$\|W\|_{p,q} := \left(\sum_i \left(\sum_t |w_{it}|^p \right)^{\frac{q}{p}} \right)^{\frac{1}{q}},$$

where w_{it} is the i-th component of $\mathbf{w}_t$. When $q = 1$, it becomes the L_1 norm of the L_p norm of the rows, and the sparse inducing property of L_1 norm encourages the rows to have L_p norm 0, i.e., the corresponding feature is not used by *any* task. Other choices of p and q are also possible.

Entropy regularizer The entropy regularizer is useful in boosting, and it works in a slightly different way from the above regularizers. Boosting aims to find a convex combination of hypotheses, such that the training data is accurately classified by the ensemble. At each step, the boosting algorithm maintains a distribution $\mathbf{d}$ ($d_i > 0$ and $\sum_i d_i = 1$) over the training examples, feeds $\mathbf{d}$ to an oracle which returns a new hypothesis, and then updates $\mathbf{d}$ and go on. As a "simple" ensemble means a small number of weak hypotheses, the boosting algorithm is expected to find an accurate ensemble by taking as few steps as possible. This can be achieved by exponentiated gradient descent (Kivinen and Warmuth 1997), which stems from the relative entropy regularizer $\sum_i d_i \log \frac{d_i}{1/n}$ applied at each step. It also attracts $\mathbf{d}$ toward the uniform distribution, which helps avoid overfitting the noise, i.e., trying hard to match the (incorrect) label of a few training examples.

Miscellaneous Instead of using a function that directly measures the complexity of the model $\mathbf{w}$, regularization can also be achieved by penalizing the complexity of the *output* of the model on the training data. This is called value regularization (Rifkin and Lippert 2007). It not only yields neat derivations of standard algorithms but also provides much convenience in studying the learning theory and optimization.

Furthermore, the regularized risk minimization framework in (1) is not the only approach to regularization. For example, in online learning where the model is updated iteratively, early stopping is an effective form of regularization, and it has been widely used in training neural networks. Suppose the available dataset is divided into a training set and a validation set and the model is learned online from the training set, then the algorithm terminates when the performance of the model on the validation set stops improving.

Measuring the Capacity of Model Class

Besides penalizing the complexity of the model, we can restrict the complexity of the model class $\mathcal{F}$ in the first place. For example linear regression is intrinsically "simpler" than quadratic regression. Decision stumps are "simpler" than linear classifiers. In other words, regularization can be achieved by restricting the capacity of the model class, and the key question is how to quantify this capacity. Some commonly used measures in the context of binary classification are the following:

VC dimension The Vapnik-Chervonenkis dimension (▶ VC dimension) quantifies how many data points can be arbitrarily labeled by using the functions in $\mathcal{F}$ (Vapnik and Chervonenkis 1971). $\mathcal{F}$ is said to *shatter* a set of data points $\mathbf{x}_1, \ldots, \mathbf{x}_n$ if, for any assignment of labels to these points, there exists a function $f \in \mathcal{F}$ which yields this labeling. The VC dimension of $\mathcal{F}$ is the maximum n such that any n data points can be shattered by $\mathcal{F}$. For example, decision stumps have VC dimension 2, and linear classifiers (with bias) in a p dimensional space have VC dimension $p + 1$.

Covering number The idea of covering number (Guo et al. 1999) is to characterize the inherent "dimension" of $\mathcal{F}$, in a way that follows the standard concept of vector dimension. Given n data points $\mathbf{x}_1, \ldots, \mathbf{x}_n$, we may endow the model class $\mathcal{F}$ with the following metric:

$$d_n(f, g) := \frac{1}{n}\sum_{i=1}^{n} \delta(f(\mathbf{x}_i) \neq g(\mathbf{x}_i)), \ \forall\, f, g \in \mathcal{F},$$

where $\delta(\cdot) = 1$ if $\cdot$ is true and 0 otherwise. A set of functions $f_1, \ldots, f_m$ is said to be a cover of $\mathcal{F}$ at radius ϵ if, for any function $f \in \mathcal{F}$, there exists an f_i such that $d_n(f, f_i) < \epsilon$. Then the covering number of $\mathcal{F}$ at radius $\epsilon > 0$ with respect to d_n is the minimum size of a cover of radius ϵ.

To understand the motivation of the definition, consider the unit ball in $\mathbb{R}^p$. To cover it by ϵ radius balls, one needs order $N(\epsilon, p) = \epsilon^{-p}$ balls. Then the dimension p can be estimated from the rate of growth of $\log N(\epsilon, p) = -p \log \epsilon$ with respect to ϵ. The covering number is an analogy of $N(\epsilon, p)$, and the dimension of $\mathcal{F}$ can be estimated in the same spirit.

Rademacher average The Rademacher average is a soft variant of the VC dimension. Instead of requiring the model class to shatter n data points, it allows that the labels be violated at some cost. Let $\sigma_i \in \{-1, 1\}$ be an arbitrary assignment of the labels, and assume all functions in $\mathcal{F}$ range in $\{-1, 1\}$ (this restriction can be relaxed). Then a model $f \in \mathcal{F}$ is considered as the most consistent with $\{\sigma_i\}$ if it maximizes $\frac{1}{n}\sum_{i=1}^{n} \sigma_i f(\mathbf{x}_i)$. This term equals 1 if $\mathcal{F}$ does contain a model consistent with $\{\sigma_i\}$. Then we take an average over all possible assignments of σ_i, i.e., treating σ_i as a binary random variable with $P(\sigma_i = 1) = P(\sigma_i = -1) = 0.5$ and calculating the expectation over $\{\sigma_i\}$:

$$\mathcal{R}_n(\mathcal{F}) = \mathop{\mathbb{E}}_{\sigma}\left[\sup_{f \in \mathcal{F}} \frac{1}{n}\sum_{i=1}^{n} \sigma_i f(\mathbf{x}_i)\right].$$

Furthermore, we may take expectation over the samples $\mathbf{x}_1, \ldots, \mathbf{x}_n$:

$$\mathcal{R}(\mathcal{F}) = \mathop{\mathbb{E}}_{\mathbf{x}_i \sim P_x} \mathop{\mathbb{E}}_{\sigma}\left[\sup_{f \in \mathcal{F}} \frac{1}{n}\sum_{i=1}^{n} \sigma_i f(\mathbf{x}_i)\right].$$

Therefore, similar to VC dimension, the Rademacher average is high if the model class $\mathcal{F}$ is "rich" and can match most assignments of $\{\sigma_i\}$.

Applications

In many applications such as bioinformatics, the training examples are expensive and the number of features p is much higher than the number of labeled examples n. In such cases, regularization is crucial, e.g., Zhang et al. (2008).

L_1 regularization has gained much popularity recently in the field of compressed sensing, and it has been widely used in imaging for radar, astronomy, medical diagnosis, and geophysics. See an ensemble of publications at http://dsp.rice.edu/cs.

The main spirit of regularization, namely, a preference for models with lower complexity, has been used by some ▸ model evaluation techniques. Examples include Akaike information criterion (AIC), Bayesian information criterion (BIC), ▸ minimum description length (MDL), and the minimum message length (MML).

University of Texas at Austin, Austin, TX, USA

Abstract

This entry provides an overview of Reinforcement Learning (RL), with cross-references to specific RL algorithms.

Reinforcement learning describes a large class of learning problems characteristic of autonomous agents interacting in an environment: sequential decision-making problems with delayed reward. Reinforcement-learning algorithms seek to learn a policy (mapping from states to actions) that maximizes the reward received over time.

Unlike in ► supervised learning problems, in reinforcement-learning problems, there are no labeled examples of correct and incorrect behavior. However, unlike ► unsupervised learning problems, a reward signal can be perceived.

Many different algorithms for solving reinforcement-learning problems are covered in other entries. This entry provides just a brief high-level classification of the algorithms.

Perhaps the most well-known approach to solving reinforcement-learning problems, as covered in detail by Sutton and Barto (1998), is based on learning a value function, which represents the long-term expected reward of each state the agent may encounter, given a particular policy. This approach typically assumes that the environment is a ► Markov decision process in which rewards are discounted over time, though it is also possible to optimize for average reward per time step as in ► average-reward reinforcement learning. If a complete model of the environment is available, ► dynamic programming, or specifically ► value iteration, can be used to compute an optimal value function, from which an optimal policy can be derived.

If a model is not available, an optimal value function can be learned from experience via model-free techniques such as ▸ temporal difference learning, which combine elements of dynamic programming with Monte Carlo estimation. Partly due to Watkins' elegant proof that ▸ Q-learning converges to the optimal value function (Watkins 1989), temporal difference methods are currently among the most commonly used approaches for reinforcement-learning problems.

Watkins' convergence proof relies on executing a policy that visits every state infinitely often. In practice, Q-learning does converge in small, discrete domains. However in larger and particularly in continuous domains, the learning algorithm must generalize the value function across states, a process known as ▸ value function approximation. Examples include ▸ instance-based reinforcement learning, ▸ Gaussian process reinforcement learning, and ▸ relational reinforcement learning.

Even when combined with value function approximation, the most basic value-free methods, such as Q-learning and SARSA, are very inefficient with respect to experience: they are not sample-efficient. With the view that experience is often more costly than computation, much research has been devoted to making more efficient use of experience, for instance, via ▸ hierarchical reinforcement learning, ▸ reward shaping, or ▸ model-based reinforcement learning in which the experience is used to learn a domain model, which can then be solved via dynamic programming.

Though these methods make efficient use of the experience that is presented to them, the goal of optimizing sample efficiency also motivates the study of ▸ efficient exploration in reinforcement learning. The study of exploration methods can be isolated from the full reinforcement-learning problem by removing the notion of temporally delayed reward as is done in ▸ associative reinforcement learning or by removing the notion of states altogether as is done in ▸ k-armed bandits. k-Armed bandit algorithms focus entirely on the exploration versus exploitation challenge, without having to worry about generalization across states or delayed rewards. Back in the context of the full RL problem, ▸ Bayesian reinforcement learning enables optimal exploration given prior distributions over the parameters of the learning problem. However, its computational complexity has limited its use so far to very small domains.

Although most of the methods above revolve around learning a value function, reinforcement-learning problems can also be solved without learning value functions, by directly searching the space of potential policies via policy search. Effective ways of conducting such a search include ▸ policy gradient reinforcement learning, ▸ least squares reinforcement-learning methods, and evolutionary reinforcement learning.

As typically formulated, the goal of a reinforcement-learning algorithm is to learn an optimal (or high-performing) policy based on knowledge of, or experience of, a reward function (and state transition function). However, it is also possible to take the opposite perspective that of trying to learn the reward function based on observation of the optimal policy. This problem formulation is known as ▸ inverse reinforcement learning.

Leveraging this large body of theory and algorithms, a current focus in the field is deploying large-scale, successful applications of reinforcement learning. Two such applications treated herein are ▸ autonomous helicopter flight using reinforcement learning and ▸ robot learning.

Problem Definition

Relational learning refers to learning in a context where there may be relationships between learning examples, or where these examples may have a complex internal structure (i.e., consist of multiple components and there may be relationships between these components). In other words, the "relational" may refer to both an internal or external relational structure describing the examples. In fact, there is no essential difference between these two cases, as it depends on the definition of an example whether relations are internal or external to it. Most methods, however, are clearly set in one of these two contexts.

Learning from Examples with External Relationships

This setting considers learning from a set of examples where each example itself has a relatively simple description, for instance in the attribute-value format, and relationships may be present among these examples.

Example 1 Consider the task of web-page classification. Each web-page is described by a fixed set of attributes, such as a bag of words representation of the page. Web-pages may be related through hyperlinks, and the class label of a given page typically depends on the labels of the pages to which it links.

Example 2 Consider the Internet Movie Database (www.imdb.com). Each movie is described by a fixed set of attributes, such as its title and genre. Movies are related to other entity types, such as *Studio*, *Director*, *Producer*, and *Actor*, each of which is in turn described by a different set of attributes. Note that two movies can be related through the other entity types. For example, they can be made by the same studio or star the same well-known actor. The learning task in this domain could be, for instance, predicting the opening weekend box office receipts of the movies.

If relationships are present among examples, then the examples may not be independent and identically distributed (i.i.d.), an assumption made by many learning algorithms. Relational data that violates this assumption can be detrimental to learning performance as Jensen and Neville (2002) show. Relationships among examples can, on the other hand, also be exploited by the learning algorithm. ▶ Collective classification techniques (Jensen et al. 2004), for example, take the class labels of related examples into account when classifying a new instance.

Learning from Examples with a Complex Internal Structure

In this setting, each example may have a complex internal structure, but no relationships exist that relate different examples to one another. Learning algorithms typically use individual-centered representations in this setting, such as logical interpretations or strongly typed terms (Lloyd 2003), which store together all data of a given example. An important advantage of individual-centered representations is that they scale better to large datasets. Special cases of this setting include applications where the examples can be represented as graphs, trees, or sequences.

Example 3 Consider a database of candidate chemical compounds to be used in drugs. The molecular structure of each compound can be represented as a graph where the vertices are atoms and the edges are bonds. Each atom is labeled with its element type and the bonds can be single, double, triple, or aromatic bonds. Compounds are classified as active or inactive with regard to a given disease and the goal is to build models that are able to distinguish active from inactive compounds based on their molecular structure. Such models can, for instance, be used to gain insight in the common substructures, such as binding sites, that determine a compound's activity.

Approaches to Relational Learning

Many different kinds of learning tasks have been defined in relational learning, and an even larger number of approaches have been proposed for tackling these tasks. We give an overview of different learning settings that can be considered instances of relational learning.

Inductive Logic Programming

In ▶ inductive logic programming (ILP), the input and output knowledge of a learner are described in (variants of) first-order predicate logic. Languages based on first-order logic are highly expressive from the point of view of knowledge representation, and indeed, a language such as Prolog (Bratko 1986) can be used without adaptations to represent objects and the relationships between them, as well as background knowledge that one may have about the domain.

Example 4 This example is based on the work by Finn et al. (1998). Consider a data set that describes chemical compounds. The active compounds in the set are ACE inhibitors, which are used in treatments for hypertension. The molecular structure of the compounds is represented as a set of Prolog facts, such as: atom(m1, a1, o).

atom(m1, a2, c).
...
bond(m1, a1, a2, 1).
...
coord(m1, a1, 5.91, – 2.44, 1.79).
coord(m1, a2, 0.57, – 2.77, 0.33).
...

which states that molecule m1 includes an oxygen atom a1 and a carbon atom a2 that are single bonded. The coord/5 predicate lists the 3D coordinates of the atoms in the given conformer. Background knowledge, such as the concepts zinc site, hydrogen donor, and the distance between atoms, are defined by means of Prolog clauses. Figure 1 shows a clause learned by the inductive logic programming system Progol (Džeroski and Lavraè 2001, Ch. 7) that makes use of these background knowledge predicates. This clause is the description of a pharmacophore, that is, a submolecular structure that causes a certain observable property of a molecule.

More details on the theory of inductive logic programming and descriptions of algorithms can be found in the entry on ▶ Inductive Logic Programming in this encyclopedia, or in references (De Raedt 2008; Džeroski and Lavraè 2001).

Learning from Graphs

A graph is a mathematical structure consisting of a set of nodes V and a set of edges $E \subseteq V^2$ between those nodes. The set of edges is by definition a binary relation defined over the nodes. Hence, for any learning problem where the relationships between examples can be described using a single binary relation, the training set can be represented straightforwardly as a graph. This setting covers a wide range of relational learning tasks, for example, web mining (the set of links between pages is a binary relation), social network analysis, etc. Non-binary relationships can be represented as hypergraphs; in a hypergraph, edges are defined as subsets of V of arbitrary size, rather than elements of V^2.

In graph-based learning systems, there is a clear distinction between approaches that learn from examples with external relationships, where the whole data set is represented as a single graph and each node is an example, and individual-centered approaches, where each example by itself is a graph. In the first kind of approaches, the goal is often to predict properties of existing nodes or edges, to predict the existence or non-existence of edges ("link discovery"), to predict whether two nodes actually refer to the same object ("node identification"), detection of subgraphs that frequently occur in the graph, etc. When learning from multiple graphs, a typical goal is to learn a model for classifying the graphs, to find frequent substructures (where frequency is defined as the number of graphs a subgraphs occurs in), etc.

Compared to other methods for relational learning, graph-based methods typically focus more on the structure of the graph, and less on properties of single nodes. They may take node and edge labels into account, but typically do not allow for more elaborate information to be associated with each node.

▶ Graph mining methods are often more efficient than other relational mining methods because they avoid certain kinds of overhead, but are typically still NP-complete, as they generally rely on subgraph isomorphism testing. Nevertheless, researchers have been able to significantly improve efficiency or even avoid NP-completeness by looking only for linear or tree-shaped patterns, or by restricting the graphs analyzed to a relatively broad subclass. As an example, Horváth et al. (2006) show that a large majority of molecules belong to the class of outerplanar graphs, and propose an efficient algorithm for subgraph isomorphism testing in this class.

More information about mining graph data can be found in the ▸ graph mining entry in this encyclopedia, or in Cook and Holder (2007) and Washio and Motoda (2003).

Multi-relational Data Mining

Multi-relational data mining approaches relational learning from the relational database point of view. The term "multi-relational" refers to the fact that from the database perspective, one learns from information spread over multiple tables or relations, as opposed to ▸ attribute-value learning, where one learns from a single table.

Multi-relational data mining systems tightly integrate with relational databases. Mainly rule and decision tree learners have been developed in this setting. Because practical relational databases may be huge, most of these systems pay much attention to efficiency and scalability, and use techniques such as sampling and precomputation (e.g., materializing views). An example of a scalable and efficient multi-relational rule learning system is CrossMine (Yin et al. 2006).

An alternative approach to relational learning and multi-relational data mining is ▸ propositionalization. Propositionalization consists of automatically converting the relational representation into an attribute-value representation and then using attribute-value data mining algorithms on the resulting representation. An important line of research within multi-relational data mining investigates how database approaches can be used to this end. Database oriented propositionalization creates a view in which each example is represented by precisely one row. Information from related entities is incorporated into this row by adding derived attributes, computed by means of aggregation. In the movie database (Example 2), the view representing movies could include aggregated attributes such as the number of actors starring in the movie. A comparison of propositionalization approaches is presented by Krogel et al. (2003), and a discussion of them is also included in this volume.

Finally, note that most inductive logic programming systems are directly applicable to multi-relational data mining by representing each relational table as a predicate. This is possible because the relational representation is essentially a subset of first-order logic (known as datalog). Much research on multi-relational data mining was developed within the ILP community (Džeroski and Lavraè 2001).

Statistical Relational Learning/Probabilistic Logic Learning

Research on relational learning, especially in the beginning, has largely focused on how to handle the relational structure of the data, and ignored aspects such as uncertainty. Indeed, the databases handled in multi-relational data mining, or the knowledge assumed given in inductive logic programming, are typically assumed to be deterministic. With the rise of probabilistic representations and algorithms within machine learning has come an increased interest in enabling relational learners to cope with uncertainty in the input data. This goal has been approached from at least two different directions: statistical learning approaches have been extended toward the relational setting, giving rise to the area of ▸ statistical relational learning, whereas inductive logic programming researchers have investigated how to extend their knowledge representation and learning algorithms to cater for probabilistic information, referring to this research area as probabilistic logic learning. While there are some differences in terminology and approaches, both research areas essentially address the same research question, namely how to integrate relational and probabilistic learning.

Among the best known approaches for statistical relational learning is the learning of probabilistic relational models (PRMs, Džeroski and Lavraè 2001, Chap. 13). PRMs extend Bayesian networks to the relational representation used in relational databases. PRMs model the joint probability distribution over the non-key attributes in a relational database schema. Similar to Bayesian networks, PRMs are ▶ graphical models. Each attribute corresponds to a node and direct dependencies are modeled by directed edges. Such edges can connect attributes from different entity types that are (indirectly) related (such a relationship is called a "slot chain"). Inference in PRMs occurs by constructing a ▶ Bayesian network by instantiating the PRM with the data in the database and performing the inference in the latter. To handle 1:N relationships in the Bayesian network, PRMs make use of aggregation, similar to the propositionalization techniques mentioned above.

Bayesian logic programs (BLPs) (Kersting 2006) aim at combining the inference power of Bayesian networks with that of first-order logic reasoning. Similar to PRMs, the semantics of a BLP is defined by translating it to a Bayesian network. Using this network, the probability of a given interpretation or the probability that a given query yields a particular answer can be computed.

The acyclicity requirement of Bayesian networks carries over to representations such as PRMs and BLPs. Markov logic networks (MLNs) (Richardson and Domingos 2006) upgrade ▶ Markov networks to first-order logic and allow networks with cycles. MLNs are defined as sets of weighted first-order logic formulas. These are viewed as "soft" constraints on logical interpretations: the fewer formulas a given interpretation violates, the higher its probability. The weight determines the contribution of a given formula: the higher its weight, the greater the difference in log probability between an interpretation that satisfies the formula and one that does not, other things being equal. The Alchemy system implements structure and parameter learning for MLNs.

More specific statistical learning techniques such as Naïve Bayes and Hidden Markov Models have also been upgraded to the relational setting. More information about such algorithms and about statistical relational learning in general can be found in Getoor and Taskar (2007) and Kersting (2006).

In probabilistic logic learning, two types of semantics are distinguished (De Raedt and Kersting 2003): the model theoretic semantics and the proof theoretic semantics. Approaches that are based on the model theoretic semantics define a probability distribution over interpretations and extend probabilistic attribute-value techniques, such as Bayesian networks and Markov networks, while proof theoretic semantics approaches define a probability distribution over proofs and upgrade, e.g., stochastic context free grammars.

Example 5 Consider the case where each example is a sentence in natural language. In this example, a model theoretic approach would define a probability distribution directly over sentences. A proof theoretic approach would define a probability distribution over "proofs," in this case possible parse trees of the sentence (each sentence may have several possible parses). Note that the proof theoretic view is more general in the sense that the distribution over sentences can be computed from the distribution over proofs.

Stochastic logic programs (SLPs) (Muggleton 1996) follow most closely the proof theoretic view and upgrade stochastic context free grammars to first-order logic. SLPs are logic programs with probabilities attached to the clauses such that the probabilities of clauses with the same head sum to 1.0. The probability of a proof is then computed as the product of the probabilities of the clauses that are used in the proof. PRISM (Sato and Kameya 1997) follows a related approach where the probabilities are defined on ground facts.

Like with standard graphical models, learning algorithms may include both parameter learning (estimating the probabilities) and structure learning (learning the program). For most frameworks mentioned above, such techniques have been or are being developed.

For a more detailed treatment of statistical relational learning and probabilistic logic learning, we refer to the entry on statistical relational learning in this volume, and to several reference works (De Raedt and Kersting 2003; Getoor and Taskar 2007; Kersting 2006; De Raedt et al. 2008).

Relational Reinforcement Learning

Relational reinforcement learning (RRL) (Džeroski et al. 2001; Tadepalli et al. 2004) is reinforcement learning upgraded to the relational setting. Reinforcement learning is concerned with how an agent should act in a given environment to maximize its accumulated reward. In RRL, both the state of the environment and the actions are represented using a relational representation, typically in the form of a logic program.

Much research in RRL focuses on Q-learning, which represents the knowledge of the agent by means of a Q-function mapping state–action pairs to real values. During exploration, the agent selects in each state the action that is ranked highest by the Q-function. The Q-function is typically represented using a relational regression technique. Several techniques, such as relational regression trees, relational instance based learning, and relational kernel based regression have been considered in this context. Note that the regression algorithms must be able to learn incrementally: each time the agent receives a new reward, the Q-function must be incrementally updated for the episode (sequence of state-action pairs) that led to the reward. Due to the use of relational regression techniques, the agent is able to generalize over states: it will perform similar actions in similar states and therefore scales better to large application domains.

More recent topics in RRL include how expert knowledge can be provided to the agent in the form of guidance, and how learned knowledge can be transferred to related domains ("transfer learning"). More details on these techniques and more specific information on the topic of relational reinforcement learning can be found in its corresponding encyclopedia entry and in the related entry on ▶ symbolic dynamic programming, as well as in references Džeroski et al. (2001) and Tadepalli et al. (2004).

Maastricht University, Maastricht, The Netherlands

Synonyms

Learning in worlds with objects; Reinforcement learning in structured domains

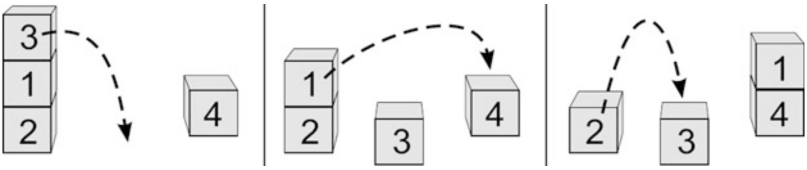
Definition

Relational reinforcement learning is concerned with learning behavior or control policies based on a numerical feedback signal, much like standard reinforcement learning, in complex domains where states (and actions) are largely characterized by the presence of objects, their properties, and the existing relations between those objects. Relational reinforcement learning uses approaches similar to those used for standard reinforcement learning, but extends these with methods that can abstract over specific object identities and exploit the structural information available in the environment.

Motivation and Background

▶ Reinforcement learning is a very attractive machine learning framework, as it tackles, in a sense, the whole artificial intelligence problem at a small scale: an agent acts in an unknown environment and has to learn how to behave optimally by reinforcement, i.e., through rewards and punishment. Reinforcement learning has produced some impressive and promising results. However, the applicability of reinforcement learning has been greatly limited by its difficulty in dealing with large problem spaces and its inability to generalize the learned knowledge to new but related problem domains.

Relational Reinforcement Learning, Fig. 1 Structure of the RRL system



While standard reinforcement learning methods represent the learning environment as a set of unrelated states or, when using ▸ attribute-value representations, as a vector space consisting of a fixed number of independent dimensions, humans tend to think about their environment in terms of objects, their properties, and the relations between them. Examples of objects in everyday life are chairs, people, streets, trees, etc. This representation allows people to treat or use most of the new objects that they encounter correctly, without requiring training time to learn (again) how to use them. For example, people are able to drink their coffee from any cup that will hold it, even if they have never encountered that specific cup before, because they already have experience with drinking their coffee from other cup-type objects. Standard reinforcement learning agents do not have this ability. Their state and action representations do not allow them to abstract away from specific object identities and recognize them as a type of object they are already accustomed to.

Relational reinforcement learning tries to overcome this problem by representing states of the learning agent's environment as sets of objects, their properties, and the relationships between them, similar to the approaches used in ▸ relational learning and ▸ inductive logic programming. These structural representations make it possible for the relational reinforcement learning agent to abstract away from specific identities of objects and often also from the amount of objects present, the exact learning environment, or even the specific task to be performed.

The term "relational reinforcement learning" was introduced by Džeroski et al. (1998) when they first teamed the Q-learning algorithm with a first-order regression algorithm. From then on, relational reinforcement learning gained a large amount of interest.

Structure of the Learning System

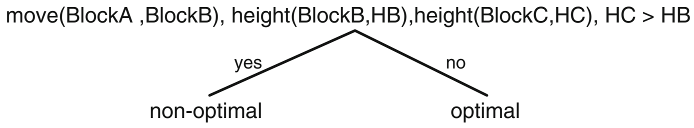
In principle, the structure of a relational reinforcement learning system is very similar to that of standard reinforcement learning systems (Fig. 1). At a high level, the learning agent interacts with an environment by performing actions that influence that environment, and the environment provides the learning agent with a description of its current state and a numerical feedback of the performance of the agent. The goal of the agent is to maximize some cumulative form of this feedback signal. The major difference between standard reinforcement learning and relational reinforcement learning is the representation of the state–action–space. Relational reinforcement learning works on ▸ Markov decision processes where states and actions have been relationally factored, so-called relational Markov decision processes (RMDPs).

An RMDP can be defined as follows:

Definition 1 (Relational Markov Decision Process) Let P_S be a set of state-related predicates, P_A a set of action-related predicates, and C a set of constants in a logic Λ. Let $\mathcal{B}$ be a theory defined in that logic.

An RMDP is defined as $< S, A, T, R >$, where $S \equiv \{s \subset H^{P_S \cup C} | s \models \mathcal{B}\}$ represents the set of states; $A \equiv \{a \subset H^{P_A \cup C} | a \models \mathcal{B}\}$ represents the set of actions, in which H^X is the set of facts that can be constructed given the symbols in X; and T and R represent the transition probabilities and reward function, respectively: $T : S \times A \times S \to [0, 1]$ and $R : S \to \mathbb{R}$.

In less formal language, this means that the states and actions in an RMDP are represented using a set of constants C and a set of predicates P_S and P_A, respectively, and constrained by a background theory $\mathcal{B}$. This means that the background theory $\mathcal{B}$ defines which states are possible



move(BlockA ,BlockB), height(BlockB,HB),height(BlockC,HC), HC > HB
yes
no
non-optimal
optimal

Relational Reinforcement Learning, Fig. 2 Example state–action pairs in the blocks world

in the domain and which actions can be executed in which states.

The following example illustrates these concepts. Consider the blocks world depicted in Fig. 2. To represent this environment in first-order logic, one could use:

- State-related predicates: $P_S = \{\text{on/2, clear/1}\}$
- Action-related predicate: $P_A = \{\text{move/2}\}$
- Constants: $C = \{1,2,3,4,\text{floor}\}$

The set of facts $H^{P_S \cup C}$ would then include, for example, $on(1,2)$, $on(4, floor)$, and $clear(2)$ but also $on(3,3)$ and $on(floor, 2)$. To constrain the possible states to those that actually make sense in a standard, i.e., real-world view of the blocks world, the theory $\mathcal{B}$ can include rules to make states that include these kinds of facts impossible. For example, to make sure that a block cannot be on top of itself, $\mathcal{B}$ could include the following constraint:

$$\texttt{false} \leftarrow on(X, X).$$

One can also include more extensive rules to define the exact physics of the blocks world that one is interested in. For example, by including

$$\texttt{false} \leftarrow on(Y, X), on(Z, X), X \neq floor,$$
$$Y \neq Z$$

as part of the theory $\mathcal{B}$, one can exclude states where two blocks are on top of the same block. The action space given by $H^{P_A \cup C}$ consists of facts such as $move(3,2)$ and $move(floor, 1)$ and can be constrained by rules such as

$$\texttt{false} \leftarrow move(floor, X),$$

which makes sure that the floor cannot be placed on top of a block.

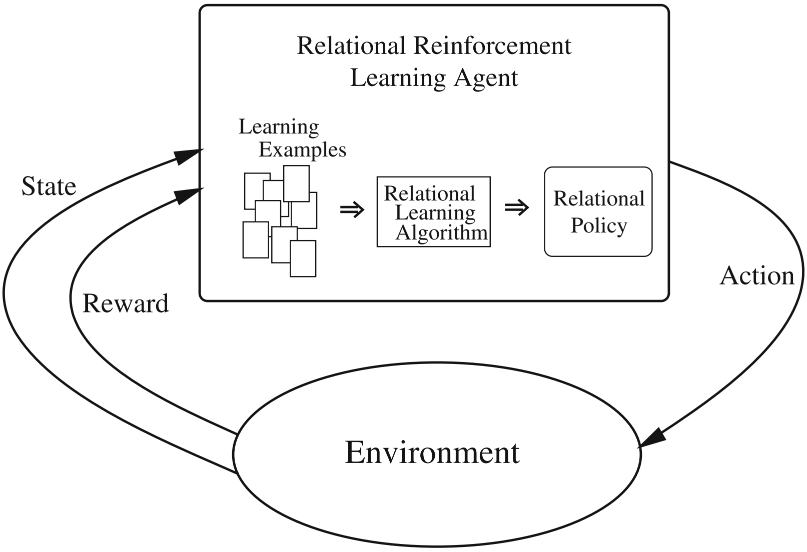
The leftmost state–action pair of Fig. 2 can be fully specified by the following set of facts (state description on the left, action on the right):

on(2,floor).	clear(3).
on(1,2).	clear(4).
on(3,1).	clear(floor).
on(4,floor).	move(3,floor).

One can easily generalize over specific states and create abstract states (or state–action pairs) that represent sets of states (or state–action pairs) by using variables instead of constants and by listing only those parts of states and actions that hold for each element of the abstract state (or state–action pair). For example, the abstract state "$on(1,2), on(2, floor)$" represents all states in which block 1 is on top of block 2, which in turn is on the floor. The abstract state does not specify the locations of any other blocks. Of the three states depicted in Fig. 2, the set of states represented by the abstract state would include the left and middle states. Abstract states can also be represented by using variables when one does not want to specify the location of any specific block, but wants to focus on structural aspects of the states and actions. The abstract state–action pair "$move(X, Y), on(Y, floor)$" represents all state–action pairs where a block is moved on top of another block that is on the floor, for example, the middle and right state–action pairs of Fig. 2.

Benefits of Relational Reinforcement Learning

We already stated that the real world is made of interacting objects or at least that humans often think about the real world as such. Relational reinforcement learning allows this same representation to be used by reinforcement learning agents, which in turn leads to more human-interpretable learning results.



Relational Reinforcement Learning, Fig. 3 Simple relational policy for stacking any number of blocks

As a consequence of the used logical or relational representation of states and actions, the results learned by a relational reinforcement learning agent can be reused more easily when some of the parameters of the learning task change. Because relational reinforcement learning algorithms try to solve the problem at hand at an abstract level, the solutions will often carry over to different instantiations of that abstract problem. For example, the resulting policies learned by the RRL system (Driessens 2004) discussed below, a very simple example of which is shown in Fig. 3, often generalize over domains with a varying number of objects. If only actions which lead to the *optimal* leaf are executed, the shown policy tree will organize any number of blocks into a single stack.

As another example of this, the relational approximate policy iteration approach, also discussed below, is able to learn task-specific control knowledge from random walks in the environment. By treating the resulting state of such a random walk as a goal state and generalizing over the specifics of that goal (and the rest of the random walk), relational approximate policy iteration can learn domain-specific, but goal-independent, policies. This generalization of the policy is accomplished by parameterization of the goal and focusing on the relations between objects in the goal, states, and actions when representing the learned policy.

Another practical benefit of relational reinforcement learning lies in the field of inductive transfer. Transfer learning is concerned with the added benefits of having experience with a related task when being confronted with a new one. Because of the structural representation of learned results, the transfer of knowledge learned by relational reinforcement learning agents can be accomplished by recycling those parts of the results that still hold valid information for the new task. Depending on the relation between the two tasks, this can yield substantial benefits concerning the required training experience.

The use of first-order logic as a representational language in relational reinforcement learning also allows the integration of reasoning methods with traditional reinforcement learning approaches. One example of this is ▸ symbolic dynamic programming, which uses logical regression to compute necessary preconditions that allow an agent to reach certain goals. This same integration allows the use of search or planning knowledge as background information to extend the normal description of states and actions.

Example Relational Reinforcement Learning Approaches

Relational Q-Learning

Relational reinforcement learning was introduced with the development of the RRL system (Džeroski et al. 1998). This is a Q-learning system that employs a relational regression algorithm to generalize the Q-table used by standard Q-learning algorithms into a Q-function. The differences with a standard Q-learning agent are mostly located inside the learning agent. One important difference is the agent's representation of the current state. In relational reinforcement learning, this representation contains structural or relational information about the environment.

Inside the learning agent, the information consisting of encountered states, chosen actions, and the associated rewards is translated into learning examples. These examples are then processed by a relational learning system that produces a relational Q-function and/or policy as a result. The relational representation of the Q-function allows the RRL system to use the structural properties of states and actions when assigning a Q-value to them.

Several relational regression approaches have been developed and applied in this context. While the original approach used an off-the-shelf relational regression algorithm that processed the learning examples in batch and had to be restarted to be able to process newly available learning experiences, a number of incremental algorithms have been developed for use in relational reinforcement learning since then. These include an incremental first-order regression tree algorithm, incremental relational instance-based regression, kernel-based regression that uses Gaussian processes, and graph kernels and algorithms that include combinations of the above (Driessens 2004).

It is possible to translate the learned Q-function approximations into a function that directly represents its policy. Using the values predicted by the learned Q-function, one can generate learning examples that represent state–action pairs and label them as either part of the learned policy or not. This results in a binary classification problem that can be handled by a supervised relational learning algorithm such as TILDE (Blockeel and De Raedt 1998), as used to produce first-order decision tree policies in the original work. This technique is known as P-learning. It exhibits better generalization performance across related learning problems than the Q-learning approach described above. Other than the aforementioned first-order decision trees, rule-based learners have also been applied to this kind of policy learning.

Nonparametric Policy Gradients

Nonparametric policy gradients (Kersting and Driessens 2008), also a model-free approach, apply Friedmann's gradient boosting (Friedman 2001) in an otherwise standard policy gradient approach for reinforcement learning. To avoid having to represent policies using a fixed number of parameters, policies are represented as a weighted sum of regression models grown in a stage-wise optimization. (This allows the number of parameters to grow as the experience of the learner increases, hence the name nonparametric.) While this does not make nonparametric policy gradients a technique specifically designed for relational reinforcement learning, it allows, like the relational Q-learning approach described above, the use of relational regression models and is not constrained to the attribute-value setting of standard policy gradients.

The idea behind the approach is that instead of finding a single, highly accurate policy, it is easier to find many rough rules of thumb of how to change the way the agent currently acts. The learned policy is represented as

$$\pi(s,a) = \frac{e^{\Psi(s,a)}}{\sum_b e^{\Psi(s,b)}} ,$$

where instead of assuming a linear parameterization for Ψ as is done in standard policy gradients, it is assumed that Ψ will be represented by a linear combination of functions. Specifically, one starts with some initial function Ψ_0, e.g., based on the zero potential, and iteratively adds corrections $\Psi_m = \Psi_0 + \Delta_1 + \cdots + \Delta_m$. In contrast to the standard gradient approach, Δ_m here denotes the so-called functional gradient, which is sampled during interaction with the environment and then generalized by an off-the-shelf regression algorithm.

The advantages of policy gradients over value-function techniques are that they can learn non-deterministic policies and that convergence of the learning process can be guaranteed, even when using function approximation (Sutton et al. 2000). Experimental results show that nonparametric policy gradients have the potential to significantly outperform relational Q-learning (Kersting and Driessens 2008).

Relational Approximate Policy Iteration

A different approach, which also directly learns a policy, is taken in relational approximate policy iteration (Fern et al. 2006). Like standard policy iteration (Sutton and Barto 1998), the approach iteratively improves its policy through interleaving evaluation and improvement steps. In contrast to standard policy iteration, it uses a policy language bias and a generalizing policy function.

Instead of building a value-function approximation for each policy evaluation step, relational approximate policy iteration evaluates the current policy and its closely related neighbors by sampling the state–action–space through a technique called policy rollout. This technique generates a set of trajectories from a given state, by executing every possible action in that state and following the current policy for a number of steps afterward. (It is also possible to improve convergence speed by following the next policy.) These trajectories and their associated costs result in a number of learning examples – one for each possible action in each selected state – that can be used, together with the policy language bias to generate the next, improved policy.

Because every possible action in each sampled state needs to be evaluated, this approach does require a model or a resettable simulator of the environment. However, relational approximate policy iteration has been shown to work well for learning domain-specific control knowledge and performs very well on planning competition problems.

Relational Cross Entropy Policy Search

The most recent addition to direct relational policy search uses the cross entropy method to evaluate, select, expand, and combine those pieces of a modular policy that lead to high-performance behavior (Sarjant et al. 2014). The policy pieces are singular condition-action rules. The rules are constructed and adapted automatically using a partial model of the environment inferred from interactions with that environment. The model defines the minimal conditions needed to take an action, the possible specialization conditions per rule, and a set of simplification rules to remove redundant and illegal rule conditions. Rule construction and specialization follow a principled approach toward exploration of the rule space by beginning with the relative least general generalization (RLGG) rules and then exploring incremental specializations of interesting rules.

The cross entropy method (CEM) (Rubinstein 1997) is used to find these interesting rules. CEM tunes the selection probabilities of the rules according to the performance of policies that they participate in. Rules with high selection probabilities also become candidates for specialization, possibly giving rise to even better rules.

The resulting systems can learn behavior that is competitive to specialized approaches on complex tasks, while the built-in simplification of the rules and CEM bias toward compact policies result in comprehensive and effective relational policies.

Symbolic Dynamic Programming

In contrast to the previous techniques, ▶ symbolic dynamic programming (SDP) does not learn a policy through exploration of the environment. Instead, it is a model-based approach that uses knowledge about preconditions and consequences of actions to compute the fastest way to reach a given goal. Like other dynamic programming techniques, SDP starts from the goal the agent wants to reach and reasons backward to find the policy that is needed to reach that goal. In contrast to other dynamic programming techniques, it does not solve specific instantiations of the problem domain, but instead solves the problem at an abstract level, thereby solving it for all possible instantiations of the problem at once.

SDP treats the required goal conditions as an abstract state definition. Because pre- and post-conditions of actions are known, SDP can compute the necessary conditions that allow actions to reach the abstract goal state. These conditions define abstract states from which it is possible to reach a goal state in one step. Starting from these abstract states, the same approach can be used to discover abstract states that allow the goal to be reached in two steps and so on.

This approach was first proposed by Boutilier et al. (2001), implemented as a working system by Kersting et al. (2004), and later improved upon by Sanner and Boutilier (2005). This last approach won second place in the probabilistic programming competition at ICAPS in 2006.

Further Information

The field of relational reinforcement learning has given rise to a number of PhD dissertations in the last few years (Croonenborghs 2009; Driessens 2004; van Otterlo 2008; Sanner 2008). The dissertation of Martijn van Otterlo resulted in a book (van Otterlo 2009) which provides a recent and reasonably complete overview of the relational reinforcement learning research field. Other publications that present an overview of relational reinforcement learning research include the proceedings of the two workshops on representational issues in (relational) reinforcement learning at the International Conferences on Machine Learning in 2004 and 2005 (Driessens et al. 2005; Tadepalli et al. 2004).

Relevance Feedback

Relevance feedback provides a measure of the extent to which the results of a search match the expectations of the user who initiated the query. Explicit feedback require users to assess relevance by choosing one out of a number of choices, or to rank documents to reflect their perceived degree of relevance. Implicit feedback is obtained by monitoring user's behavior such as time spent browsing a document, amount of scrolling performed while browsing a document, number of times a document is visited, etc. Relevance feedback is one the techniques used to support query reformulation and turn the search into an iterative and interactive process.

Reservoir Computing

Risto Miikkulainen
Department of Computer Science, The University of Texas at Austin, Austin, TX, USA

Synonyms

Echo state network; Liquid state machine

Definition

Reservoir computing is an approach to sequential processing where recurrency is separated from the output mapping (Jaeger 2003; Maass et al. 2002). The input sequence activates neurons in a recurrent neural network (a reservoir, where activity propagates as in a liquid). The recurrent network is large, nonlinear, randomly connected, and fixed. A linear output network receives activation from the recurrent network and generates the output of the entire machine. The idea is that if the recurrent network is large and complex enough, the desired outputs can likely be learned as linear transformations of its activation. Moreover, because the output transformation is linear, it is fast to train. Reservoir computing has been successful in particular in speech and language processing and vision and cognitive neuroscience.

Heuristic rewards; Reward selection

Definition

Reward shaping is a technique inspired by animal training where supplemental rewards are provided to make a problem easier to learn. There is usually an obvious natural reward for any problem. For games, this is usually a win or loss. For financial problems, the reward is usually profit. Reward shaping augments the natural reward signal by adding additional rewards for making progress toward a good solution.

Motivation and Background

Reward shaping is a method for engineering a reward function in order to provide more frequent feedback on appropriate behaviors. It is most often discussed in the ▶ reinforcement learning framework. Providing feedback is crucial during early learning so that promising behaviors are tried early. This is necessary in large domains, where reinforcement signals may be few and far between.

A good example of such a problem is chess. The objective of chess is to win a match, and an appropriate reinforcement signal should be based on this. If an agent were to learn chess without prior knowledge, it would have to search for a great deal of time before stumbling onto a winning strategy. We can speed up this process by rewarding the agent more frequently. One possibility is to reward the learner for capturing enemy pieces, and punish the learner for losing pieces. This new reward creates a much richer learning environment, but also runs the risk of distracting the agent from the true goal (winning the game).

Another domain where feedback is extremely important is in robotics and other real-world applications. In the real world, learning requires a large amount of interaction time, and may be quite expensive. Mataric noted that in order to mitigate “thrashing” (repeatedly trying ineffective actions) rewards should be supplied as often as possible (Mataric 1994).

If a problem is inherently described by sparse rewards, it may be difficult to change the reward structure without disrupting progress to the original goal. The behavior that is optimal with a richer reward function may be quite different from the intended behavior, even if relatively small shaping rewards are added. A classic example of this is found in Randlov and Alstrom (1998). While training an agent to control a bicycle simulation, they rewarded an agent whenever it moved toward a target destination. In response to this reward, the agent learned to ride in a tight circle, receiving reward whenever it moved in the direction of the goal.

Theory

We assume a reinforcement learning framework. For every time step t, the learner observes state s_t, takes action a_t, and receives reward r_t. The goal of reinforcement learning is to find a policy $\pi(s)$ that produces actions that optimize some long-term measurement of reward. We define the value function for every state as the expected infinite horizon discounted reward

$$V(s) = \max_{\pi} \mathrm{E}\left[\sum_{t=0}^{\infty} \gamma^t r_t | s_0 = s, a_t = \pi(s_t)\right],$$

where γ is the discount rate. A reinforcement learner's goal is to learn a good estimate of $V(s)$, and to use this estimate to choose a good policy.

A natural reward source should be fairly obvious from the problem at hand. Financial problems should use net monetary gain or loss as reward. Games and goal-directed problems should reward winning the game or reaching the goal. It is usually advantageous to augment this natural reward with a shaping reward f_t. We define the augmented value function V' for the reinforcement learning problem with shaping rewards

$$V'(s) = \max_{\pi'} \mathrm{E}\Bigg[\sum_{t=0}^{\infty} \gamma^t (r_t + f_t)|s_0 \\ = s, a_t = \pi'(s_t)\Bigg].$$

Ideally, the policy that optimizes the augmented value function will differ much from the previous optimal policy.

Constructing an appropriate shaping reward system is inherently a problem-dependent task, though a line of research aids in the implementation of these reward signals. *Potential-based shaping* provides a formal framework for translating imperfect knowledge of the relative value of states and actions into a shaping reward.

Potential-Based Shaping

Ng et al. proposed a method for adding shaping rewards in a way that guarantees the optimal policy maintains its optimality (Ng et al. 1999). They define a potential function $\Phi()$ over the states. The shaping reward f for transitioning from state s to s' is defined as the discounted change in this state potential:

$$f(s, s') = \gamma\Phi(s') - \Phi(s).$$

This potential-based shaping reward is added to the natural reward for every state transition the learner experiences. Call the augmented reward $r'_t = r_t + f(s_t, s_{t+1})$, and the value function based on this reward $V'(s)$. The potential-based shaping concept can also be applied to actions as well as states. See Wiewiora et al. (2003) for details.

It can be shown that the augmented value function is closely related to the original:

$$V'(s) = V(s) - \Phi(s).$$

An obvious choice for the potential function is $\Phi(s) \approx V(s)$, making $V'()$ close to zero. This intuition is strengthened by results presented by Wiewiora (2003). This paper shows that for most reinforcement learning systems, the potential function acts as an initial estimate of the natural value function $V()$.

However, even if the potential function used for shaping is very close to the true natural value function, learning may still be difficult. Koenig et al. have shown that initial estimates of the value function have a large influence on the efficiency of reinforcement learning (Koenig and Simmons 1996). With an initial estimate of the value function set below the optimal value, many reinforcement learning algorithms could require learning time exponential in the state and action space in order to find a highly rewarding state. On the other hand, in nonrandom environments, an optimistic initialization the value function creates learning time that is polynomial in the state-action space before a goal is found.

Definition

▸ Robot learning consists of a multitude of machine learning approaches, particularly ▸ reinforcement learning, ▸ inverse reinforcement learning, and ▸ regression methods, that have been adapted sufficiently to domain so that they allow learning in complex robot systems such as helicopters, flapping-wing flight, legged robots, anthropomorphic arms, and humanoid robots. While classical artificial intelligence-based robotics approaches have often attempted to manually generate a set of rules and models that allows the robot systems to sense and act in the real world, ▸ robot learning centers around the idea that it is unlikely that we can foresee all interesting real-world situations sufficiently accurate. Hence, the field of ▸ robot learning assumes that future robots need to be able to adapt to the real world, and domain-appropriate machine learning might offer the most approach in this direction.

Robot Learning Systems

As learning has found many backdoor entrances to robotics, this section can only scratch the surface. However, robot learning has clearly been successful in several areas: (i) model learning, (ii) imitation and apprenticeship learning, and (iii) reinforcement learning as well as in various other topics.

Model Learning

Model learning is the machine learning counterpart to classical system identification (Farrell and Polycarpou 2006; Schaal et al. 2002). However, while the classical approaches heavily rely on the structure of physically based models, specification of the relevant state variables, and hand-tuned approximations of unknown nonlinearities, model learning approaches avoid many of these labor-intensive steps and the entire process to be more easily automated. Machine learning and system identification approaches often assume an observable state of the system to estimate the mapping from inputs to outputs of the system. However, a learning system is often able to learn this mapping including the statistics needed to cope with unidentified state variables and can hence cope with a larger class of systems. Two types of models are commonly learned, i.e., forward and inverse models.

Forward models predict the behavior of the system based either on the current state or a history of preceding observations. They can be viewed as "learned simulators" that may be used for optimizing a policy or for predicting future information. Examples of the application of such learned simulators range from the early work in the late 1980s by Atkeson and Schaal in robot arm-based cart pole swing-ups to Ng's recent extensions for stabilizing an inverted helicopter. Most forward models can directly be learned by ▸ regression.

Conversely, *inverse models* attempt to predict the input to a system in order to achieve a desired output in the next step, i.e., it uses the model of the system to directly generate control signals. In traditional control, these are often called approximation-based control systems (Farrell and Polycarpou 2006). Inverse model learning can be straightforwardly by ▸ regression when the system dynamics can be inverted uniquely, e.g., as in inverse dynamic learning for a fully actuated system. However, for underactuated or redundantly actuated systems (Tedrake 2009), operational space control (Peters and Schaal 2008a), etc., such unique inverses do not exist and additional optimization is needed.

Imitation and Apprenticeship Learning

A key problem in robotics is to ease the problem of programming a complex behavior. Traditional robot programming approaches rely on accurate, manual modeling of the task and removal of all uncertainties so that they work well. In contrast to classical robot programming, learning from demonstration approaches aims at recovering the instructions directly from a human demonstration. Numerous unsolved problems exist in this context such as discovering the intent of the teacher or determining the mapping from the teacher's kinematics to the robot's kinematics (often called the correspondence problem). Two different approaches are common in this area, i.e., direct imitation learning and apprenticeship learning.

In *imitation learning* (Schaal et al. 2003), also known as ▸ behavioral cloning, the robot system directly estimates a policy from a teachers presentation, and, subsequently, the robot system reproduces the task using this policy. A key advantage of this approach is that it can often learn a task successfully from few demonstrations. In areas where human demonstrations are straightforward to obtain, e.g., for learning racket sports, manipulation, drumming on anthropomorphic systems, direct imitation learning often proved to be an appropriate approach. Its major shortcomings are that it cannot explain why the derived policy is a good one, and it may struggle with learning from noisy demonstrations.

Hence, *apprenticeship learning* (Coates et al. 2009) has been proposed as an alternative where a reward function is used as explanation of the teachers' behavior. Here, the reward function is chosen under which the teacher appears to act optimally, and the optimal policy for this reward function is subsequently computed as a solution. This approach transforms the problem of learning from demonstrations onto the harder problem of approximate optimal control or reinforcement learning; hence it is also known as inverse optimal control or ▸ inverse reinforcement learning. As a result, it is limited to problems that can be solved by current reinforcement learning methods. Additionally, it often has a hard time dealing with tasks where only few demonstrations with low variance exist. Hence, inverse reinforcement learning has been particularly successful in areas where it is hard for a human to demonstrate the desired behavior such as for helicopter acrobatics or in robot locomotion.

Further information on learning by demonstration may be found in Coates et al. (2009) and Schaal et al. (2003).

Robot Reinforcement Learning

The ability to self-improve with respect to an arbitrary reward function, i.e., ▸ reinforcement learning, is essential for robot systems to become more autonomous. Here, the system learns about its policy by interacting with its environment and receiving scores (i.e., rewards or costs) for the quality of its performance. Unlike supervised learning approaches used in model learning or imitation learning, reinforcement learning can still be considered to be in its infancy. Few off-the-shelf reinforcement learning methods scale into the domain of robotics both in terms of dimensionality and the number of trials needed to obtain an interesting behavior. Three different but overlapping styles of reinforcement learning can be found in robotics, i.e., model-based reinforcement learning, ▸ value function approximation methods, and direct ▸ policy search.

Model-based reinforcement learning relies upon a learned forward model used for simulation-based optimization as discussed before. While often highly efficient, it frequently suffers from the fact that learned models are imperfect, and hence, the optimization method can be guaranteed to be biased by the errors in the model. To date, a full Bayesian treatment of the model uncertainty appears to be a promising way for alleviating this shortcoming of this otherwise powerful approach.

Value function approximation methods have been the core approach used in reinforcement learning during the 1990s. These techniques rely upon approximating the expected rewards for every possible action in every visited state. Subsequently, the controller chooses the actions in accordance to this value. Such approximation requires a globally consistent value function where the quality of the policy is determined by the largest error of the value function at any possible state. As a result, these methods have been problematic for anthropomorphic robotics as the high-dimensional domains often defy learning such a global construct. However, it has been highly successful in low-dimensional domains such as mobile vehicle control and robot soccer, as well as on well-understood test domains such as cart-pole systems.

Unlike the previous two approaches, *policy search* attempts to directly learn the optimal policy from experience without solving intermediary learning problems. Policies often have significantly fewer parameters than models or value functions. For example, for balancing a ball on a plate (where the plate is mounted on a robot end effector) optimally with respect to a quadratic reward function, the number of policy parameters grows linearly in the number state dimensions, while it grows quadratically for both model and value function for this analytically tractable problem (in general cases, the number of parameters of value functions grows exponentially in the number of states which is known as the "curse of dimensionality"). This insight has given rise to policy search methods, particularly, ▸ policy gradient methods and probabilistic approaches to policy search such as the reward-weighted regression or PoWER. To date, application results of direct policy search approaches range from gait optimization in locomotion to various motor learning examples (e.g., Kendama, T-Ball, or throwing darts).

Further information on reinforcement learning for robotics may be found in Tedrake et al. (2004), Peters and Schaal (2008b), and Riedmiller et al. (2009).

Application Domains

The possible application domains for robot learning have not been fully explored, one could even aggressively state that we have barely started to bring learning into robotics. Nevertheless, robot learning has been successful in several application domains.

For accurate execution of desired trajectories, model learning has scaled to learning the full inverse dynamics for a humanoid robot in real time more accurately than achievable with physical models. Current work focusses mainly on improving the concurrent execution of tasks as well as control of redundant or underactuated systems.

Various approaches have been successful in task learning. Learning by demonstration approaches is moving increasingly toward industrial grade solutions where fast training of complex tasks becomes possible. Skills ranging from motor toys, e.g., basic movements, paddling a ball, etc., to complex tasks such as cooking a complete meal, basic table tennis strokes, helicopter acrobatics, or foot placement in locomotion have been learned from human teachers. Reinforcement learning has yielded better gaits in locomotion, jumping behaviors for legged robots, perching with fixed wing flight robots, forehands in table tennis, as well as various applications to learning of motor toys.

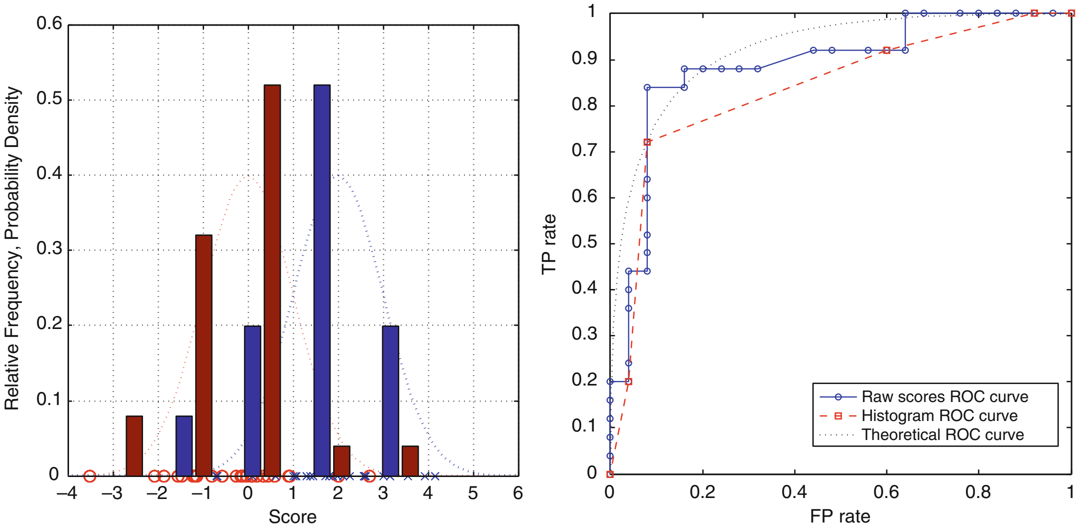
ROC Analysis, Fig. 1 The table on the *left* gives the scores assigned by a classifier to 10 positive and 10 negative examples. Each threshold on the classifier's score results in particular true and false positive rates, e.g., thresholding the score at 0.5 results in three misclassified positives ($tpr = 0.7$) and three misclassified negatives ($fpr = 0.3$); thresholding at 0.65 yields $tpr = 0.6$ and $fpr = 0.1$. Considering all possible thresholds gives the ROC curve on the *right*; this curve can also be constructed without explicit reference to scores, by going down the examples sorted on decreasing score and making a step up (to the *right*) if the example is positive (negative)

and false positive rates. Varying the decision threshold from its maximal to its minimal value results in a piecewise linear curve from $(0, 0)$ to $(1, 1)$, such that each segment has a nonnegative slope (Fig. 1). This *ROC curve* is the main tool used in ROC analysis. It can be used to address a range of problems, including: (1) determining a decision threshold that minimizes ▶ error rate or misclassification cost under given class and cost distributions; (2) identifying regions where one classifier outperforms another; (3) identifying regions where a classifier performs worse than chance; (4) obtaining calibrated estimates of the class posterior.

Motivation and Background

ROC analysis has its origins in *signal detection theory* (Egan 1975). In its simplest form, a detection problem involves determining the value of a binary signal contaminated with random noise. In the absence of any other information, the most sensible decision threshold would be halfway between the two signal values. If the noise distribution is zero centered and symmetric, sensitivity and specificity at this threshold have the same expected value, which means that the corresponding *operating point* on the ROC curve is located at the intersection with the descending diagonal $tpr + fpr = 1$. However, we may wish to choose different operating points, for instance, because false negatives and false positives have different costs. In that case, we need to estimate the noise distribution.

A slight reformulation of the signal detection scenario clarifies its relevance in a machine learning setting. Instead of superimposing random noise on a deterministic signal, we can view the resulting noisy signal as coming from a ▶ mixture distribution consisting of two compo-



ROC Analysis, Fig. 2 (*left*) Artificial classifier "scores" for two classes were obtained by sampling 25 points each from two ▶ Gaussian distributions with mean 0 and 2 and unit variance. The figure shows the raw scores on the x-axis and normalized histograms obtained by uniform five-bin discretization (*right*) The jagged ROC curve was obtained by thresholding the raw scores as before. The histogram gives rise to a smoothed ROC curve with only five segments. The *dotted line* is the theoretical curve obtained from the true Gaussian distributions

nent distributions with different means. The detection problem is now to decide, given a received value, from which component distribution it was drawn. This is essentially what happens in a binary ▶ classification scenario, where the scores assigned by a trained classifier follow a mixture distribution with one component for each class. The random variations in the data are translated by the classifier into random variations in the scores, and the classifier's performance depends on how well the per-class score distributions are separated. Figure 2 illustrates this for both discrete and continuous distributions. In practice, empirical ROC curves and distributions obtained from a test set are discrete because of the finite resolution supplied by the test set. This resolution is further reduced if the classifier only assigns a limited number of different scores, as is the case with ▶ decision trees; the histogram example illustrates this.

Solutions

For convenience, we will assume henceforth that score distributions are discrete and that decision thresholds always fall between actual scores (the results easily generalize to continuous distributions using probability density functions). There is a useful duality between thresholds and scores: decision thresholds correspond to operating points connecting two segments in the ROC curve, and actual scores correspond to segments of the ROC curve connecting two operating points. Let $f(s|+)$ and $f(s|-)$ denote the relative frequency of positive (negative) examples from a test set being assigned score s. (Note that s itself may be an estimate of the likelihood $p(x|+)$ of observing a positive example with feature vector x. We will return to this later.)

Properties of ROC Curves

The first property of note is that the true (false) positive rate achieved at a certain decision threshold t is the proportion of the positive (negative) score distribution to the right of the threshold; that is, $tpr(t) = \sum_{s>t} f(s|+)$ and $fpr(t) = \sum_{s>t} f(s|-)$. In Fig. 2, setting the threshold at 1 using the discretized scores gives a true positive rate of 0.72 and a false positive rate of 0.08, as can be seen by summing the bars of the histogram to the right of the threshold. Although the ROC curve does not display thresholds or scores, this allows us to reconstruct the range of thresholds yielding a particular operating point from the score distributions.

If we connect two distinct operating points on an ROC curve by a straight line, the slope of that line segment is equal to the ratio of positives to negatives in the corresponding score interval; that is,

$$slope(t_1, t_2) = \frac{tpr(t_2) - tpr(t_1)}{fpr(t_2) - fpr(t_1)} = \frac{\sum_{t_1<s<t_2} f(s|+)}{\sum_{t_1<s<t_2} f(s|-)}$$

Choosing the score interval small enough to cover a single segment of the ROC curve corresponding to score s, it follows that the segment has slope $f(s|+)/f(s|-)$. This can be verified in Fig. 2, e.g., the top-right segment of the smoothed curve has slope 0 because the leftmost bin of the histogram contains only negative examples. For continuous distributions, the slope of the ROC curve at any operating point is equal to the ratio of probability densities at that score.

It can happen that $slope(t_1, t_2) < slope(t_1, t_3) < slope(t_2, t_3)$ for $t_1 < t_2 < t_3$, which means that the ROC curve has a "dent" or *concavity*. This is inevitable when using raw classifier scores (unless the positives and negatives are perfectly separated), but can also be observed in the smoothed curve in the example: the rightmost bin of the histogram has a positive-to-negative ratio of 5, while the next bin has a ratio of 13. Consequently, the two leftmost segments of the ROC curve display a slight concavity. What this means is that performance can be improved by combining those two bins, leading to one large segment with slope 9. In other words, ROC curve concavities demonstrate locally suboptimal behavior of a classifier. An extreme case of suboptimal behavior occurs if the entire curve is concave or at least below the ascending diagonal: in that case, performance can simply be improved by assigning all test instances the same score, resulting in an ROC curve that follows the ascending diagonal. A *convex* ROC curve is one without concavities.

The AUC Statistic

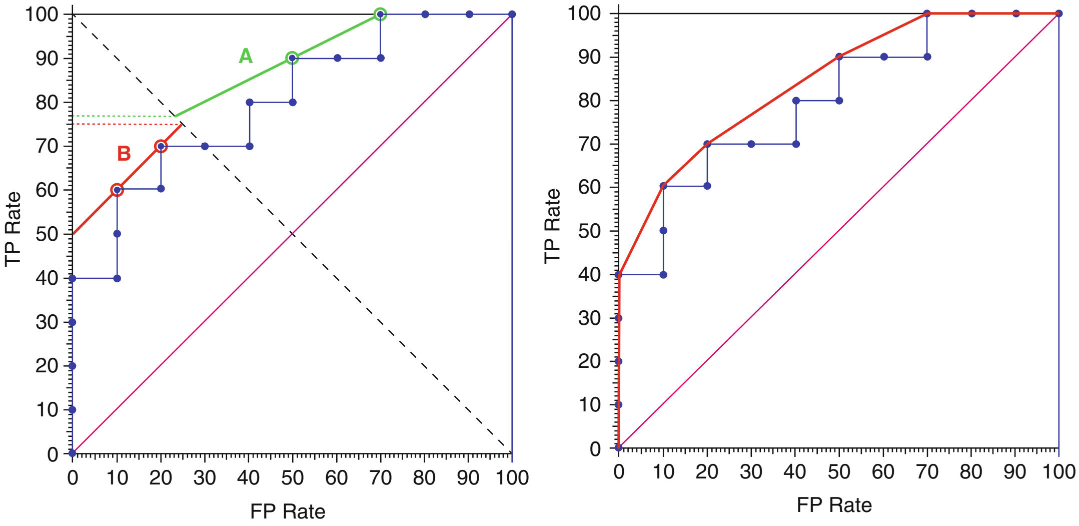
The most important statistic associated with ROC curves is the *area under (ROC) curve* or *AUC*. Since the curve is located in the unit square, we have $0 \leq AUC \leq 1$. $AUC = 1$ is achieved if the classifier scores every positive higher than every negative; $AUC = 0$ is achieved if every negative is scored higher than every positive. $AUC = 1/2$ is obtained in a range of different scenarios, including: (i) the classifier assigns the same score to all test examples, whether positive or negative, and thus the ROC curve is the ascending diagonal; (ii) the per-class score distributions are similar, which results in an ROC curve close (but not identical) to the ascending diagonal; and (iii) the classifier gives half of a particular class the highest scores and the other half the lowest scores. Notice that, although a classifier with *AUC* close to one half is often said to perform randomly, there is nothing random in the third classifier: rather, its excellent performance on some of the examples is counterbalanced by its very poor performance on some others (Sometimes a linear rescaling $2 \cdot AUC - 1$ called the *Gini coefficient* is preferred, which has a related use in the assessment of income or wealth distributions using Lorenz curves: a Gini coefficient close to 0 means that income is approximately evenly distributed. Notice that this Gini coefficient is often called the Gini index, but should not be confused with the impurity measure used in ▸ decision tree learning).

AUC has a very useful statistical interpretation: it is the expectation that a (uniformly) randomly drawn positive receives a higher score than a randomly drawn negative. It is a normalized version of the *Wilcoxon-Mann-Whitney sum of ranks test*, which tests the null hypothesis that two samples of ordinal measurements are drawn from a single distribution. The "sum of ranks" epithet refers to one method to compute this statistic, which is to assign each test example an integer rank according to decreasing score (the highest-scoring example gets rank 1, the next gets rank 2, etc.); sum up the ranks of the n^- negatives, which we want to be high; and subtract $\sum_{i=1}^{n^-} i = n^-(n^- + 1)/2$ to achieve 0 if all negatives are ranked first. The *AUC* statistic is then obtained by normalizing by the number of pairs of one positive and one negative, n^+n^-. There are several other ways to calculate *AUC*, for instance, we can calculate, for each negative, how many positives precede it, which basically is a columnwise calculation and yields an alternative view of *AUC* as the expected true positive rate if the operating point is chosen just before a randomly drawn negative.

Identifying Optimal Points and the ROC Convex Hull

In order to select an operating point on an ROC curve, we first need to specify the objective function we aim to optimize. In the simplest case, this will be ▶ accuracy, the proportion of correctly predicted examples. Denoting the proportion of positives by *pos*, we can express accuracy as a weighted average of the true positive and true negative rates $pos \cdot tpr + (1 - pos)(1 - fpr)$. It follows that points with the same accuracy lie on a straight line with slope $a = (1 - pos)/pos$; these parallel lines are the *isometrics* for accuracy (Peter 2003). In order to find the optimal operating point for a given class distribution, we can start with an accuracy isometric through $(0, 1)$ and slide it down until it touches the ROC curve in one or more points (Fig. 3 (left)). In the case of a single point, this uniquely determines the operating point and thus the threshold. If there are several points in common between the accuracy isometric and the ROC curve, we can make an arbitrary choice or interpolate stochastically. We can read off the achieved accuracy by intersecting the accuracy isometric with the descending diagonal, on which $tpr = 1 - fpr$, and therefore the true positive rate at the intersection point is equal to the accuracy associated with the isometric.

We can generalize this approach to any objective function that is a linear combination of true and false positive rates. For instance, let predicting class i for an instance of class j



ROC Analysis, Fig. 3 (*left*) The slope of accuracy isometrics reflects the class ratio. Isometric A has slope 1/2: this corresponds to having twice as many positives as negatives, meaning that an increase in true positive rate of x is worth a $2x$ increase in false positive rate. This selects two optimal points on the ROC curve. Isometric B corresponds to a uniform class distribution and selects optimal points which make fewer positive predictions. In either case, the achieved accuracy can be read off on the y-axis after intersecting the isometric with the descending diagonal (slightly higher for points selected by A). (*right*) The convex hull selects those points on an ROC curve which are optimal under some class distribution. The slope of each segment of the convex hull gives the class ratio under which the two end points of the segment yield equal accuracy. All points under the convex hull are non-optimal incur cost $cost(i|j)$, so, for instance, the cost of a false positive is $cost(+|-)$ (profits for correct predictions are modeled as negative costs, e.g., $cost(+|+) < 0$). Cost isometrics then have slope

$$\frac{cost(+|-) \; - \; cost(-|-)}{cost(-|+) \; - \; cost(+|+)}$$

Nonuniform class distributions are simply taken into account by multiplying the class and cost ratio, giving a single *skew ratio* expressing the relative importance of negatives compared to positives.

This procedure of selecting an optimal point on an ROC curve can be generalized to select among points lying on more than one curve or even an arbitrary set of points (e.g., points representing different categorical classifiers). In such scenarios, it is likely that certain points are never selected for any skew ratio; such points are said to be *dominated*. For instance, points on a concave region of an ROC curve are dominated. The nondominated points are optimal for a given closed interval of skew ratios and can be joined to form the *convex hull* of the given ROC curve or set of ROC points (Fig. 3 (right)); in multi-objective optimization, this concept is called the *Pareto front*. This notion of the ROC convex hull (sometimes abbreviated to ROCCH) is extremely useful in a range of situations. For instance, if an ROC curve displays concavities, the convex hull represents a discretization of the scores which achieves higher AUC. Alternatively, the convex hull of a set of categorical classifiers can be interpreted as a hybrid classifier that can reach any point on the convex hull by stochastic interpolation between two neighboring classifiers (Foster and Tom 2001).

Obtaining Calibrated Estimates of the Class Posterior

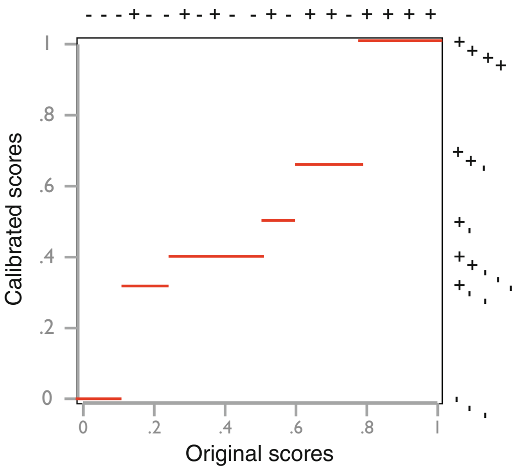
Recall that each segment of an ROC curve has slope $slope(s) = f(s|+)/f(s|-)$, where s is the score associated with the segment, and $f(s|+)$ and $f(s|-)$ are the relative frequencies of positives and negatives assigned score s. Now consider the function

$$\begin{aligned} cal(s) &= \frac{pos \cdot f(s|+)}{pos \cdot f(s|+) \; + \; (1-pos) \cdot f(s|-)} \\ &= \frac{slope(s)}{slope(s) + a} \end{aligned}$$

with $a = (1-pos)/pos$. The *calibration map* $s \mapsto cal(s)$ adjusts the classifier's scores to reflect the empirical probabilities observed in the test set. If the ROC curve is convex, $slope(s)$ and $cal(s)$ are monotonically nonincreasing with decreasing s, and thus replacing the scores s with $cal(s)$ does not change the ROC curve (other than merging neighboring segments with different scores but the same slope into a single segment).

Consider ▸ decision trees as a concrete example. Once we have trained (and possibly pruned) a tree, we can obtain a score in each leaf l by taking the proportion of positive training examples in that leaf: $score(l) = p(+|l)/(p(+|l) + p(-|l))$. Each leaf of the tree then gives rise to a different segment of the ROC curve, which, by the nature of how the scores were calculated, will be convex. Furthermore, we have that $cal(score(l)) = score(l)$, which means that the tree produces posterior probabilities that are perfectly calibrated with respect to the training set. If we anticipate changes in class distribution, we may choose to calibrate with a different a. For example, if we use $a = 1$, the calibrated scores $cal(score(l))$ are adjusted for a uniform prior.

If the ROC curve is not convex, the mapping $s \mapsto cal(s)$ is not monotonic; while the scores $cal(s)$ would lead to improved performance on the data from which the ROC curve was derived, this is very unlikely to generalize to other data and thus leads to ▸ overfitting. This is why, in practice, a less drastic calibration procedure involving the convex hull is applied (Tom and Alexandru 2007). Let s_1 and s_2 be the scores associated with the start and end segments of a concavity, i.e., $s_1 > s_2$ and $slope(s_1) < slope(s_2)$. Let $slope(s_1 s_2)$ denote the slope of the line segment of the convex hull that repairs this concavity, which implies $slope(s_1) < slope(s_1 s_2) < slope(s_2)$. The calibration map will then map any score in the interval $[s_1, s_2]$ to $slope(s_1 s_2)/(slope(s_1 s_2) + 1)$ (Fig. 4).



ROC Analysis, Fig. 4 The piecewise constant calibration map derived from the convex hull in Fig. 3. The original score distributions are indicated at the *top* of the figure, and the calibrated distributions are on the *right*. We can clearly see the combined effect of binning the scores and redistributing them over the interval [0, 1]

This ROC-based calibration procedure, which is also known as *isotonic regression* (Barbara and Charles 2002), not only produces calibrated probability estimates but also improves AUC. This is in contrast with other calibration procedures such as logistic calibration which do not bin the scores and therefore do not change the ROC curve. ROC-based calibration can be shown to achieve the lowest *Brier score* (Glenn 1950), which measures the mean squared error in the probability estimates as compared with the ideal probabilities (1 for a positive and 0 for a negative), among all probability estimators that do not reverse pairwise rankings. On the other hand, being a nonparametric method, it typically requires more data than parametric methods in order to estimate the bin boundaries reliably. See ▶ Classifier Calibration for further details.

Future Directions

ROC analysis in its original form is restricted to binary ▶ classification, and its extension to more than two classes gives rise to many open problems. c-class ROC analysis requires $c(c-1)$ dimensions, in order to distinguish each possible misclassification type. Srinivasan proved that basic concepts such as the ROC polytope and its linearly interpolated convex hull generalize to the c-class case (Ashwin 1999). In theory, the volume under the ROC polytope can be employed for assessing the quality of a multi-class classifier (César et al. 2003), but this volume is hard to compute as – unlike the two-class case, where the segments of an ROC curve can simply be enumerated in $O(n \log n)$ time by sorting the n examples on their score (Tom 2006; Peter 2004) – there is no simple way to enumerate the ROC polytope. Mossman considers the special case of three-class ROC analysis, where for each class the two possible misclassifications are treated equally (a so-called one-versus-rest scenario) (Douglas 1999). Hand and Till propose the average of all one-versus-rest AUCs as an approximation of the area under the ROC polytope (David and Robert 2001). Various algorithms for minimizing a classifier's misclassification costs by reweighting the classes are considered in Nicolas and Peter (2003) and Chris et al. (2008).

Other research directions include the explicit visualization of misclassification costs (Chris and Robert 2006) and using ROC analysis to study the behavior of machine learning algorithms and the relations between machine learning metrics (Johannes and Peter 2005).

ROC Convex Hull

The convex hull of an ▶ ROC curve is a geometric construction that selects the points on the curve that are optimal under some class and cost distribution. It is analogous to the Pareto front in multiobjective optimization. See ▶ ROC Analysis.

ROC Curve

The ROC curve is a plot depicting the trade-off between the ▶ true positive rate and the ▶ false positive rate for a classifier under varying decision thresholds. See ▶ ROC Analysis.

Rotation Forests

Rotation Forests is an ▶ ensemble learning technique. It is similar to the ▶ Random Forests approach to building decision tree ensembles. In the first step, the original feature set is split randomly into K disjoint subsets. Next, ▶ principal components analysis is used to extract n principal component dimensions from each of the K subsets. These are then pooled, and the original data projected linearly into this new feature space. A tree is then built from this data in the usual manner. This process is repeated to create an ensemble of trees, each time with a different random split of the original feature set.

As the tree learning algorithm builds the classification regions using hyperplanes parallel to the feature axes, a small rotation of the axes may lead to a very different tree. The effect of rotating the axes is that classification regions of high accuracy can be constructed with far fewer trees than in ▶ Bagging and ▶ Adaboost.

Rule Learning

Johannes Fürnkranz
Knowledge Engineering Group, TU Darmstadt,
Darmstadt, Deutschland
Department of Information Technology,
University of Leoben, Leoben, Austria

Abstract

Informally, rule learning denotes all algorithms that learn or discover patterns in data, which are formulated in the form of a ▸ rule. These can be predictive (e.g., ▸ classification rules) or descriptive rules (e.g., ▸ association rules or ▸ supervised descriptive rule induction). Consequently, the learning algorithms typically differ in the type of search they use for finding these rules in the search space. Exhaustive search is more common in descriptive rule mining, whereas heuristic search using a variety of quality criteria is more commonly used in predictive rule learning. An overview of the field can be found in Fürnkranz et al. (2012).

Learning Individual Rules

Conceptually, rule learning may be viewed as a search in the space of possible ▸ rules. The first algorithms, such as the candidate elimination algorithm, aimed at identifying the ▸ version space of all complete and consistent rules (Mitchell 1982). ▸ Association rule discovery algorithms look for all rules that satisfy certain constraints, typically all rules with a minimum coverage and a minimum support. Most flexible are algorithms that use heuristic search for optimizing given quality criteria. Such algorithms are also often used in ▸ supervised descriptive rule induction.

```
procedure FindBestRule(Examples,BestRule)

Input: Examples, a set of positive and negative examples
for a class c.

InitRule = InitializeRule(Examples)
InitVal = EvaluateRule(InitRule)
BestRule = <InitVal,InitRule>
Rules = {BestRule}
while Rules ≠ ∅ do
    Candidates = SelectCandidates(Rules,
    Examples)
    Rules = Rules \ Candidates
    for Candidate ∈ Candidates do
        Refinements = RefineRule(Candidate,
        Examples)
        for Refinement ∈ Refinements do
            Evaluation = EvaluateRule(Refinement,
            Examples)
            if StoppingCriterion(Refinement,
              Examples)
                then next Refinement
            NewRule = <Evaluation,Refinement>
            Rules = InsertSort(NewRule, Rules)
            if NewRule > BestRule
            then BestRule = NewRule
        endfor
    endfor
    Rules = FilterRules(Rules, Examples)
endwhile

Output: BestRule
```

FindBestRule is a prototypical algorithm that searches for a rule which optimizes a given quality criterion defined in EvaluateRule. The value of this heuristic function is the higher the more positive and the less negative examples are covered by the candidate rule. FindBestRule maintains *Rules*, a sorted list of candidate rules, which is initialized by the procedure InitializeRule. New rules will be inserted in appropriate places (InsertSort), so that *Rules* will always be sorted in decreasing order of the heuristic evaluations of the rules. At each cycle, SelectCandidates selects a subset of these candidate rules, which are then refined using the refinement operator RefineRule. Each refinement is evaluated and inserted into the sorted *Rules* list unless the StoppingCriterion prevents this. If the evaluation of the *NewRule* is better than the best rule found previously, *BestRule* is set to *NewRule*. FilterRules selects the subset of the ordered rule list that will be used in subsequent iterations. When all candidate rules have been processed, the best rule will be returned.

Different choices of these functions allow the definition of different biases for the separate-and-conquer learner. The search bias is defined by the choice of a search strategy (InitializeRule and RefineRule), a search algorithm (SelectCandidates and FilterRules), and a search heuristic (EvaluateRule). The refinement operator RefineRule constitutes the language bias of the algorithm. An overfitting avoidance bias can be implemented via some StoppingCriterion and/or in a post-processing phase.

For example, InitializeRule and RefineRule may be defined so that they realize a top-down (general-to-specific), a bottom-up (specific-to-general), or a bidirectional search. Exhaustive breadth-first, depth-first, or best-first searches can be realized by appropriate choices of EvaluateRule and no filtering or candidate selection. FilterRules can, e.g., be used to realize a hill-climbing or ▸ beam search by maintaining only the best or the *BeamWidth* best rules. Evolutionary algorithms and stochastic local search can also be easily realized.

The most common algorithm for finding the best rule is a top-down hill-climbing algorithm. It basically constructs a rule by consecutively adding conditions to the rule body so that a given quality criterion is greedily optimized. This constitutes a simple greedy hill-climbing algorithm for finding a local optimum in the hypothesis space defined by the feature set. InitializeRule will thus return the most general rule, the rule with the body {`true`}, and RefineRule will return all possible extensions of the rule by a single condition. FilterRules will only let the best refinement pass for the next iteration, so that SelectCandidates will always have only one choice. The search heuristic, the StoppingCriterion, and the post-processing are discussed in the next sections.

Rule Learning Heuristics

The goal of rule learning is to find a rule or a ▸ rule set that is as *complete* and *consistent* as possible. Thus, each rule should cover as many positive examples and as few negative examples as possible. A few important ones are (assume that p out of P positive examples and n out of N negative examples are covered by the rule):

Laplace estimate (Lap $= \frac{p+1}{p+n+2}$) computes the fraction of positive examples in all covered examples, where each class is initialized with one virtual example in order to penalize rules with low coverage.

***m*-Estimate** (m $= \frac{p+m\cdot P/(P+N)}{p+n+m}$) is a generalization of the Laplace estimate which uses m examples for initialization, which are distributed according to the class distribution in the training set (Cestnik 1990).

Information gain (ig $= p\cdot(\log_2 \frac{p}{p+n} - \log_2 \frac{p'}{p'+n'})$, where p' and n' are the number of positive and negative examples covered by the rule's predecessor) is Quinlan's (1990) adaptation of the information gain heuristic used for decision tree learning. The main difference is that this only focuses on a single branch (a rule), whereas the decision tree version tries to optimize all branches simultaneously.

correlation and χ^2 (corr$=\frac{p(N-n)-(P-p)n}{\sqrt{PN(p+n)(P-p+N-n)}}$) computes the four-field correlation of covered/uncovered positive/negative examples. It is equivalent to a χ^2 statistic ($\chi^2 = (P+N)\,\text{corr}^2$).

An exhaustive overview and theoretical comparison of various search heuristics in coverage space, a variant of ROC space can be found in Fürnkranz and Flach (2005).

Overfitting Avoidance

It is trivial to find a rule set that is complete and consistent on the training data. To achieve this, one only needs to convert each positive example into a rule. Each of these rules is consistent (provided the data set is not inconsistent), and collectively they cover the entire example set (completeness). However, this is clearly a bad case of ▸ overfitting because the theory will not generalize to new positive examples.

Overfitting is to some extent handled by the search heuristics described above, but most algorithms use additional ▸ pruning techniques. One can discriminate between *pre-pruning* techniques, where a separate criterion is used to filter out unpromising rules. For example, CN2 computes the *likelihood ratio statistic* lrs $= 2 \cdot (p \log \frac{p}{e_p} + n \log \frac{n}{e_n})$, where $e_p = (p + n)\frac{P}{P+N}$ and $e_n = (p+n)\frac{N}{P+N} = (p+n) - e_p$ are the number of positive and negative examples one could expect if the $p + n$ examples covered by the rule were distributed in the same way as the $P + N$ examples in the full data set. This statistic follows a χ^2 distribution, which allows to filter out rules for which the distribution of the covered examples is not statistically significantly different from the distribution of examples in the full data set. Other pre-pruning criteria are simple thresholds that define a minimum acceptable value for the search heuristic or FOIL's ▸ minimum description length criterion that relates the length of a rule to the number of examples it covers.

However, it can be shown experimentally that CN2 or FOIL still has a tendency to overfit the data. Instead, state-of-the-art algorithms post-prune a rule right after it has been learned. For this purpose, one-third of the training data are reserved for pruning. After a rule has been learned, its accuracy is greedily simplified on the pruning set. Simplifications can be the deletion of the last condition, a final sequence of conditions, or an arbitrary condition of the rule. If the simplification does not decrease the accuracy of the rule on the pruning set, it will be performed. This so-called *incremental reduced error pruning* algorithm (Fürnkranz and Widmer 1994) is used in the rule learning algorithm RIPPER.

A survey and experimental comparison of pruning techniques for rule learning can be found in Fürnkranz (1997).

Learning Rule Sets

In many cases, rule learning is used for solving a ▸ classification problem via the induction of a ▸ rule set or a ▸ decision list. In these cases, individual rules are learned as above but then combined to form a theory that is able to classify all examples. The principal approach is the so-called ▸ covering or ▸ separate-and-conquer algorithm, which learns one rule at a time, successively removing the covered examples. Individual algorithms within this framework differ primarily in the way they learn single rules.

An obvious generalization of covering is to not entirely remove covered examples but to reduce their example ▸ weights, thus decreasing their importance in subsequent iterations (see, e.g., the SLIPPER algorithm (Cohen and Singer 1999)).

Rules can also be learned by alternative strategies. There have been numerous proposals, and we can only mention the most influential. Each path from the root to a leaf of a ▸ decision tree corresponds to a rule and so rules can be learned by first learning a decision tree and then post-processing it (see, e.g., the C4.5RULES algorithm, (Quinlan 1993)). It is also possible to use the ▸ Apriori algorithm for an exhaustive search for classification rules and to use a subsequent covering algorithm to combine the rules into a rule set (see, e.g., the CBA algorithm (Liu et al. 1998)). RISE (Domingos 1996) combines bottom-up generalization with ▸ nearest neighbor algorithms to learn a theory via "conquering without separating."

Well-Known Rule Learning Algorithms

AQ can be considered as the original covering algorithm. Its original version was conceived by Ryszard Michalski in the 1960s (Michalski 1969), and numerous versions and variants of the algorithm appeared subsequently in the literature. AQ uses a top-down beam search for finding the best rule. It does not search all possible specializations of a rule but only considers refinements that cover a particular example, the so-called *seed example*. This idea is basically the same as the use of a ▸ bottom clause in ▸ inductive logic programming.

CN2 (Clark and Niblett 1989; Clark and Boswell 1991) employs a beam search guided by the Laplace or m-estimates, and the abovementioned likelihood ratio significance test to fight overfitting. It can operate in two modes, one for learning ▸ rule sets (by modeling each class independently) and one for learning ▸ decision lists.

FOIL (Quinlan 1990) was the first relational learning algorithm that received attention beyond the field of ▸ inductive logic programming. It learns a concept with the covering loop and learns individual concepts with a top-down refinement operator, guided by information gain. The main difference to previous systems is that FOIL allowed the use of first-order background knowledge. Instead of only being able to use tests on single attributes, FOIL could employ tests that compute relations between multiple attributes and could also introduce new variables in the body of a rule.

RIPPER was the first rule learning system that effectively countered the overfitting problem via *incremental reduced error pruning*, as described above. It also added a post-processing phase for optimizing a rule set in the context of other rules. The key idea is to remove one rule out of a previously learned rule set and try to relearn it not only in the context of previous rules (as would be the case in the regular covering rule) but also in the context of subsequent rules. RIPPER is still state of the art in inductive rule learning. A freely accessible re-implementation can be found in the WEKA machine learning library under the name of JRIP.

OPUS (Webb 1995) was the first rule learning algorithm to demonstrate the feasibility of a full exhaustive search through all possible rule bodies for finding a rule that maximizes a given quality criterion (or heuristic function). The key idea is the use of *ordered search* that prevents that a rule is generated multiple times. This means that even though there are $l!$ different orders of the conditions of a rule of length l, only one of them can be taken by the learner for finding this rule. In addition, OPUS uses several techniques that prune significant parts of the search space, so that this search method becomes feasible. Follow-up work has shown that this technique is also an efficient alternative for ▸ association rule discovery, provided that the database to mine fits into the memory of the learning system.

CBA was one of the first and best-known algorithms that employed association rule learning algorithms for learning predictive rules (Liu et al. 1998). In its simplest version, the algorithm selects the final rule sets by sorting all class association rules according to confidence and incrementally adding rules to the final set until all examples are covered or the quality of the rule set decreases.

Rule Set

Johannes Fürnkranz
Knowledge Engineering Group, TU Darmstadt,
Darmstadt, Deutschland
Department of Information Technology,
University of Leoben, Leoben, Austria

Abstract

A rule set is a collection of individual ▶ classification rules that collectively form a classifier. In contrast to a ▶ decision list, the rules in the set do not have an inherent order, and all rules in the set have to be tried for deriving a prediction for an example.

Discussion

This may cause two types of problems that have to be resolved with additional algorithms:

Multiple rules fire: More than one rule can fire on a single example, and these rules can make contradicting predictions. This type of conflict is typically resolved by preferring rules that cover a higher fraction of training examples of their class (typically estimated with Laplace correction, see ▶ rule learning). This is equivalent to converting the rule set into a decision list that is ordered according to this evaluation heuristic. More elaborate tie-breaking schemes, such as using a *Naive Bayes* algorithm, or inducing a separate rule set for handling these conflicts (*double induction* (Lindgren and Boström 2004)), have also been tried.

No rule fires: It may also occur that no rule fires for a given example. Such cases are typically handled via a so-called *default rule*, which typically predicts the majority class. Again, a more complex algorithm, such as trying to find the closest rule (*rule stretching* (Eineborg and Boström 2001)), has been proposed.

A rule set that only contains rules for a single class, as is the result of ▶ concept learning problems, typically contains an implicit default rule for the other class (very much like a Prolog program). If all rules are conjunctive, such rule sets may be interpreted as a definition in *disjunctive normal form* for this class.

Samuel's Checkers Player

Definition

Samuel's Checkers Player is the first machine learning system that received public recognition. It pioneered many important ideas in game playing and machine learning. The two main papers describing his research (Samuel 1959, 1967) became landmark papers in Artificial Intelligence. In one game, the resulting program was able to beat one of America's best players of the time.

Description of the Learning System

Samuel's checkers player featured a wide variety of learning techniques. First, his checkers player remembered positions that it frequently encountered during play. This simple form of *rote learning* allowed it to save time, and to search deeper in subsequent games whenever a stored position was encountered on the board or in some line of calculation. Next, it featured the first successful application of what is now known as ▶ Reinforcement Learning for tuning the weights of its evaluation function. The program trained itself by playing against a stable copy of itself. After each move, the weights of the evaluation function were adjusted in a way that moved the evaluation of the root position after a quiescence search closer to the evaluation of the root position after searching several moves deep. This technique is a variant of what is nowadays known as Temporal-Difference Learning and commonly used in successful game-playing programs. Samuel's program not only tuned the weights of the evaluation but also employed on-line ▶ Feature Selection for constructing the evaluation function with the terms that seem to be the most significant for evaluating the current board situation. ▶ Feature Construction was recognized as the key problem that still needs to be solved. Later, Samuel changed his evaluation function from a linear combination of terms into a structure that closely resembled a 3-layer ▶ Neural Network. This structure was trained with ▶ Preference Learning from several thousand positions from master games.

Search Engines: Applications of ML

Eric Martin
University of New South Wales, Sydney, NSW, Australia

Abstract

The general structure of a search engine is described. An overview of those information retrieval methods that are relevant to web search in that they take the existence of hyperlinks between documents into account, is provided. A suggested classification of web queries as either navigational, transactional, or informational has been suggested. More generally, a good understanding of users' needs and practice allows for query rewriting or for redirection to domain-specific databases.

Definition

Search engines provide users with Internet resources—links to websites, documents, text snippets, images, videos, . . .—in response to queries. They use techniques that are part of the field of information retrieval and rely on statistical and pattern matching methods. Search engines have to take into account many key aspects and requirements of this specific instance of the information retrieval problem. First is the fact that they have to be able to process hundreds of millions of searches a day and answer queries in a matter of milliseconds. Second is the fact that the resources on the World Wide Web are constantly updated, with information being continuously added, removed, or changed—the overall contents changing by up to 8 % a week—in a pool consisting of billions of documents. Third is the fact that users will express possibly semantically complex queries in a language with limited expressive power and often not make use or proper use of available syntactic features of that language—for instance, the Boolean *or* operator occurs in less than 3 % of queries.

Motivation and Background

Web searching is technically initiated by sending a query to a search engine, but the whole search process starts earlier, in the mind of the person who conducts the search. To be successful, the process needs to provide users with words, text snippets, images, or movies that fulfill the users' quest for information. So even though a search is technically the implementation of a procedure that maps a query to some digital material, it spans a larger spectrum of activities, from a psychological trigger to a psychological reward. For a given set of digital material that, if provided, would be deemed perfectly satisfactory by a number of users looking for the same information, different users will issue different queries. That might be because they have varying skills at conveying what they are after in the form of a few words. That might be because their understanding of the technology prompts them to formulate what they are after in a form that, rightly or wrongly, they consider appropriate for a computing device to process. That might be for a number of different reasons that all point to the fact that the quality of the search is not determined by its adequacy to the query, but by its adequacy to the psychological trigger that produced the query. This makes web searching an especially challenging and exciting area in the field of ▶ information retrieval.

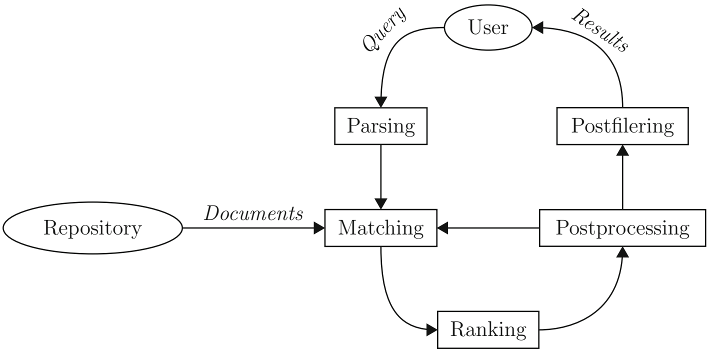
In Andrei (2002), it is suggested that web queries can be classified in three classes.

- **Navigational queries** expect the search to return a particular URL. For instance, http://www.cityrail.info is probably the expected result to the query `Cityrail` for a Sydneysider.
- **Transactional queries** expect the search to return links to sites that offer further interaction, for example, for online shopping or to download music. For instance, http://www.magickeys.com/books/, where books for young children are available for download, is probably a good result to the query `children stories`.
- **Informational queries** expect the search to reveal a piece of information that is the correct answer to a question. This piece of information can be immediately provided in the page where theresults of the search are displayed, as, for instance, `Bern` for the query `capital of switzerland`. Or it can be provided in the pages accessible from the first links returned by the search, as for instance, `Italy` that is easily found in the web page accessed from the first link returned in response to the query `football world champion 1982`.

Answering an informational query with the information itself, rather than with links to documents where the information is to be found, is one of the most difficult challenges that search engine developers have addressed. Some argue that the final goal is to deliver the best possible content that a user would like to have in a given moment and that instead of pulling information, information be pushed to the user depending on the context (Ricardo and Prabhakar 2010).

Structure of the Learning System

The general structure of a search engine can be illustrated as follows:



A ▶ string matching algorithm is applied to the parsed query issued by the user and to an indexed representation of a set of documents, resulting in a ranked subset of the latter. This ranked set of documents can be subjected to a postprocessing procedure whose aim is to improve the results by either refining the query or by analyzing further the documents, possibly over many iterations, until the results stabilize and can be returned to the user, following a postfiltering procedure to display the information appropriately.

Retrieval Methods

What distinguishes search engines from other information retrieval applications is the existence of hyperlinks between documents. All techniques developed in the field of information retrieval are potentially relevant for extracting information from the web, but will benefit from a proper analysis of the cross-reference structure. That is, to measure the degree of relevance of a document to a given query, one can take advantage of a prior ranking of all documents independent of that query or any other, following a sophisticated version of the PageRank (Lawrence et al. 1999) link analysis algorithm. One of the simplest versions of the algorithm recursively defines the PageRank PR(T) of a page T which pages $T_1, \ldots, T_n$ point to, among the $c_1, \ldots, c_n$ pages $T_1, \ldots, T_n$ point to, respectively, as

$$\frac{1-d}{N} + d(\mathrm{T}_1/c_1 + \cdots + \mathrm{T}_\mathrm{n}/c_n)$$

where N is the total number of pages and d, a *damping factor*, represents the probability that a user decides to follow a link rather than randomly visit another page; normalizing the solution so that the PageRanks of all pages add up to 1, PR(T) then represents the probability that a user visits T by clicking on a link.

Boolean retrieval is one of the simplest methods to retrieve a set of documents that match exactly a query expressed as a Boolean combination of keywords. The match is facilitated by using an *inverted file* indexing structure which associates every possible keyword with links to the documents in which it occurs (Justin and Alistair 2006). If extra information is kept on the occurrences of keywords in documents (number of occurrences, part of the document in which they occur, font size and font type used for their display, etc.), then the results can also be ranked. But *best match* models, as opposed to *exact match* models, are better suited to producing ranked results. The *vector space* model is one of the earliest and most studied models of this kind. It represents documents and queries as vectors over a space each of whose dimensions represents a possible keyword and measures the similarity between the vectors $\vec{q}$ and $\vec{d}$ that record for each keyword whether it occurs at least once in query and document, respectively, as the cosine of the angle formed by $\vec{q}$ and $\vec{d}$, namely,

$$\frac{\vec{q}.\vec{d}}{\|\vec{q}\|.\|\vec{d}\|},$$

that is all the most closer to 1 that query and document have more in common. The *term-frequency-inverse-document-frequency* (tf-idf) model refines the encoding given by $\vec{d}$ by replacing a value of 1 in the ith dimension, indicating the existence of an occurrence of the ith keyword in $\vec{d}$, with

$$c_1.\log\left(\frac{N}{c_2}\right)$$

where c_1 is the number of occurrences of the ith keyword in the document, N is the total number of documents, and c_2 is the number of documents in the whole collection that contains at least one occurrence of the ith keyword; so more weight is given to keywords that occur more and that occur "almost exclusively" in the document under consideration. One of the most obvious issues with this approach is that the number of dimensions is huge and the vectors are sparse. Another important issue is that set of vectors determined by the set of keywords is not orthogonal and not even linearly independent, because two given keywords can be synonyms (sick and ill), not semantically related (garlic and manifold), or more or less semantically related (wheel and tire).

The *extended vector space* model (Wong et al. 1987) addresses this issue assuming that the similarity between two keywords is captured by the symmetric difference between the set of documents that contain a keyword and the set of documents that contain the other, ranging from identical sets (similar keywords) to disjoint sets (unrelated keywords). Let $D_1, \ldots, D_{N'}$ be an enumeration of the quotient relation over the set of all documents such that two documents are equivalent if they contain precisely the same keywords (so N' is at most equal to N, the number of documents in the whole collection). Conceive an N'-dimensional vector space S which $D_1, \ldots, D_{N'}$ is a basis of. Associate the ith keyword with the vector $\vec{v_i}$ of S defined as $\frac{1}{\sqrt{w_1^2+\cdots+w_{N'}^2}}(w_1, \ldots, w_{N'})$ where for all nonzero

$k \leq N'$, w_k is the number of occurrences of the ith keyword in all documents that belong to class D_k. Then associate a document with the vector $\vec{d}$ of S defined as $\alpha_1 \vec{v}_1 + \cdots + \alpha_{N''} \vec{v}_{N''}$ where N'' is the number of keywords, and for all nonzero $k \leq N''$, α_k is the number of occurrences of the ith keyword in that document, and associate a query with the vector $\vec{q}$ of S defined as $\beta_1 \vec{v}_1 + \cdots + \beta_{N''} \vec{v}_{N''}$ where for all nonzero $k \leq N''$, β_k is equal to 1 if the ith keyword occurs in the query and to 0 otherwise. The similarity between $\vec{q}$ and $\vec{d}$ is then measured as described for the simple vector space method.

The *topic-based vector space* model (Jörg and Dominik 2003) also replaces the original vector space with a different vector space of a different dimension, addressing the issue of nonorthogonality between keywords, thanks to *fundamental topics*, assumed to be pairwise independent, using ontologies; the fundamental topics then provide the vector basis which a given keyword is a linear combination of. So the topic-based vector space model conceives the meaning of words as the semantic relationships that emerge from the common use of a language by the members of a given community, whereas the extended vector space model conceives the meaning of words as the syntactic relationship of term co-occurrence with respect to the repository of documents being processed.

Probabilistic retrieval frameworks aim at estimating the probability that a given document is relevant to a given query. Given a keyword w, denote by p_w^+ the probability that w occurs in a document relevant to w, and denote by p_w^- the probability that w occurs in a document not relevant to w. Many probabilistic retrieval frameworks then define the relevance of a document to a query as follows, where $w_1, \ldots, w_n$ are the keywords that occur both in the query and in the document:

$$\sum_{i=1}^{n} \log\left(\frac{p_{w_i}^+ (1 - p_{w_i}^-)}{p_{w_i}^- (1 - p_{w_i}^+)}\right).$$

This quantity increases all the more that the document contains more words more likely to occur in relevant documents and more words less likely to occur in irrelevant documents. Different frameworks suggest different ways to evaluate the values of $p_{w_i}^+$ and $p_{w_i}^-$. For instance, p_i is sometimes assumed to be constant and $p_{w_i}^-$ defined as n_i/N where N is the total number of documents and n_i the number of documents in which w_i occurs, capturing the fact that a document containing a keyword appearing in few other documents is likely to be relevant to that keyword, in which case the previous formula can be rewritten

$$c \times \sum_{i=1}^{n} \log\left(\frac{N - n_i}{n_i}\right).$$

for some constant c. More sophisticated methods have been developed to better estimate the probabilities, such as the *Okapi weighting document score* (Stephen et al. 1999) which defines the relevance of a document to a query as

$$\sum_{i=1}^{n} \log\left(\frac{N - n_i + 0.5}{n_i + 0.5}\right). \\ \frac{(k_1 + 1)c_i}{\left(k_1(1-b) + b\frac{l}{\beta}\right) + c_i} \cdot \frac{(k_3 + 1)d_i}{k_3 + d_i}$$

where the notation is as above, with the addition of c_i to denote the number of occurrences of w_i in the document, d_i to denote the number of occurrences of w_i in the query, l to denote the number of bytes in the document, β to denote the average number of bytes in a document, and b, k_1, and k_3 to denote constants.

Query Classification

The development of effective methods of information retrieval from web resources requires a good understanding of users' needs and practice. In Karen (2007a), the following questions are identified as being especially relevant toward gaining such an understanding:

> *What characterizes the queries that end users submit to online IR systems? What search features do people use? What features would enable them to improve on the retrievals they have*

> *in hand? What features are hardly ever used? What do end users do in response to the systems retrievals?*

This paper indicates that many of the basic features of information retrieval systems are poorly used. For instance, less than 15 %, 3 %, and 2 % of queries make use of the *and*, *or*, and *not* Boolean operators, respectively, and less than 15 % of queries of enclosing quotes; the wrong syntax is often used, resulting in incorrect use of advanced search features in one third of the cases; less than 10 % of queries take advantage of ▶ relevance feedback. Based on those findings, the second part (Karen 2007b) of the article suggests *two-dozen new research questions* for researchers in information retrieval while noting that about 70 % of users are satisfied with their search experience.

Evaluating search satisfaction has received lots of attention. In Steve et al. (2005), both explicit and implicit measures of satisfaction are collected. Explicit measures are obtained by prompting the user to evaluate a search result as satisfying, partially satisfying, or not satisfying and similarly to evaluate satisfaction gained from a whole search session. Implicit measures are obtained by recording mouse and keyboard actions, time spent on a page, scrolling actions and durations, number of visits to a page, position of page in results list, number of queries submitted, number of results visited, etc. A Bayesian model can be used to infer the relationships between explicit and implicit measures of satisfaction. This paper reports on two ▶ Bayesian networks that were built to predict satisfaction for individual page visits and satisfaction for entire search sessions—w.r.t. the feedback obtained from both kinds of prompts—with evidence that a combination of well-chosen implicit satisfaction measures can be a good predictor of explicit satisfaction. Referring to the categorization of web queries in Andrei (2002) as *user goals*, it is proposed in Uichin et al. (2005) to build *click distributions* by sorting results to a query following the numbers of clicks they received from all users and suggested that highly skewed distributions should correspond to navigational queries, while flat distributions should correspond to informational queries. The same kind of considerations are also applied to *anchor-link distributions*, the anchor-link distribution of a query being defined as the function that maps a URL to the number of times that URL is the destination of an anchor that has the same text as the query.

Finer techniques of query classification are proposed in Steven et al. (2007), where a rule-based automatic classifier is produced from *selectional preferences*. A query consisting of at least two keywords is split into a head x and a tail y and then converted into a *forward* pair (x, u) and a *backward* pair (u, y) where u represents a category, that is, a generic term that refers to a list of semantically related words in a thesaurus. For instance, the query "interest rate" can (only) be split into (interest, rate) and converted to the forward pair (interest, personal finance) where "personal finance" denotes the list consisting of the terms "banks," "rates," "savings," etc; so the first keyword—"interest"–provides context for the second one. Given a large query log, the *maximum likelihood estimate* (MLE) of $P(u/x)$, the probability that a query decomposed as (x, z) is such that z belongs to category u, is defined as the quotient between the number of queries in the log that have (x, u) as a forward pair and the number of queries in the log that can be decomposed as (x, z). This allows one to write a forward rule of the form "x Y classified as u with weight p" where p is the MLE of $P(u/x)$, provided that the *selectional preference strength* of x be above some given threshold. The rule can then be applied to incoming queries, such as "interest only loan" by matching a final or initial segment of the query—depending on whether forward or backward rules are under consideration—and suggest possible classifications; with the running example, "interest only loan" would then be classified as "personal finance with weight p" if a forward rule of the form "interest *Y* classified as personal finance with weight p" had been discovered. Such a classification can then be used to rewrite the query or to send it to an appropriate database backend if many domain-specific databases are available.

Synonyms

Kohonen maps; Self-organizing feature maps; SOM

Definition

Self-organizing map (SOM), or Kohonen Map, is a computational data analysis method which produces nonlinear mappings of data to lower dimensions. Alternatively, the SOM can be viewed as a ▶ clustering algorithm which produces a set of clusters organized on a regular grid. The roots of SOM are in neural computation (see ▶ neural networks); it has been used as an abstract model for the formation of ordered maps of brain functions, such as sensory feature maps. Several variants have been proposed, ranging from dynamic models to Bayesian variants. The SOM has been used widely as an engineering tool for data analysis, process monitoring, and information visualization, in numerous application areas.

Motivation and Background

The SOM (Kohonen 1982, 2001) was originally introduced in the context of modeling of how the spatial organization of brain functions forms. Formation of feature detectors selective to certain sensory inputs, such as orientation-selective visual neurons, had earlier been modeled by ▶ competitive learning in neural networks, and some models of how the feature detectors become spatially ordered had been published (von der Malsburg 1973). The SOM introduced an *adaptation kernel* or *neighborhood function* that governs the adaptation in such networks; while in plain competitive learning only the winning neuron that best matches the inputs adapts, in SOM all neurons within a local neighborhood of the winner learn. The neighborhood is determined by the neighborhood function. The SOM is an algorithm for computing such ordered mappings.

While some of the motivation of the SOM comes from neural computation, its main uses have been as a practical data analysis method. The SOM can be viewed as a topographic vector quantizer, a nonlinear projection method, or a clustering method. In particular, it is a clustering-type algorithm that orders the clusters. Alternatively, it is a nonlinear projection-type algorithm that clusters, or more specifically quantizes, the data.

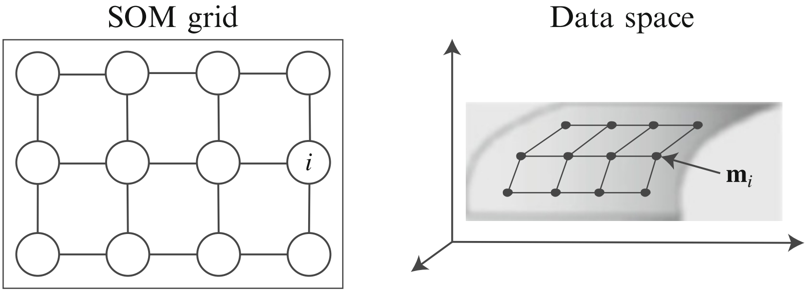
The SOM was very popular in the 1990s and still is; it is intuitively relatively easily understandable, yet hard to analyze thoroughly. It connects many research traditions and works well in practice. An impressive set of variants have been published over the years, of which probabilistic variants (e.g., Bishop et al. (1998) and Heskes (2001)) are perhaps closest to the current mainstream machine learning. While there currently are excellent alternative choices for many of the specific tasks SOMs have been applied for over the years, even the basic SOM algorithm is still viable as a versatile engineering tool in data-analysis tasks.

Structure of Learning System

The SOM consists of a regular grid of nodes (Fig. 1). A *model* of data has been attached to each node. For vector-valued data $\mathbf{x} = [x_1, \ldots, x_d]^T$, the models are vectors in the same space; the model at the ith node is $\mathbf{m}_i = [m_{i1}, \ldots, m_{id}]$. The models define a mapping from the grid to the data space. The coordinates on the grid are uniquely determined by the index i of a node, and the model $\mathbf{m}_i$ gives the location in the data space. The whole grid becomes mapped into an “elastic net” in the data space. While being a mapping from the grid to the input space, the SOM defines a projection from the input space to the discrete grid locations as well; each data point is projected to the node having the closest model.

The original online SOM algorithm updates the model vectors toward the current input vector at time t,

$$\mathbf{m}_i(t+1) = \mathbf{m}_i(t) + h_{ci}(t)(x(t) - \mathbf{m}_i(t)).$$



Self-Organizing Maps, Fig. 1 A schematic diagram showing how the SOM grid of units (*circles* on the *left*, neighbors connected with *lines*) corresponds to an “elastic net” in the data space. The mapping from the grid locations, determined by the indices i, to the data space is given by the model vectors $\mathbf{m}_i$ attached to the units i

Here c is the index of the unit having the closest model vector to $\mathbf{x}(t)$, and $h_{ci}(t)$ is the neighborhood function or adaptation kernel. The kernel is a decreasing function of the distance between the units i and c on the grid; it forces neighboring units to adapt toward similar input samples. The height and width of h are decreasing functions of time t. In an iteration over time and over the different inputs, the model vectors become ordered and specialize to represent different regions of the input space.

The online version of ▶ K-means clustering is a special case of the SOM learning rule, where only the closest model vector is adapted. That is, the neighborhood function is $h_{ci}(t) = \alpha(t)$ for $i = c$ and $h_{ci} = 0$ otherwise. Here $\alpha(t)$ is the adaptation coefficient, a decreasing scalar. In short, K-means and SOM use the prototypes in the same way, but in SOM the prototypes have an inherent order that stems from fixing them onto a grid and updating the prototypes to represent both the data mapped to themselves and to their neighbors.

A neural interpretation of the SOM adaptation process is that the nodes are feature detector neurons or processing modules that in a ▶ competitive learning process become specialized to represent different kinds of inputs. The neighborhood function is a plasticity kernel that forces neighboring neurons to adapt at the same time. The kernel transforms the discrete set of feature detectors into feature maps analogous to ordered brain maps of sensor inputs, and more generally to maps of more abstract properties of the input data.

A third interpretation of the SOM is as a vector quantizer. The task of a vector quantizer is to encode inputs with indexes of prototypes, often called codebook vectors, such that a distortion measure is minimized. If there is noise that may change the indexes, the distribution of the noise should be used as the neighborhood function, and then the distortion becomes minimized by a variant of SOM (Luttrell 1994). In summary, the SOM can be viewed as an algorithm for producing codebooks ordered on a grid.

While it has turned out to be hard to rigorously analyze the properties of the SOM algorithm (Fort 2006), its fixed points may be informative. In a fixed point the models must fulfill

$$m_i = \frac{\sum_x h_{c(x),i}\,\mathbf{x}}{\sum_{\mathbf{x}} h_{c(\mathbf{x},i)}},$$

that is, each model vector is in the centroid of data projected to it and its neighbors. The definition of a *principal curve* (Hastie et al. 2001), a nonlinear generalization of principal components (see ▶ Principal Component Analysis), essentially is that the curve goes through the centroid of data projected to it. Hence, one interpretation of the SOM is a discretized, smoothed, nonlinear generalization of principal components. In short, SOMs aim to describe the variation in the data nonlinearly with their discrete grids.

Finally, a popular prototype-based classifier, ▶ learning vector quantization (LVQ) (Kohonen 2001), can be loosely interpreted as a variant of SOMs, although it does not have the neighborhood function and hence, the prototypes do not have an order.

Programs and Data

The SOM has been implemented in several commercial packages and as freeware. Two examples, SOM_PAK written in C and Matlab SOM Toolbox (http://www.cis.hut.fi/research/software) came from Kohonen's group.

Applications

The SOM can be used as a nonlinear dimensionality reduction method, by projecting each data vector into the grid location having the closest model vector. An image of the grid can be used for *information visualization*. Since all grid locations are clusters, the SOM display actually visualizes an ordered set of clusters, or a quantized image of the principal manifold in data. More specifically, the SOM units can be thought of as subclusters, and data clusters may form larger areas on the SOM grid.

SOM-based visualizations can be used for illustrating the proximity relationships of data vectors, such as documents in the WEBSOM document maps (Kohonen et al. 2000), or monitoring the change of a system such as an industrial process or the utterances of a speaker, as a trajectory on the SOM display. More applications can be found in a collected bibliography (the latest one is Pöllä et al. 2009).

Abstract

In this article, we present the topic of semantic annotation of text using open semantic resources. We present an introduction to the concept and its history, provide basic notions around semantic annotations and open semantic resources, in particular illustrating commonly used open semantic resources repositories such as Wikipedia, Wordnet, or DB-Pedia. Further, we discuss the issues around creating open semantic resources, both from the annotation perspective, and from the format perspective. Finally, we introduce two well-known semantic annotation tasks, entity linking (or named entity disambiguation), and semantic parsing, with corresponding sample implementations, explaining in particular how they work and how make use of open semantic resources.

Synonyms

Synopsis: Text annotation is the association of metadata to fragments of text. When the associated metadata provides a model for interpreting the fragment of text, we talk about *semantic annotation of text*. A common case is the use of knowledge extracted from thesauri, or ontologies to provide the machine with structure and inference mechanisms for the meaning of the text under consideration (Völkel et al. 2006).

The spreading of the Semantic Web (Berners-Lee et al. 2001) and Linked Open Data (http://linkeddata.org/) movements led to the adoption of open data sets having well defined for semantic annotations. Examples include disambiguation of word senses using knowledge bases or the analysis of the actions and roles described in a fragment of text.

Introduction

Semantic annotations are used to improve the quality of several applications including text classification, question answering, machine reading, and understanding. They are used in a variety of domains including, media, genomics marketing, and social policies. (Uren et al. 2006).

Using *open semantic resources* for semantic annotation has become common in the state-of-the-art semantic annotation systems. Open semantic resources provide an accessible framework for people and applications to link structured semantic information to text, effectively allowing ideas like the Semantic Web to come alive, offering an exponentially large set of annotated documents (Völkel et al. 2006). An exemplar is Wikipedia, which provides a large corpus of semi-structured text associated with concepts and entities, wide multilingual coverage, and a large network of internal links providing both structure and a dictionary of surface forms for the linked concepts and entities. At the same time, Wikipedia offers limited breadth in specific domains and an uneven distribution of quality and thoroughness throughout concepts and languages (Bradesko et al. 2015).

Background Knowledge

In this section, we present examples of different types of open semantic resources. Further, we show some of the problems typically encountered when obtaining annotated corpora and finally problems associated with the representation of annotations.

The most used repositories of open semantic resources fall in two categories, *lexical databases* and *knowledge bases*. Lexical databases are repositories of words and metadata associated with them. Knowledge bases, instead, are organized collections of structured data and their relationships. Examples of lexical databases include *WordNet* and *FrameNet* (https://framenet.icsi.berkeley.edu/fndrupal/about).

WordNet is a lexical database where words are related through synonymy and are grouped into *synsets*, sets of terms having the same meaning. Synsets are related by hyperonimy (ISA relationship), meronimy (part-whole relationship), and antinomy (opposite relationship), among the others (Fellbaum 2005).

FrameNet is a lexical database that is both human and machine readable, containing more than 10,000 word senses, and more than 170,000 manually annotated sentences provide a unique training data set for *semantic role labeling* (Gildea and Jurafsky 2002). FrameNet is based on the frame semantics theory (Baker et al. 1998) in which meaning is conveyed with a semantic frame structure that includes the type of an event, the participants, and their roles and relations. For example, the frame *apply heat* is used in the context of cooking and contains *frame elements* (FEs): *cook*, *food*, *heating instrument*, and *container*. Words such as *fry*, *bake*, and *boil*, are called *lexical units* (LUs) of the *apply heat* frame and are used to detect if the sentence should be interpreted in the context of the specified frame.

Knowledge bases, instead, constitute part of the critical infrastructure of a knowledge system. Knowledge bases are traditionally studied in knowledge representation and reasoning that, according to Brachman *et al.*, is "the area of artificial Intelligence (AI) concerned with how knowledge can be represented symbolically and manipulated in an automated way by reasoning programs" (Brachman and Levesque 2004). Notable open knowledge bases used in semantic annotation systems include DBPedia, YAGO, and Wikidata. DBPedia is a large-scale, multilingual knowledge base created by extracting structured data from Wikipedia editions in 111 languages. The DBPedia project maps Wikipedia infoboxes from 27 different language editions to a single shared ontology consisting of 320 classes and 1,650 properties. DBPedia has more than 27 million links to other open data repositories via the `owl::sameas` relation, including common sense ontologies and government data (Lehmann et al. 2015). YAGO is another ontology automatically built from Wikipedia, with links to Geonames (http://geonames.org) and WordNet. Among other things, it features spatial and temporal knowledge and inference, and as in the case of DBpedia, it covers different languages (Mahdisoltani et al. 2015).

The other knowledge base mentioned, Wikidata, was created as the knowledge base of Wikipedia. Later, it absorbed the popular collaborative knowledge base Freebase (Bollacker et al. 2008). Wikidata is the central data management platform of Wikipedia. The data are highly interlinked and connected to many other data sets, and, since 2014, RDF exports that connect Wikidata to the Linked Data Web are available (Erxleben et al. 2014). Other open knowledge bases worth mentioning include BabelNet (http://babelnet.org) and OpenCyc (http://opencyc.org).

While knowledge bases provide the resources for systems to perform semantic annotations, corpora annotated with those resources are necessary to train evaluate the performance of systems. Manually annotated corpora are difficult and expensive to build, as exemplified by the CLEF corpus (Roberts et al. 2007), a set of structured and unstructured annotated health records. Examples of corpora annotations with open semantic resources include the data sets released for the shared tasks of the Conference on Natural Language Learning (CoNLL) (Surdeanu et al. 2008; Hajič et al. 2009) as the treebanks made available for semantic parsing or named entities and semantic role labeling. As mentioned before, Wikipedia, together with its derivative knowledge bases, constitutes one of the largest manually annotated corpora, albeit the ever-evolving and with varying degrees of quality and consistency in the annotations.

Finally, we want to touch on the choice of the representation for semantic annotations. First, we should distinguish between format (i.e., *how* to represent, e.g., XML) and model (i.e., *what* to represent, e.g., RDF). Annotations formats and models vary by syntax style (e.g., markup vs declarative language), expressive power, or computational complexity. Notably, RDF, the Resource Description Framework (http://www.w3.org/TR/1999/REC-rdf-syntax-19990222/), and RDF Schema, a data-modeling oriented extension of RDF, provide the mechanics of the popular triple representation: subject, predicate, and object. After the introduction of RDF, other logical representations such as OWL (W3C 2009), Description Logics (Baader et al. 2010) and Schema.org (http://schema.org/docs/about.html) followed, with the aim of implementing the Semantic Web vision. Formalisms, like the Knowledge Interchange Format (http://www.ksl.stanford.edu/knowledge-sharing/kif/), propose higher-level constructs at the price of a more complex and verbose language, while others, like the Knowledge Annotation Format (Bosma et al. 2009), aim to address nesting and integration of different annotation sources.

Structure of Learning Systems

Common types of semantic annotations include, but are not limited to, the *disambiguation* of terms (words or phrases) and to the *parsing* of sentences from a semantic point of view. We will focus on these two in the remainder of this section.

The task of disambiguating the meaning of fragments of text can range from generic word-sense disambiguation (Navigli 2009), in which the system is given the task of assigning a unique sense to a word or expression from a specific set of canonical senses to more specialized problems, such as the one commonly known as *wikification*, the task of linking words or expression to a Wikipedia entry (Mihalcea and Csomai 2007; Cucerzan 2007; Milne and Witten 2008), or named-entity disambiguation, that is, word-sense disambiguation applied to entities bearing a proper name (e.g., people, organizations, or locations) (Hoffart et al. 2011; Nguyen et al. 2014; Mendes et al. 2011).

Examples of features used by algorithms for disambiguation problems include *prior probability*, the probability that a given surface form refers to a specific sense or entity, calculated from annotated training data sets; *similarity*, in which segment of texts are compared with gloss overlap or other similarity measures (Lesk 1986; Banerjee and Pedersen 2002); *co-occurrence*, the learned probability that a pair of senses or entities appear together in a document; and *coherence* a calculated measure of relatedness between senses or entities (e.g., number of incoming links shared by two Wikipedia entries or gloss overlap of the description of two entities). These features can be directly used in classification algorithms like support vector machines or combined to create different features. For examples, relatedness graphs between mentions and senses can be created, using features like the ones mentioned, to calculate the weights of the graph. In that spirit, recent state-of-the-art solutions apply algorithms similar to *page rank* to such graphs. As a result, the annotations with the highest ranking form a reasonably coherent set of annotations (Pershina et al. 2015). Other unsupervised approaches include identifying senses of n-grams based on contextual windows of text around the candidate n-gram (Navigli 2009).

Disambiguation algorithms typically follow three stages: (1) finding the fragments of text that require disambiguation, (2) producing a list of candidate senses, and (3) choosing the target sense for the disambiguation. Implementations vary in how they tackle these steps. For example, named-entity recognition algorithms can be run on the text to identify the surface forms of named entities requiring disambiguation, as in Hoffart et al. (2011), while wikification algorithms rely on either user selection or by automatically selecting n-grams that appear as anchor links in Wikipedia with a probability higher than a given threshold (Cucerzan 2007; Milne and Witten 2008). Candidates are selected by reverse lookup in dictionaries built from annotated examples or using lexical similarity functions such locality-sensitive hashing to address wrong or alternative spellings (e.g., *traveling* vs *travelling*).

The other common semantic annotation task is semantic parsing. Semantic parsing is the process of mapping fragments of text into a representation that reflects their meaning. It can also be seen as the reverse of language generation. Representation languages range from more expressive, such as first-order logic and lambda calculus, to more simple database query languages designed specifically for a small domain, like Geoquery (Zelle and Mooney 1996).

Parsing is usually divided into assigning meaning representations to lexical units and composing these representations into a single one. In some cases, syntactic parsing is performed on the input text, and the results are used to derive the semantics from the syntax tree (Poon and Domingos 2009). Other methods perform syntactic and semantic parsing together using formalisms like combinatory categorial grammars (CCG) (Zettlemoyer and Collins 2009) or different variations of context-free grammars (CFG)(Wong and Mooney 2006).

Early semantic parsers were mostly handcrafted (Warren 1981). It turned out that developing training corpora is not more difficult than manually designing robust semantic parsers. With the availability of training corpora and improved hardware, learning approaches started to emerge. These approaches automatically learn from sets of sentence meaning representation pairs. Usually, an expectation-maximization-like algorithm is used to train a model, which selects the most likely representation for a given sentence.

Training corpora are usually expensive to develop and limited to a particular domain. This led to the development of methods that are large scale, domain independent, and to the use of other forms of supervision. The level of supervision ranges from unsupervised methods (Poon and Domingos 2009), which bootstrap from a small set of training pairs, to weakly supervised methods (Cai and Yates 2013), which use knowledge from a target knowledge base, like Freebase, to methods that learn from question answer pairs (Berant et al. 2013). Lately, methods that use neural models to model the semantics have been developed (Bordes et al. 2012). The evaluation of semantic parsing can be performed by manually inspecting the generated meaning representations or in a question answer setting, where questions are mapped to database queries. The queries are then executed to obtain a set of answers, which are compared to the golden set of answers.

Notable systems for semantic annotations include AIDA, a system developed by the Max Planck Institute for named-entity disambiguation, able to link named entities contained in text to entities in the YAGO2 ontology; DBPedia Spotlight (https://github.com/dbpedia-spotlight/dbpedia-spotlight/wiki), a system from Free University of Berlin for extracting entities from text and linking them to the DBpedia ontology; and Babelfy (http://babelfy.org).

Semi-naive Bayesian Learning

Fei Zheng[1] and Geoffrey I. Webb[2]
[1]Faculty of Information Technology, Monash University, Clayton, Melbourne, VIC, Australia
[2]Faculty of Information Technology, Monash University, Victoria, Australia

Definition

Semi-naive Bayesian learning refers to a field of ► Supervised Classification that seeks to enhance the classification and conditional probability estimation accuracy of ▶ naive Bayes by relaxing its attribute independence assumption.

Motivation and Background

The assumption underlying ▶ naive Bayes is that attributes are independent of each other, given the class. This is an unrealistic assumption for many applications. Violations of this assumption can render naive Bayes' classification suboptimal. There have been many attempts to improve the classification accuracy and probability estimation of naive Bayes by relaxing the attribute independence assumption while at the same time retaining much of its simplicity and efficiency.

Taxonomy of Semi-naive Bayesian Techniques

Semi-naive Bayesian methods can be roughly subdivided into five high-level strategies for relaxing the independence assumption.

- The first strategy forms an attribute subset by deleting attributes to remove harmful interdependencies and applies conventional naive Bayes to this attribute subset.
- The second strategy modifies naive Bayes by adding explicit interdependencies between attributes.
- The third strategy accommodates violations of the attribute independence assumption by applying naive Bayes to a subset of training set. Note that the second and third strategies are not mutually exclusive.
- The fourth strategy performs adjustments to the output of naive Bayes without altering its direct operation.
- The fifth strategy introduces hidden variables to naive Bayes.

Methods that Apply Naive Bayes to a Subset of Attributes

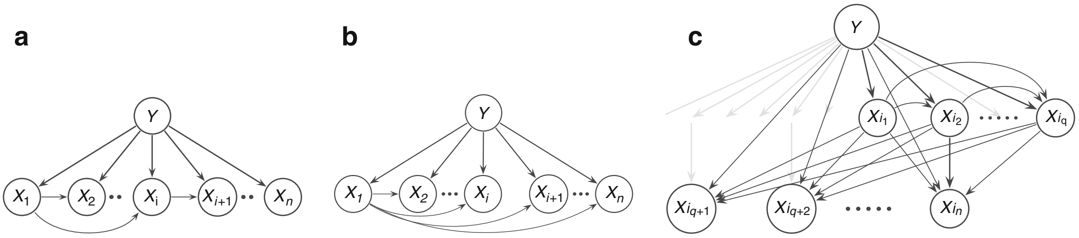
Due to the attribute independence assumption, the accuracy of naive Bayes is often degraded by the presence of strongly correlated attributes. Irrelevant attributes may also degrade the accuracy of naive Bayes, in effect increasing variance without decreasing bias. Hence, it is useful to remove both strongly correlated and irrelevant attributes.

Backward sequential elimination (Kittler 1986) is an effective wrapper technique to select an attribute subset and has been profitably applied to naive Bayes. It begins with the complete attribute set and iteratively removes successive attributes. On each iteration, naive Bayes is applied to every subset of attributes that can be formed by removing one further attribute. The attribute whose deletion most improves training set accuracy is then removed, and the process repeated. It terminates the process when subsequent attribute deletion does not improve training set accuracy. Conventional naive Bayes is then applied to the resulting attribute subset.

One extreme type of interdependencies between attributes results in a value of one being a generalization of a value of the other. For example, *Gender* = *female* is a generalization of *Pregnant* = *yes*. Subsumption resolution (SR) (Zheng et al. 2012) identifies at classification time pairs of attribute values such that one appears to subsume (be a generalization of) the other and delete the generalization. It uses the criterion $|T_{xi}| = |T_{x_i,x_j}| \geq u$ to infer that attribute value x_j is a generalization of attribute value x_i, where $|T_{x_i}|$ is the number of training cases with value x_i, $|T_{x_i}, x_j|$ is the number of training cases with both values, and u is a user-specified minimum frequency. When SR is applied to naive Bayes, the resulting classifier acts as naive Bayes except that it deletes generalization attribute-values at classification time if a specialization is detected.

Methods that Alter Naive Bayes by Allowing Interdependencies Between Attributes

Interdependencies between attributes can be addressed directly by allowing an attribute to depend on other non-class attributes. Sahami (1996) introduces the terminology of the z-dependence



Semi-naive Bayesian Learning, Fig. 1 Bayesian Network. (**a**) one-dependence classifier, (**b**) SuperParent one-dependence classifier and (**c**) z-dependence classifier $(z \geq 0)$

Bayesian classifier, in which each attribute depends upon the class and at most z other attributes. Figure 1 depicts methods in this group from the ▶ Bayesian Network perspective.

In Fig. 1a, each attribute depends on the class and at most one another attribute. ▶ Tree Augmented Naive Bayes (TAN) (Friedman et al. 1997) is a representative one-dependence classifier. It efficiently finds a directed spanning tree by maximizing the log-likelihood and employs this tree to perform classification. SuperParent TAN (Keogh and Pazzani 1999) is an effective variant of TAN.

A SuperParent one-dependence classifier (Fig. 1b) is a special case of one-dependence classifiers, in which an attribute called the SuperParent (X_1 in this graph), is selected as the parent of all the other attributes. ▶ Averaged One-Dependence Estimators (AODE) (Webb et al. 2005) selects a restricted class of one-dependence classifiers and aggregates the predictions of all qualified classifiers within this class. Maximum a posteriori linear mixture of generative distributions (MAPLMG) (Cerquides and Mántaras 2005) extends AODE by assigning a weight to each one-dependence classifier.

Two z-dependence classifiers ($z \geq 0$) are NBTree (Kohavi 1996) and lazy Bayesian rules (LBR) (Zheng and Webb 2000), both of which may add any number of non-class-parents for an attribute. In Fig. 1c, attributes in $\{X_{i_{q+1}}, \ldots, X_{i_n}\}$ depend on all the attributes in $\{X_{i_1}, \ldots, X_{i_q}\}$. The main difference between these two methods is that NBTree builds a single tree for all training instances while LBR generates a Bayesian rule for each test instance.

Methods that Apply Naive Bayes to a Subset of the Training Set

Another effective approach to accommodating violations of the conditional independence assumption is to apply naive Bayes to a subset of the training set, as it is possible that the assumption, although violated in the whole training set, may hold or approximately hold in a subset of the training set. NBTree and LBR use a local naive Bayes to classify an instance and can also be classified into this group. Locally weighted naive Bayes (LWNB) (Frank et al. 2003) applies naive Bayes to a neighborhood of the test instance, in which each instance is assigned a weight decreasing linearly with the Euclidean distance to the test instance. The number of instances in the subset is determined by a user-specified parameter. Only those instances whose weights are greater than zero are used for classification.

Methods that Calibrate Naive Bayes' Probability Estimates

Methods in this group make adjustments to the distortion in estimated posterior probabilities resulting from violations of independence assumption. Isotonic regression (IR) (Zadrozny and Elkan 2002) is a nonparametric calibration method which produces a monotonically increasing transformation of the probability outcome of naive Bayes. It uses a pair-adjacent violators algorithm (Ayer et al. 1955) to perform calibration. To classify a test instance, IR first finds the interval in which the estimated posterior probability fits and predicts the isotonic regression estimate of this interval as the calibrated posterior probability. Adjusted probability naive Bayesian classification (Webb and Pazzani 1998) makes adjustments to class probabilities, using a simple hill-climbing search to find adjustments that maximize the ▸ leave-one-out cross validation accuracy estimate. Starting with the conditional attribute-value frequency table generated by naive Bayes, iterative Bayes (Gama 2003) iteratively updates the frequency table by cycling through all training instances.

Methods that Introduce Hidden Variables to Naive Bayes

Creating hidden variables or joining attributes is another effective approach to relaxing the attribute independence assumption. Backward sequential elimination and joining (BSEJ) (Pazzani 1996) extends BSE by creating new Cartesian product attributes. It considers joining each pair of attributes and creates new Cartesian product attributes if the action improves leave-one-out cross validation accuracy. It deletes original attributes and also new Cartesian product attributes during a hill-climbing search. This process of joining or deleting is repeated until there is no further accuracy improvement. Hierarchical naive Bayes (Zhang et al. 2004) uses conditional mutual information as a criterion to create a hidden variable whose value set is initialized to the Cartesian product over all the value sets of its children. Values of a hidden variable are then collapsed by maximizing conditional log-likelihood via the ▸ minimum description length principle (Rissanen 1978).

Selection Between Semi-naive Bayesian Methods

No algorithm is universally optimal in terms of generalization accuracy. General recommendations for selection between semi-naive Bayesian methods is provided based on ▸ bias-variance tradeoff together with characteristics of the application to which they are applied.

Error can be decomposed into bias and variance (see ▸ bias variance decomposition). Bias measures how closely a learner is able to approximate the decision surfaces for a domain and variance measures the sensitivity of a learner to random variations in the training data. Unfortunately, we cannot, in general, minimize bias and variance simultaneously. There is a bias-variance tradeoff such that bias typically decreases when variance increases and vice versa. Data set size usually interacts with bias and variance and in turn affects error. Since differences between samples are expected to decrease with increasing sample size, differences between models formed from those samples are expected to decrease and hence variance is expected to decrease. Therefore, the bias proportion of error may be higher on large data sets than on small data sets and the variance proportion of error may be higher on small data sets than on large data sets. Consequently, low bias algorithms may have advantage in error on large data sets and low variance algorithms may have advantage in error on small data sets (Brain and Webb 2002).

Zheng and Webb (2005) compare eight semi-naive Bayesian methods with naive Bayes. These methods are BSE, FSS, TAN, SP-TAN, AODE, NBTree, LBR, and BSEJ. NBTree, SP-TAN, and BSEJ have relatively high training time complexity, while LBR has high classification time complexity. BSEJ has very high space complexity. NBTree and BSEJ have very low bias and high variance. Naive Bayes and AODE have very low variance. AODE has a significant advantage in error over other semi-naive Bayesian algorithms tested, with the exceptions of LBR and SP-TAN. It achieves a lower error for more data sets than LBR and SP-TAN without SP-TAN's high training time complexity and LBR's high test time complexity. Subsequent researches (Cerquides and Mántaras 2005; Zheng and Webb 2006) show that MAPLMG and SR can in practice significantly improve both classification accuracy and the precision of conditional probability estimates of AODE. However, MAPLMG imposes very high training time overheads on AODE, while SR imposes no extra training time overheads and only modest test time overheads on AODE.

Within the prevailing computational complexity constraints, we suggest using the lowest bias semi-naive Bayesian method for large training data and lowest variance semi-naive Bayesian method for small training data. An appropriate tradeoff between bias and variance should be sought for intermediate size training data. For extremely small data, naive Bayes may be superior and for large data NBTree and BSEJ may be more appealing options if their computational complexity satisfies the computational constraints of the application context. AODE achieves very low variance, relatively low bias and low training time and space complexity. MAPLMG and SR further enhance AODE by substantially reducing bias and error and improving probability prediction with modest time complexity. Consequently, they may prove competitive over a considerable range of classification tasks. Furthermore, MAPLMG may excel if the primary consideration is attaining the highest possible classification accuracy and SR may have an advantage if one wishes efficient classification.

Co-training; Learning from labeled and unlabeled data; Transductive learning

Definition

Semi-supervised learning uses both labeled and unlabeled data to perform an otherwise ▸ supervised learning or ▸ unsupervised learning task.

In the former case, there is a distinction between inductive semi-supervised learning and transductive learning. In inductive semi-supervised learning, the learner has both labeled training data $\{(x_i, y_i)\}_{i=1}^{l} \overset{iid}{\sim} p(\mathbf{x}, y)$ and unlabeled training data $\{\mathbf{x}_i\}_{i=l+1}^{l+u} \overset{iid}{\sim} p(\mathbf{x})$, and learns a predictor $f : \mathcal{X} \mapsto \mathcal{Y}, f \in \mathcal{F}$, where $\mathcal{F}$ is the hypothesis space. Here $\mathbf{x} \in \mathcal{X}$ is an input instance, $y \in \mathcal{Y}$ its target label (discrete for ▸ classification or continuous for ▸ regression), $p(\mathbf{x}, y)$ the unknown joint distribution and $p(\mathbf{x})$ its marginal, and typically $l \ll u$. The goal is to learn a predictor that predicts future test data better than the predictor learned from the labeled training data alone. In transductive learning, the setting is the same except that one is solely interested in the predictions on the unlabeled training data $\{\mathbf{x}_i\}_{i=l+1}^{l+u}$, without any intention to generalize to future test data.

In the latter case, an unsupervised learning task is enhanced by labeled data. For example, in semi-supervised clustering (a.k.a. ▸ constrained clustering) one may have a few must-links (two instances must be in the same cluster) and cannot-links (two instances cannot be in the same cluster) in addition to the unlabeled instances to be clustered; in semi-supervised ▸ dimensionality reduction one might have the target low-dimensional coordinates on a few instances.

This entry will focus on the former case of learning a predictor.

Motivation and Background

Semi-supervised learning is initially motivated by its practical value in learning faster, better, and cheaper. In many real world applications, it is relatively easy to acquire a large amount of unlabeled data $\{\mathbf{x}\}$. For example, documents can be crawled from the Web, images can be obtained from surveillance cameras, and speech can be collected from broadcast. However, their corresponding labels $\{y\}$ for the prediction task, such as sentiment orientation, intrusion detection, and phonetic transcript, often requires slow human annotation and expensive laboratory experiments. This labeling bottleneck results in a scarce of labeled data and a surplus of unlabeled data. Therefore, being able to utilize the surplus unlabeled data is desirable.

Recently, semi-supervised learning also finds applications in cognitive psychology as a computational model for human learning. In human categorization and concept forming, the environment provides unsupervised data (e.g., a child watching surrounding objects by herself) in addition to labeled data from a teacher (e.g., Dad points to an object and says “bird!”). There is evidence that human beings can combine labeled and unlabeled data to facilitate learning.

The history of semi-supervised learning goes back to at least the 1970s, when self-training, transduction, and Gaussian mixtures with the expectation-maximization (EM) algorithm first emerged. It enjoyed an explosion of interest since the 1990s, with the development of new algorithms like co-training and transductive support vector machines, new applications in natural language processing and computer vision, and new theoretical analyses. More discussions can be found in section 1.1.3 in Chapelle et al. (2006).

Theory

Unlabeled data $\{\mathbf{x}_i\}_{i=l+1}^{l+u}$ by itself does not carry any information on the mapping $\mathcal{X} \mapsto \mathcal{Y}$. How can it help us learn a better predictor $f : \mathcal{X} \mapsto \mathcal{Y}$? Balcan and Blum pointed out in 2009 that the key lies in an implicit ordering of $f \in \mathcal{F}$ induced by the unlabeled data. Informally, if the implicit ordering happens to rank the target predictor f^* near the top, then one needs less labeled data to learn f^*. This idea will be formalized later on using PAC learning bounds. In other contexts, the implicit ordering is interpreted as a prior over $\mathcal{F}$ or as a regularizer.

A semi-supervised learning method must address two questions: what implicit ordering is induced by the unlabeled data, and how to algorithmically find a predictor near the top of this implicit ordering and fits the labeled data well. Many semi-supervised learning methods have been proposed, with different answers to these two questions (Abney 2007; Chapelle et al. 2006; Seeger 2001; Zhu and Goldberg 2009). It is impossible to enumerate all methods in this entry. Instead, we present a few representative methods.

Generative Models

This semi-supervised learning method assumes the form of joint probability $p(\mathbf{x}, y \mid \theta) = p(y \mid \theta)p(\mathbf{x} \mid y, \theta)$. For example, the class prior distribution $p(y \mid \theta)$ can be a multinomial over $\mathcal{Y}$, while the class conditional distribution $p(\mathbf{x} \mid y, \theta)$ can be a multivariate Gaussian in $\mathcal{X}$ (Castelli and Cover 1995; Nigam et al. 2000). We use $\theta \in \Theta$ to denote the parameters of the joint probability. Each θ corresponds to a predictor f_θ via Bayes rule:

$$\begin{aligned} f_\theta(\mathbf{x}) &\equiv \mathrm{argmax}_y\, p(y|\mathbf{x}, \theta) \\ &= \mathrm{argmax}_y \frac{p(\mathbf{x}, y|\theta)}{\sum_{y'} p(\mathbf{x}, y'|\theta)}. \end{aligned}$$

Therefore, $\mathcal{F} = \{f_\theta : \theta \in \mathit{\Theta}\}$.

What is the implicit ordering of f_θ induced by unlabeled training data $\{\mathbf{x}_i\}_{i=l+1}^{l+u}$? It is the large to small ordering of log likelihood of θ on unlabeled data:

$$\log p\left(\{\mathbf{x}_i\}_{i=l+1}^{l+u} \middle| \theta\right) = \sum_{i=l+1}^{l+u} \log\left(\sum_{y\in\mathcal{Y}} p(\mathbf{x}_i, y|\theta)\right).$$

The top ranked f_θ is the one whose θ (or rather the generative model with parameters θ) best fits the unlabeled data. Therefore, this method assumes that the form of the joint probability is correct for the task.

To identify the f_θ that both fits the labeled data well and ranks high, one maximizes the log likelihood of θ on both labeled and unlabeled data:

$$\begin{aligned} &\mathrm{argmax}_\theta \log p(\{\mathbf{x}_i, y_i\}_{i=1}^{l}|\theta) \\ &\quad + \lambda \log p(\{\mathbf{x}_i\}_{i=l+1}^{l+u}|\theta), \end{aligned}$$

where λ is a balancing weight. This is a non-concave problem. A local maximum can be found with the EM algorithm, or other numerical optimization methods. (See also, ▸ generative learning.)

Semi-supervised Support Vector Machines

This semi-supervised learning method assumes that the decision boundary $f(\mathbf{x}) = 0$ is situated in a low-density region (in terms of unlabeled data) between the two classes $y \in \{-1, 1\}$ (Joachims 1999; Vapnik 1998). Consider the following hat loss function on an unlabeled instance $\mathbf{x}$:

$$\max(1 - |f(\mathbf{x})|, 0),$$

which is positive when $-1 < f(x) < 1$, and zero outside. The hat loss thus measures the violation in (unlabeled) large margin separation between f and $\mathbf{x}$. Averaging over all unlabeled training instances, it induces an implicit ordering from small to large over $f \in \mathcal{F}$:

$$\frac{1}{u} \sum_{i=l+1}^{l+u} \max(1 - |f(\mathbf{x})|, 0).$$

The top ranked f is one whose decision boundary avoids most unlabeled instances by a large margin.

To find the f that both fits the labeled data well and ranks high, one typically minimizes the following objective:

$$\operatorname{argmin}_f \frac{1}{l}\sum_{i=1}^{l}\max(1-y_i(\mathbf{x}_i),0)$$

$$+\lambda_1\|f\|^2+\lambda_2\frac{1}{u}\sum_{i=l+1}^{l+u}\max(1-|f(\mathbf{x})|,0),$$

which is a combination of the objective for supervised support vector machines, and the average hat loss. Algorithmically, the optimization problem is difficult because the hat loss is non-convex. Existing solutions include semi-definite programming relaxation, deterministic annealing, continuation method, concave-convex procedure (CCCP), stochastic gradient descent, and Branch and Bound. (See also ▶ support vector machines.)

Graph-Based Models

This semi-supervised learning method assumes that there is a graph $G = \{V, E\}$ such that the vertices V are the labeled and unlabeled training instances, and the undirected edges E connect instances i, j with weight w_{ij} (Blum and Chawla 2001; Zhu et al. 2003; Belkin et al. 2006). The graph is sometimes assumed to be a random instantiation of an underlying manifold structure that supports $p(\mathbf{x})$. Typically, w_{ij} reflects the proximity of $\mathbf{x}_i$, $\mathbf{x}_j$. For example, the Gaussian edge weight function defines $w_{ij} = \exp(-\|\mathbf{x}_i - \mathbf{x}_j\|^2/\sigma^2)$. As another example, the kNN edge weight function defines $w_{ij} = 1$ if $\mathbf{x}_i$ is within the k nearest neighbors of $\mathbf{x}_j$ or vice versa, and $w_{ij} = 0$ otherwise. Other commonly used edge weight functions include ε-radius neighbors, b-matching, and combinations of the above.

Large w_{ij} implies a preference for the predictions $f(\mathbf{x}_i)$ and $f(\mathbf{x}_j)$ to be the same. This can be formalized by the graph energy of a function f:

$$\sum_{i,j=1}^{l+u} w_{ij}(f(\mathbf{x}_i)-f(\mathbf{x}_j))^2.$$

The graph energy induces an implicit ordering of $f \in \mathcal{F}$ from small to large. The top ranked function is the smoothest with respect to the graph (in fact, it is any constant function). The graph energy can be equivalently expressed using the so-called unnormalized graph Laplacian matrix. Variants including the normalized Laplacian and the powers of these matrices.

To find the f that both fits the labeled data well and ranks high (i.e., being smooth on the graph or manifold), one typically minimizes the following objective:

$$\operatorname{argmin}_f \frac{1}{l}\sum_{i=1}^{l} c(f(\mathbf{x}_i), y_i) + \lambda_1\|f\|^2$$

$$+\lambda_2\sum_{i,j=1}^{l+u} w_{ij}(f(\mathbf{x}_i)-f(x_j))^2,$$

where $c(f(\mathbf{x}), y)$ is a convex loss function such as the hinge loss or the squared loss. This is a convex optimization problem with efficient solvers.

Co-training and Multiview Models

This semi-supervised learning method assumes that there are multiple, different learners trained on the same labeled data, and these learners agree on the unlabeled data. A classic algorithm is co-training (Blum and Mitchell 1998). Take the example of web page classification, where each web page $\mathbf{x}$ is represented by two subsets of features, or "views" $\mathbf{x} = \langle \mathbf{x}^{(1)}, \mathbf{x}^{(2)}\rangle$. For instance, $\mathbf{x}^{(1)}$ can represent the words on the page itself, and $\mathbf{x}^{(2)}$ the words on the hyperlinks (on other web pages) pointing to this page. The co-training algorithm trains two predictors: $f^{(1)}$ on $\mathbf{x}^{(1)}$ (ignoring the $\mathbf{x}^{(2)}$ portion of the feature) and $f^{(2)}$ on $\mathbf{x}^{(2)}$, both initially from the labeled data. If $f^{(1)}$ confidently predicts the label of an unlabeled instance $\mathbf{x}$, then the instance-label pair $(\mathbf{x}, f^{(1)}(\mathbf{x}))$ is added to $f^{(2)}$'s labeled training data, and vice versa. Note this promotes $f^{(1)}$ and $f^{(2)}$ to predict the same on $\mathbf{x}$. This repeats so that each view teaches the other. Multiview models generalize co-training by utilizing more than two predictors, and relaxing the requirement of having separate views (Sindhwani et al. 2005).

In either case, the final prediction is obtained from a (confidence weighted) average or vote among the predictors.

To define the implicit ordering on the hypothesis space, we need a slight extension. In general, let there be m predictors $f^{(1)}, \ldots, f^{(m)}$. Now let a hypothesis be an m-tuple of predictors $\langle f^{(1)}, \ldots, f^{(m)} \rangle$. The disagreement of a tuple on the unlabeled data can be defined as

$$\sum_{i=l+1}^{l+u} \sum_{u,v=1}^{m} c(f^{(u)}(\mathbf{x}_1), f^{(v)}(\mathbf{x}_i)),$$

where $c()$ is a loss function. Typical choices of $c()$ are the 0–1 loss for classification, and the squared loss for regression. Then the disagreement induces an implicit ordering on tuples from small to large.

It is important for these m predictors to be of diverse types, and have different ▶ inductive biases. In general, each predictor $f^{(u)}, u = 1 \ldots m$ may be evaluated by its individual loss function $c^{(u)}$ and regularizer $\Omega^{(u)}$. To find a hypothesis (i.e., m predictors) that fits the labeled data well and ranks high, one can minimize the following objective:

$$\underset{\langle f^{(1)},\ldots f^{(m)} \rangle}{\operatorname{argmin}} \sum_{u=1}^{m} \left(\frac{1}{l} \sum_{i=1}^{l} c^{(u)}(f^{(u)}(\mathbf{x}_i), y_i) + \lambda_1 \Omega^{(u)}(f^{(u)}) \right)$$
$$+ \lambda_2 \sum_{i=l+1}^{l+u} \sum_{u,v=1}^{m} c(f^{(u)}(\mathbf{x}_i), f^{(v)}(\mathbf{x}_i)).$$

Multiview learning typically optimizes this objective directly. When the loss functions and regularizers are convex, numerical solution is relatively easy to obtain. In the special cases when the loss functions are the squared loss, and the regularizers are squared ℓ_2 norms, there is a closed form solution. On the other hand, the co-training algorithm, as presented earlier, optimizes the objective indirectly with the iterative procedure. One advantage of co-training is that the algorithm is a wrapper method, in that it can use any "blackbox" learners $f^{(1)}$ and $f^{(2)}$ without the need to modify the learners.

A PAC Bound for Semi-supervised Learning

Previously, we presented several semi-supervised learning methods, each induces an implicit ordering on the hypothesis space using the unlabeled training data, and each attempts to find a hypothesis that fit the labeled training data well as well as rank high in that implicit ordering. We now present a theoretical justification on why this is a good idea. In particular, we present a uniform convergence bound by Balcan and Blum (Theorem 11 in Balcan and Blum 2009). Alternative theoretical analyses on semi-supervised learning can be found by following the recommended reading.

First, we introduce some notations. Consider the 0–1 loss for classification. Let $c^* : \mathcal{X} \mapsto \{0, 1\}$ be the unknown target function, which may not be in $\mathcal{F}$. Let err $(f) = E_{\mathbf{x}\sim p}[f(\mathbf{x}) \neq c^*(\mathbf{x})]$ be the true error rate of a hypothesis f, and $\widehat{\text{err}}(f) = \frac{1}{l}\sum_{i=1}^{l} f(\mathbf{x}_i) \neq c^*(\mathbf{x}_i)$ be the empirical error rate of f on the labeled training sample. To characterize the implicit ordering, we defined an "unlabeled error rate" $\text{err}_{unl}(f) = 1 - E_{\mathbf{x}\sim}p[\chi(f, \mathbf{x})]$, where the *compatibility function* $\mathcal{X} : \mathcal{F} \times \mathcal{X} \mapsto [0, 1]$ measures how "compatible" f is to an unlabeled instance $\mathbf{x}$. As an example, in semi-supervised support vector machines, if $\mathbf{x}$ is far away from the decision boundary produced by f, then $\chi(f, \mathbf{x})$ is large; but if $\mathbf{x}$ is close to the decision boundary, $\chi(f, \mathbf{x})$ is small. In this example, a large $\text{err}_{unl}(f)$ then means that the decision boundary of f cuts through dense unlabeled data regions, and thus f is undesirable for semi-supervised learning. In contrast, a small

$\mathrm{err}_{unl}(f)$ means that the decision boundary of f lies in a low density gap, which is more desirable. In theory, the implicit ordering on $f \in \mathcal{F}$ is to sort $\mathrm{err}_{unl}(f)$ from small to large. In practice, we use the empirical unlabeled error rate $\widehat{\mathrm{err}}_{\mathrm{unl}}(f) = 1 - \frac{1}{u}\sum_{i=l+1}^{l+u} \mathcal{X}(f, \mathbf{x}_i)$.

Our goal is to show that if an $f \in \mathcal{F}$ "fits the labeled data well and ranks high," then f is almost as good as the best hypothesis in $\mathcal{F}$. Let $t \in [0,1]$. We first consider the best hypothesis f_t^* in the subset of $\mathcal{F}$ that consists of hypotheses whose unlabeled error rate is no worse than t : $f_t^* = \mathrm{argmin}_{f'\mathcal{F},\mathrm{err}_{\mathrm{unl}}(f')\le t}\mathrm{err}(f')$. Obviously, $t = 1$ gives the best hypothesis in the whole $\mathcal{F}$. However, the nature of the guarantee has the form $\mathrm{err}(f) \le \mathrm{err}(f_{t^*}) + \mathrm{EstimationError}(t) + c$, where the EstimationError term increases with t. Thus, with $t = 1$ the bound can be loose. On the other hand, if t is close to 0, EstimationError(t) is small, but $\mathrm{err}(f_{t^*})$ can be much worse than $\mathrm{err}(f_{t=1}^*)$. The bound will account for the optimal t.

We introduce a few more definitions. Let $\mathcal{F}(f) = \{f' \in \mathcal{F} : \widehat{\mathrm{err}}_{unl}(f') \le \widehat{\mathrm{err}}_{unl}(f)\}$ be the subset of $\mathcal{F}$ with empirical error no worse than that of f. As a complexity measure, let $[\mathcal{F}(f)]$ be the number of different partitions of the first l unlabeled instances $\mathbf{x}_{l+1}\ldots\mathbf{x}_{2l}$, using $f \in \mathcal{F}(f)$. Finally, let $\hat{\epsilon}(f) = \sqrt{\frac{24}{l}\log(8[\mathcal{F}(f)])}$. Then we have the following agnostic bound (meaning that c^* may not be in $\mathcal{F}$, and $\widehat{\mathrm{err}}_{\mathrm{unl}}(f)$ may not be zero for any $f \in \mathcal{F}$):

Theorem 1 *Given l labeled instances and sufficient unlabeled instances, with probability at least 1 – δ, the function*

$$f = \mathrm{argmin}_{f' \in \mathcal{F}} \widehat{err}(f') + \hat{\epsilon}(f')$$

satisfies the guarantee that

$$err(f) \le \min_t(err(f_t^*)) + 5\sqrt{\frac{\log(8/\delta)}{l}}.$$

If a function f fits the labeled data well, it has a small $\widehat{\mathrm{err}}(f)$. If it ranks high, then $\mathcal{F}(f)$ will be a small set, consequently $\hat{\epsilon}(f)$ is small. The argmin operator identifies the best such function during training. The bound account for the minimum of all possible t tradeoffs. Therefore, we see that the "lucky" case is when the implicit ordering is good such that $f_{t=1}^*$, the best hypothesis in $\mathcal{F}$, is near the top of the ranking. This is when semi-supervised learning is expected to perform well. Balcan and Blum also give results addressing the key issue of how much *unlabeled* data is needed for $\widehat{\mathrm{err}}_{\mathrm{unl}}(f)$ and $\mathrm{err}_{\mathrm{unl}}(f)$ to be close for all $f \in \mathcal{F}$.

Applications

Because the type of semi-supervised learning discussed in this entry has the same goal of creating a predictor as supervised learning, it is applicable to essentially any problems where supervised learning can be applied. For example, semi-supervised learning has been applied to natural language processing (word sense disambiguation (Yarowsky 1995), document categorization, named entity classification, sentiment analysis, machine translation), computer vision (object recognition, image segmentation), bioinformatics (protein function prediction), and cognitive psychology. Follow the recommended reading for individual papers.

Future Directions

There are several directions to further enhance the value semi-supervised learning. First, we need guarantees that it will outperform supervised learning. Currently, the practitioner has to manually choose a particular semi-supervised learning method, and often manually set learning parameters. Sometimes, a bad choice that does not match the task (e.g., modeling each class with a Gaussian when the data does not have this distribution) can make semi-supervised learning worse than supervised learning. Second, we need methods that benefit from unlabeled when l, the size of labeled data, is large. It has been widely observed that the gain over supervised learning is the largest when l is small, but diminishes as l increases. Third, we need good ways to combine semi-supervised learning and ▸ active learning. In natural learning systems such as humans, we routinely observe unlabeled input, which often naturally leads to questions. And finally, we need methods that can efficiently process massive unlabeled data, especially in an ▸ online learning setting.

Synonyms

Learning from labeled and unlabeled data; Transductive learning

Definition

In contrast to supervised and unsupervised learners, which use solely labeled or unlabeled examples, respectively, semi-supervised learning systems exploit both labeled and unlabeled examples. In a typical semi-supervised framework, the system takes as input a (small) training set of labeled examples and a (larger) working set of unlabeled examples; the learner's performance is evaluated on a test set that consists of unlabeled examples. Transductive learning is a particular case of semi-supervised learning in which the working set and the test set are identical.

Semi-supervised learners use the unlabeled examples to improve the performance of the system that could be learned solely from labeled

S

data. Such learners typically exploit – directly or indirectly – the distribution of the available unlabeled examples. Text processing is an ideal application domain for semi-supervised learning because the abundance of text documents available on the Web makes it impossible for humans to label them all. We focus here on two related types of text processing tasks that were heavily studied in the semi-supervised framework: text classification and text ▶ Clustering.

Motivation and Background

In most applications of machine learning, collecting large amounts of labeled examples is an expensive, tedious, and error-prone process. In contrast, one may often have cheap or even free access to large amounts of unlabeled examples. For example, for text classification, which is the task of classifying text documents into categories such as politics, sports, entertainment, etc., one can easily crawl the Web and download billions of Web pages; however, manually labeling all these documents according to the taxonomy of interest is an extremely expensive task.

The key idea in semi-supervised learning is to complement a small amount of labeled data by a large number of unlabeled examples. Under certain conditions, the unlabeled examples can be mined for knowledge that will allow the semi-supervised learner to build a system that performs better than one learned solely from the labeled data. More precisely, semi-supervised learners assume that the learning model matches the structure of the application domain. If this is the case, the information extracted from the unlabeled data can be used to *guide* the search towards the optimal solution (e.g., by modifying or re-ranking the learned hypotheses); otherwise, the unlabeled examples may *hurt* rather than help the learning process (Cozman et al. 2003).

For the sake of concision and clarity, we have had to make several compromises in terms of the algorithms and the applications presented here. Given the vastness of the field of text processing, we have decided to focus only on the two related tasks of text classification and text clustering. They are the most studied text processing applications within the field of machine learning; furthermore, virtually all the main types of semi-supervised algorithms were applied to these two tasks. This decision has two main consequences. First, we do not consider many other text processing tasks, such as information extraction, natural language parsing, or base noun–phrase identification; for these we refer the interested reader to Muslea et al. (2006). Second, we discuss and cite approaches that were applied to text classification or clustering there is however, alone an excellent survey by Zhu (2005) covering seminal work on semi-supervised learning that was not applied to text processing.

Structure of the Learning System

Generative Models

The early work on semi-supervised text categorization (Nigam et al. 2000) was based primarily on generative models (see ▶ generative learning). Such approaches make two major assumptions: (1) the data is generated by a mixture model, and (2) there is a correspondence between the components of the mixture and the classes of the application domain. Intuitively, if these assumptions hold, the unlabeled examples become instrumental in identifying the mixture's components, while the labeled examples can be used to label each individual component.

The iterative approach proposed by Nigam et al. (2000) is based on The EM Algorithm and works as follows. First, the labeled examples are used to learn an initial classifier, which is used to probabilistically label all unlabeled data; then the newly labeled examples are added to the training set. Finally, a new classifier is learned from all the data, and the entire process is repeated till convergence is reached (or, alternatively, till the number of iterations is fixed).

Nigam et al. (2000) noticed that, in practice, the two above-mentioned assumptions about the generative model may not hold; in order to deal with this problem, the authors propose two extensions of their basic approach. First, they allow each class to be generated by multiple mixture components. Second, they introduce a weighting factor that adjusts the contribution of the unlabeled examples; this factor is tuned during the learning process so that the influence of the unlabeled examples correlates with the degree in which the data distribution is consistent with the mixture model.

The same general framework can also be applied to the related task of text clustering. In the clustering framework, the learner is not concerned with the actual label of an example; instead, it tries to find a partitioning of the examples in clusters that are similar *respect to* a predefined objective function. For example, Seeded-KMeans (Basu et al. 2002) is a semi-supervised text clustering algorithm that uses the few available labeled examples to seed the search for the data clusters. In order to optimize the target objective function, Seeded-KMeans uses an EM algorithm on a mixture of Gaussians.

Discriminative Approaches

▸ Support vector machines (SVMs) (Joachims 1999) are particularly well suited for text classification because of their ability to deal with high-dimensional input spaces (each word in the corpus is a feature) and sparse feature-value vectors (any given document contains only a small fraction of the corpus vocabulary). SVMs are called maximum margin classifiers because they minimize the empirical classification error by maximizing the geometric margin between the domain's positive and negative examples. Intuitively, this is equivalent to finding a discriminative decision boundary that avoids the high-density regions in the instance space.

Transductive SVMs (Joachims 1999) are designed to find an optimal decision boundary for a particular test set. More precisely, they have access to both the (labeled) training set and the unlabeled test set. Transductive SVMs work by finding a labeling of the test examples that maximizes the margin over all the examples in the training and the test set. This transductive approach has shown significant improvements over the traditional inductive SVMs, especially if the size of the training set is small.

In contrast to transductive SVMs, semi-supervised SVMs (S3VM) work in a true semi-supervised setting in which the test set is not available to the learner. A major difficulty in the S3VM framework is the fact that the resulting optimization problem is not convex, thus being sensitive to the issue of (non-optimal) local minima. CS3VMs (Chapelle et al. 2006) alleviate this problem by using a global optimization technique called continuation. On binary classification tasks CS3VMs compare favorably against other S3VM approaches, but applying it on multiclass domains is still an open problem.

Multiview Approaches

Multiview learners are a class of algorithms for domains in which the features can be partitioned in disjoint subsets (views), each of which is sufficient to learn the target concept. For example, when classifying Web pages, one can use either the words that appear in the documents or those that appear in the hyper-links pointing to them. Co-training (Blum and Mitchell 1998) is a semi-supervised, multiview learner that, intuitively, works by bootstrapping the views from each other. First, it uses the labeled examples to learn a classifier in each view. Then it applies the learned classifiers to the unlabeled data and detects the examples on which each view makes the most confident prediction; these examples are labeled by the respective classifiers and added to the (labeled) training set of the other view. The entire process is repeated for a number of iterations.

Multiview learners rely on two main assumptions, namely that the views are compatible and uncorrelated. The former requires that each example is identically labeled by the target concept in each view; the latter means that given an example's label, its description in each view are independent. In practice, both these assumptions are likely to be violated; in order to deal with the first issue, one can use the adaptive view validation algorithm (Muslea et al. 2002b), which predicts whether the views are sufficiently compatible for multiview learning.

With respect to view correlation Muslea et al. (2002a) have shown that by interleaving active and semi-supervised learning, multiview approaches become robust the view correlation. A similar idea was previously used in the generative, single-view framework: McCallum and Nigam (1998) have shown that by allowing the algorithm to (smartly) choose which examples to include in the training set, one can significantly improve over the performance of both supervised and semi-supervised learners that used randomly chosen training sets.

The main limitation of multiview learning is the requirement that the user identifies at least two suitable views. In order to cope with this problem, researchers have proposed algorithms that work in a way similar to co-training, but exploit multiple ▶ inductive biases instead of multiple views. For example, tri-training (Zhou and Li 2005) uses all domain features to train three supervised classifiers (e.g., a decision tree, a neural network, and a Naive Bayes classifier). These classifiers are then applied to each unlabeled example; if two of them agree on the example's label, they label it accordingly and add it to the third classifier's training set. A degenerate case is represented by *self-training*, which uses a single classifier that repeatedly goes through the unlabeled data and adds to its own training set, the examples on which its predictions are the most confident.

Graph-Based Approaches

The work on graph-based, semi-supervised text learning is based on the idea of representing the labeled and unlabeled examples as vertices in a graph. The edges of this graph are weighted by the pair-wise similarity between the corresponding examples, thus offering a flexible way to incorporate prior domain knowledge. With the learning task encoded in this manner, the problem to be solved becomes one of graph theory, namely finding a partitioning of the graph that agrees with the labeled examples. A major challenge for the graph-based approaches is to find a balanced partitioning of the graph (e.g., in a degenerate scenario, one can propose an unbalanced, undesirable partition in which, except for the negative examples in the training set, all other examples are labeled as positive).

One possible approach to cope with the issue on unbalanced partitions is to use randomized min-cuts (Blum et al. 2004). The algorithm starts with the original graph and repeatedly adds random noise to the weights of the edges. Then, for each modified graph, it finds a partitioning by using minimum cuts. Finally, the results from the various runs aggregated in order to create probabilistic labels for the unlabeled examples. This approach has the additional benefit of offering a measure of the confidence in each particular prediction.

The SGT algorithm (Joachims 2003) uses spectral methods to perform the graph partitioning. SGT can be seen as a transductive version of the k nearest-neighbor classifier; furthermore Joachims (2003) also show that co-training emerges as a special case of SGT. In contrast to transductive SVMs and co-training, SGT does not require additional heuristics for avoiding unbalanced graph partitionings (e.g., in the original co-training algorithm, the examples that are added to the training set after each iteration must respect the domain-dependent ratio of negative-to-positive examples).

LapSVM (Sindhwani et al. 2005) is a graph-based kernel method that uses a weighted combination a regularizer learned solely from labeled data and a graph Laplacian obtained from both the labeled and unlabeled examples. This approach allows LapSVM to perform a principled search for a decision boundary that is both consistent with the labeled examples and reflects the underlying geometry of all available data points.

Approaches that Exploit Background Knowledge

WHIRL-BG (Zelikovitz and Hirsh 2000) is an algorithm for classifying short text fragments. It uses an information integration approach that combines three different information sources: the training set, which consists of the labeled examples; the test set that WHIRL-BG must label;

and a secondary corpus that consists longer, related documents that are not labeled. Intuitively, WHIRL-BG exploits the secondary corpus as background knowledge that allows the system to link a test example to the most similar labeled training example. In other words, instead of trying to measure directly a (unreliable) similarity between two short strings (i.e., a test and a training example), the system searches for a background document that may include (a large fraction of) both strings.

HMRF-KMEANS (Basu et al. 2004) unifies the two main approaches to semi-supervised text clustering: the constraint-based one and the adaptive distance one. The former exploits user-provided background knowledge to find an appropriate partitioning of the data; for HMRF-KMEANS, the domain knowledge consists of must-link or cannot-link constraints, which specify whether two examples should or should not have the same label, respectively. The later uses a small number of labeled examples to learn a domain-specific distance measure that is appropriate for the clustering task at hand. HMRF-KMEANS can use any Bregman divergence to measure the clustering distortion, thus supporting a wide variety of learnable distances.

HMRF-KMEANS exploits the labeled examples in three main ways. First, it uses the neighborhoods induced from the constraints to initialize the cluster centroids. Second, when assigning examples to clusters, the algorithm tries to simultaneously minimize both the similarity to the cluster's centroid and the number of violated constraints. Last but not least, during the clustering process, HMRF-KMEANS iteratively reestimates the distance measure so that it takes into account both the background knowledge and the data variance.

Sensitivity

Synonyms

Recall; True positive rate

Sensitivity is the fraction of positive examples predicted correctly by a model. See ▸ Sensitivity and Specificity, ▸ Precision and Recall.

Sensitivity and Specificity

Kai Ming Ting
Federation University, Mount Helen, VIC,
Australia

Definition

Sensitivity and specificity are two measures used together in some domains to measure the predictive performance of a classification model or a diagnostic test. For example, to measure the effectiveness of a diagnostic test in the medical domain, sensitivity measures the fraction of people with disease (i.e., positive examples) who have a positive test result; and specificity measures the fraction of people without disease (i.e., negative examples) who have a negative test result. They are defined with reference to a special case of the ▸ confusion matrix, with two classes, one designated the *positive* class and the other the *negative* class, as indicated in Table 1.

Sensitivity and Specificity, Table 1 The outcomes of classification into positive and negative classes

		Assigned class	
		Positive	Negative
Actual class	Positive	True Positive (TP)	False Negative (FN)
	Negative	False Positive (FP)	True Negative (TN)

Sensitivity is sometimes also called *true positive rate*. Specificity is sometimes also called *true negative rate*. They are defined as follows:

$$\text{Sensitivity} = \text{TP}/(\text{TP} + \text{FN})$$
$$\text{Specificity} = \text{TN}/(\text{TN} + \text{FP})$$

Instead of two measures, they are sometimes combined to provide a single measure of predictive performance as follows:

$$\text{Sensitivity} \times \text{Specificity}$$
$$= \text{TP} * \text{TN}/[(\text{TP} + \text{FN}) * (\text{TN} + \text{FP})]$$

Note that sensitivity is equivalent to ▸ recall.

Sentiment Analysis and Opinion Mining

Lei Zhang[1] and Bing Liu[2]
[1]LinkedIn, San Francisco, CA, USA
[2]University of Illinois at Chicago, Chicago, IL, USA

Abstract

With the rapid growth of social media, sentiment analysis, also called opinion mining, has become one of the most active research areas in natural language processing. Its application is also widespread, from business services to political campaigns. This article gives an introduction to this important area and presents some recent developments.

Synonyms

Opinion extraction; Opinion mining; Sentiment analysis; Sentiment mining

Definition

Sentiment analysis or opinion mining is the computational study of people's opinions, sentiments, appraisals, attitudes, and emotions toward entities and their aspects expressed in text.

Motivation and Background

Sentiment and opinion and their related concepts, such as evaluation, appraisal, attitude, affect, emotion, and mood, are about people's subjective beliefs and feelings. They are key influencers of human behaviors. Whenever we need to make a decision, we often seek out others' opinions. This is true for both individuals and organizations.

The development of sentiment analysis coincides with the growth of *social media* (i.e., reviews, forum discussions, and blogs) on the Web. For the first time in human history, we now possess a huge volume of opinion data recorded in digital forms. These *user-generated contents* (UGC) are full of people's opinions. Mining useful knowledge from these corpora gives rise to the task of sentiment analysis. Since the early 2000s, it has been one of the most active research areas in natural language processing (NLP) (Pang and Lee 2008; Liu 2012). The research and applications have also spread from computer science to management science and social sciences because of its importance to business and society as a whole. Sentiment analysis techniques have been widely applied in practice, from business services to political campaigns.

Structure of the Task

In a nutshell, the task of sentiment analysis is to mine people's opinions and emotions from text. The term *opinion* is used as a concept represented with a quadruple (s, g, h, t) covering four components (Liu 2012): sentiment orientation s, sentiment target g opinion holder h, and time t. *Sentiment* is the underlying feeling, attitude, evaluation, or emotion associated with an opinion. Sentiment orientation can be *positive*, *negative*, or *neutral*. *Sentiment target*, also known as the *opinion target*, is an *entity* or an *aspect* of the *entity* that the sentiment has been expressed upon. *Opinion holder* is an individual or organization that holds an opinion. *Time* is when the opinion is expressed. We will discuss emotion specifically later.

We use the following camera review as an example (an ID number is associated with each sentence for easy reference):

Posted by John Smith
Date: September 10, 2011

(1) *I bought a Canon G12 camera six months ago.* (2) *I simply love it.* (3) *The picture quality is amazing.* (4) *The battery life is also long.* (5) *However, my wife thinks it is too heavy for her.*

Given the review, the task of sentiment analysis aims to extract the following opinion quadruples from sentences 2, 3, 4, and 5, respectively:

(*positive*, *Canon G12 camera*, *author*, *2011/09/10*)
(*positive*, *picture quality* of *Canon G12 camera author*, *2011/09/10*)
(*positive*, *battery life* of *Canon G12 camera*, *author*, *2011/09/10*)
(*negative*, *weight* of *Canon G12 camera, author's wife*, *2011/09/10*)

The opinion target can be an entity (*Canon G12 camera*) or an aspect of the entity (*picture quality*, *battery life*, and *weight* of the Canon G12 camera). An aspect can be *explicit* (e.g., *battery life*) or *implicit* (e.g., *weight* is indicated by *heavy*) (Hu and Liu 2004).

In many applications, it is useful to decompose opinion target to entity and aspect for more fine-grained analysis. Then, the above quadruples become the following quintuples, where GENERAL represents the entity itself (Liu 2012):

(*positive*, *Canon G12 camera*, *GENERAL*, *author*, *2011/09/10*)

S

(*positive*, *Canon G12 camera picture quality*, *author*, *2011/09/10*)
(*positive*, *Canon G12 camera*, *battery life*, *author*, *2011/09/10*)
(*negative*, *Canon G12 camera, weight, author's wife*, *2011/09/10*)

An opinion from a single opinion holder is usually not actionable in an opinion mining application. The user often needs opinions from a large number of opinion holders, which leads to opinion summary. A summary of opinions is normally constructed based on positive and negative sentiments about opinion targets, which is called aspect-based opinion summary (or feature-based opinion summary) (Hu and Liu 2004). Figure 1 shows an opinion summary generated from product reviews of Apple iPad by Google products. Generally, opinion summary needs to be quantitative, which is reflected by the proportions or the numbers of positive and negative opinions for each sentiment target or aspect.

Sentiment Analysis Methods

Researchers have studied sentiment analysis at three main levels of granularities: document, sentence, and aspect levels.

Document Sentiment Classification

Document sentiment classification classifies an opinion document (e.g., a product review) as expressing a positive or negative sentiment. It does not study or extract any information within the document. The task is also known as the *document-level sentiment classification*.

Document sentiment classification is commonly formulated as a supervised learning problem with two classes (*positive* and *negative*) or rating scores (e.g., 1–5 stars). Standard supervised learning methods such naïve Bayesian classification and support vector machines (SVM) can be applied for classification directly. Pang et al. (2002) first adopted those classification methods to classify movie reviews into two classes. Since this work, numerous other works have been reported. Like most supervised learning approaches, the main task of these works is to engineer a set of effective features. See Liu (2012) for an overview of this line of research.

There are also unsupervised approaches to document sentiment classification, which are mainly based on sentiment words and language patterns. It is quite clear that *sentiment words* (also called *opinion words*) that indicate positive or negative sentiments (e.g., *good* and *nice* are positive sentiment words, and *horrible* and *bad* are negative sentiment words) play an important role in sentiment classification (Turney 2002; Hu and Liu 2004; Kim and Hovy 2004). Turney (2002) proposed an unsupervised approach based on syntactic opinion patterns and Web search. Taboada et al. (2011) adapted a *lexicon-based approach* for document sentiment classification. It basically uses a set of sentiment words and phrases with appropriate scores and an aggregation scheme to aggregate the scores of

Sentiment Analysis and Opinion Mining, Fig. 1 Opinion summary for iPad from Google products the sentiment words appeared in a document to perform the classification. The lexicon-based approach was originally proposed for aspect-level and sentence-level sentiment classification (Hu and Liu 2004; Kim and Hovy 2004).

Researchers found that supervised sentiment classification is domain-sensitive, that is, a classifier trained using opinion documents from one domain performs poorly when it is applied or tested on opinion documents from another domain. The reason is that words used in different domains for expressing opinions can be different. Furthermore, the same word may mean positive in one domain but negative in another domain. Domain adaptation or transfer learning techniques have been employed to address the problem (Blitzer et al. 2007; Pan et al. 2010; Liu 2012).

Another interesting topic is cross-language sentiment classification, which focuses on using the extensive resources and tools available in English and automated translation to help build sentiment classifiers in other languages with few resources or tools (Wan 2009; Mihalcea et al. 2007). Existing research proposed three main strategies: (1) translate test documents in the target language into the source language and classify them using a source language classifier, (2) translate a source language training corpus into the target language and build a classifier in the target language, and (3) translate a sentiment lexicon in the source language to the target language and build a lexicon-based classifier in the target language.

Sentence Sentiment Classification

Sentence sentiment classification is similar to document sentiment classification as sentences can be regarded as short documents. However, sentence classification is usually harder because the information contained in a typical sentence is much less than that contained in a typical document. Furthermore, sentence sentiment classification needs to consider the neutral class (or no opinion) because there are many factual sentences that express no positive or negative opinion in an opinion document. Document classification normally does not consider the neutral class.

Document sentiment classification techniques can be naturally applied for sentence sentiment classification. Some sentence-specific approaches have also been proposed, e.g., hierarchical sequence learning model (McDonald et al. 2007) and deep learning methods (Socher et al. 2013). In addition, researchers found that different types of sentences may need different kinds of classification methods, e.g., *conditional sentences* and *integrative sentences* (Liu 2012).

For example, a conditional sentence describes implications or hypothetical situations and their consequences. Such a sentence typically contains two clauses that are dependent on each other: the condition clause and the consequent clause. Their relationship has significant impact on whether the sentence expresses a positive or negative sentiment (Narayanan et al. 2009). For example, the sentence *If someone makes a reliable car, I will buy it* expresses no sentiment toward any particular car, although it contains the positive sentiment word *reliable*. In Narayanan et al. (2009), supervised learning was used to deal with the problem using a set of linguistic features, e.g., sentiment words or phrases and their locations, part-of-speech tags of sentiment words, tense patterns, and conditional connectives.

Another type of difficult sentences is the *sarcasm sentences*. Sarcasm is a sophisticated form of speech act in which the speakers or the writers say or write the opposite of what they mean. In the context of sentiment analysis, it means that when one says something positive, one actually means negative, and vice versa. Sarcastic sentences are very difficult to deal with because commonsense knowledge and discourse analysis are often required to recognize them (Tsur et al. 2010; Riloff et al. 2013).

At the sentence level, another popular research problem is to identify *subjectivity* and *objective sentence*s. Subjective expressions express opinions, appraisals, evaluations, allegations, desires, beliefs, suspicions, speculations, or stances (Wiebe et al. 2004). Some of these concepts indicate positive or negative sentiments. Some of them do not, e.g., *I want to buy a* *camera that can take good photos* which is a subjective sentence but does not express a positive or negative sentiment about anything. Objective sentences state facts. However, we should note that objective sentences can imply positive or negative sentiments of their authors because there are desirable facts and undesirable facts (Zhang and Liu 2011). For example, the sentence *I bought the mattress a week ago and a valley has formed in the middle* states a fact, but the fact is undesirable. It thus implies a negative opinion about the quality of the mattress.

Aspect Sentiment Classification

Aspect-level classification classifies or determines sentiment on individual targets, which both the document-level and the sentence-level classification do not do because no sentiment target is involved at these two coarse levels of analysis. However, in applications, one often needs to know opinion targets. Without targets, any positive or negative sentiment is of limited use. For example, the sentence *trying out Chrome because Firebox works poorly* expresses a negative sentiment. But if we do not know that the negative sentiment is toward Firefox, not Chrome, the sentiment is of little use and can even be misleading. Many sentences also have mixed sentiments, e.g., *The performance of the car is great but the price is too high.* Aspect sentiment classification should find the opinion on the *performance* aspect of the car to be positive and the opinion on the *price* aspect of the car to be negative. In short, aspect sentiment classification determines sentiments expressed on entities and aspects of entities, which gives more useful information than document or sentence classification.

Although supervised learning can be applied, the kinds of features used for document and sentence sentiment classification are no longer sufficient or appropriate. The key reason is that those features do not consider (or are independent of) opinion targets and are thus unable to determine to which target an opinion refers. To remedy this problem, opinion target needs to be considered in learning. Two kinds of approaches have been proposed. The first one is to generate a set of features that are dependent on each opinion target in the sentence, e.g., weighing features based on their distances to a target. The second approach is to check the application scope of each sentiment expression to determine whether it covers the target in the sentence. For example, in the sentence *Apple is doing very well in this bad economy,* the sentiment word *bad*'s application scope covers only *economy*, not *Apple*. Current supervised learning methods mainly use the first approach but also have a flavor of the second approach (Jiang et al. 2011).

The lexicon-based approach can be employed as well. It computes the sentiment orientation on a target in a sentence by using a *sentiment aggregation function* that takes into account the distances of the sentiment expressions (sentiment words or phrases) and the opinion target in the sentence and/or by exploiting syntactic relationships of sentiment expressions and opinion targets to find the *application scope* of each sentiment expression. At the high level, the lexicon-based approach works as follows: it uses (1) a lexicon of sentiment expressions including sentiment words, phrases, idioms, and composition rules, (2) a set of rules for handling different language constructs (e.g., sentiment shifters and but-clauses) and different types of sentences, and (3) a sentiment aggregation function or a set of sentiment and target relationships derived from the parse tree to determine the sentiment orientation on each target (Ding et al. 2008; Liu 2012).

Comparative Sentences

Unlike a regular opinion sentence, a comparative sentence expresses a relation based on similarities or differences of more than one entity. In English, comparisons are usually conveyed using the *comparative* or *superlative* forms of adjectives or adverbs, e.g., *The picture quality of Canon cameras is better than that of Sony cameras.* To mine comparative opinions, aspect sentiment analysis is necessary because it does not make much sense to classify a comparative sentence as expressing a positive, negative, or neutral sentiment. See

Jindal and Liu (2006) and Liu (2015) for more details.

Supervised Learning vs. Lexicon-Based Approach

The key advantage of supervised learning for sentiment classification is that it can automatically learn from all kinds of features for classification through optimization. Most of these features are difficult to use by a lexicon-based method. However, supervised learning depends on the training data, which needs to be manually labeled for each domain. A shortcoming of the approach is that a supervised classifier trained from the labeled data in one domain often does not work in another domain. Thus, for each domain, new training data needs to be labeled, which is time consuming. Another shortcoming is that it is hard to learn things that do not occur frequently. The lexicon-based approach is able to avoid these issues to some extent and has been shown to perform well in a large number of applications. Its main advantage is domain independence, that is, it can be applied to any domain without manual labeling of a large amount of training data as required in the supervised learning approach. The lexicon-based method is also flexible in the sense that the system can be easily extended and improved. If an error occurs, the user simply corrects some existing rules and/or adds new rules to the system's rule base. However, the lexicon-based approach also has its disadvantages. It needs heavy investments in time and effort to build the initial knowledge base of lexicon, patterns, and rules. Furthermore, although the lexicon-based approach is supposed to be domain independent, some additional work is still needed to take care of the idiosyncrasies of each domain. The main issue is that it is quite hard to deal with domain-dependent or context-dependent sentiment words and phrases (see below and Liu 2015).

Aspect and Entity Extraction

The task of aspect and entity extraction is to identify and extract opinion targets (aspect or entity) from opinion documents. Since aspect extraction and entity extraction are closely related tasks, ideas and methods proposed for aspect extractions can also be shared with the entity extraction task. Much of the existing research focused on aspect extraction. Current aspect extraction methods can be roughly grouped into four categories: mining frequent noun phrases, utilizing syntactic relations of sentiment words and their targets, and applying supervised sequence learning models and topic modeling. All these approaches are used in practice.

Finding Frequent Noun Phrases

Since people often use the same words when they comment on the same product aspects, Hu and Liu (2004) makes use of this observation to mine aspects by simply finding frequent nouns and noun phrases in reviews using frequent itemset mining (Agrawal and Srikant 1994). Those more frequent noun phrases are also likely to be more important aspects because people usually comment on those more important aspects more frequently.

Exploiting Syntactic Relations of Sentiment and Target

It was observed in Hu and Liu (2004) that adjective sentiment words often modify (or describes) noun aspects (e.g., *great picture*). Hu and Liu (2004) used such relations to identify aspects that are hard to find by the frequency-based method above. Zhuang et al. (2006) formulated the idea based on the dependency grammar and extracted aspect and sentiment word pairs from movie reviews using a set of dependency relations. Qiu et al. (2011) developed the idea further and proposed an algorithm called *double propagation* (DP). DP uses a set of manually compiled dependency rules derived from some dependency relations to identify both aspects and sentiment words simultaneously through a bootstrapping process. These methods are all based on the idea that opinion always has target, and there are often syntactic relations that connect sentiment words and targets in a sentence. Thus, sentiment words can be recognized by identified aspects, and aspects can be identified by known sentiment words. The extracted sentiment words and aspects are utilized to identify new sentiment words and new aspects, which are used again to extract more sentiment words and aspects. This is the approach used in the DP method. Recently, this method was improved with automated rule selection (Liu et al. 2015) and word alignment from the machine translation research (Liu et al. 2013).

Applying Supervised Sequence Learning Models

Sequence learning models such as Hidden Markov models (HMM) and conditional random fields (CRF) are widely used in information extraction. They are thus also used for aspect extraction. Aspect extraction can be regarded as a sequence labeling task since entity, aspect, and opinion expressions are often interdependent and occur in a sequence in a sentence. Jin and Ho (2009) utilized lexicalized HMM to extract product aspects and opinion expressions from reviews. Different from traditional HMM, they integrated linguistic features such as part of speech and lexical patterns into HMM. Jakob and Gurevych (2010) utilized CRF to extract opinion aspects from opinion sentences.

Topic Modeling

Topic models such as PLSA (probabilistic latent semantic analysis) and LDA (latent Dirichlet allocation) have been popularly used to mine hidden topics from the document corpora. In the context of aspect extraction, aspects are basically topics in topic modeling. Mei et al. (2007) proposed a model for extracting both aspects and sentiment words. Titov and McDonald (2008) pointed out that global topic models such as PLSA and LDA might not be suitable for detecting aspects from reviews. To tackle this problem, they proposed some multigrain topic models to discover aspects, which models two distinct types of topics: global topics and local topics. Lin and He (2009) proposed a joint topic-sentiment model, which extended LDA by adding a sentiment layer. It detects sentiment and aspect simultaneously from the corpus. Further works along a similar line have been done in Brody and Elhadad (2010), Wang et al. (2010), Zhao et al. (2010), and Jo and Oh (2011). Recently, two new types of models were proposed*:* *knowledge-based models* (Mukherjee and Liu 2012) which can exploit prior domain knowledge to produce better results and *lifelong topic models* (Chen and Liu 2014) which exploit the big data to automatically mine prior knowledge to be used in the modeling process.

Sentiment Lexicon

It is quite clear that sentiment words are instrumental for sentiment analysis. Positive sentiment words are used to express some desired states, while negative ones are used to express some undesired states. Examples of positive sentiment words are *beautiful*, *wonderful*, and *good*. Examples of negative sentiment words are *bad*, *poor*, and *terrible*. Apart from individual words, there are also sentiment phrases and idioms. To compile a sentiment word list or lexicon, two approaches have been studied: dictionary-based approach and corpus-based approach.

Dictionary-Based Approach

This approach is based on bootstrapping using a small set of seed sentiment words and an online dictionary, e.g., WordNet or thesaurus. The strategy is to first collect a small set of sentiment words manually with known orientations and then to grow this set by searching in the WordNet or an online thesaurus to find their synonyms and antonyms. The newly found words are added to the seed list. The next iteration starts. The iterative process stops when no more new words are found (Hu and Liu 2004; Kim and Hovy 2004; Kamps et al. 2004).

Corpus-Based Approach

The corpus-based approach relies on syntactic patterns and also a seed list of sentiment words to find other sentiment words in a large corpus. One of the key ideas was proposed in Hatzivassiloglou and McKeown (1997). The technique uses the set of seed sentiment words and a set of linguistic constraints or conventions on connectives to identify additional sentiment words and their orientations. One of the constraints is about the conjunction AND, which says that conjoined adjectives usually have the same sentiment orientation. For example, if *beautiful* is known to be positive, we can infer that *spacious* is also positive from the sentence *This car is beautiful and spacious*. Rules or constraints are also designed for other connectives, OR, BUT, EITHER-OR, and NEITHER-NOR. This constraint is called *sentiment consistency*. Kanayama and Nasukawa (2006) and Ding et al. (2008) expanded this approach to intra-sentential and inter-sentential sentiment consistency. Ding et al. (2008) further showed that the same word may indicate positive sentiment in one sentence context but negative sentiment in another sentence context. For example, in the domain of car reviews, the word "quiet" expresses opposite sentiments or opinions in the following two sentences: *This car is very quiet* (positive) and *The audio system in the car is very quiet* (negative). The authors proposed to consider both the sentiment word and the aspect together in determining the sentiment orientation of the sentiment word. To determine the sentiment orientation of the pair, the above sentiment consistency idea is still used. In a similar vein, Choi and Cardie (2009) studied the problem of adapting a general-purpose sentiment lexicon to a specific domain of application.

Sentiment Analysis of Emotions

Emotions are human feelings. They are similar and also different from opinions. An opinion expresses an evaluation or appraisal about some objects, whereas an emotion expresses a human inner feeling. Human beings have many different types of emotions. However, there is still no agreement among researchers on how many kinds of emotions there are and what they are. According to Parrott (2001), humans have six basic emotions: joy, love, anger, fear, sadness, and surprise. Existing sentiment analysis of emotions is focused on classification of emotion types expressed in sentences. Both supervised learning and lexicon-based approaches have been attempted by researchers.

In supervised learning, Alm et al. (2005) classified the emotional affinity of sentences in the narrative domain of children's fairy tales. The features are not the traditional word n-grams but fourteen groups of Boolean features about each sentence and its context in the document. The classes are only two: neutral and emotional. In Mohammad (2012), a Twitter data set was annotated with emotion types based on emotion words or hashtags in Twitter posts. The author then performed classification of emotions using SVM with binary features that capture the presence or absence of unigrams and bigrams. Additional references can be found in Liu (2015).

In the lexicon-based approach, Yang et al. (2007) first constructed an emotion lexicon and then performed emotion classification at the sentence level using the lexicon. To construct the emotion lexicon, the proposed algorithm uses only sentences with a single user-provided emoticon. For each word, it computes a collocation (or association) strength of the word with each emoticon using a measure similar to pointwise mutual information (PMI). Those top-scoring words are very likely to indicate different types of emotions. For emotion classification of sentences, it experimented with two approaches: the lexicon-based approach and the supervised learning approach. For supervised learning, only the top k emotion words were used as features.

Summary

This article gave a brief introduction to sentiment analysis. Interested readers can refer to Liu (2015) for an in-depth and comprehensive coverage of the topic. Sentiment analysis is a highly challenging research problem with almost unlimited applications. It has been one of the most active research areas in natural language processing for many years. Although significant progresses have been made and numerous industrial systems have been built, the problem remains to be very difficult. The accuracy results in many cases are still unsatisfactory. However, the practical application needs and technical challenges will keep the field vibrant and lively for years to come.

Growth function

Definition

The shattering coefficient $S_{\mathcal{F}}(n)$ is a function that measures the size of a function class $\mathcal{F}$ when its functions $f : \mathcal{X} \to \mathbb{R}$ are restricted to sets of points $\mathbf{x} = (x_1, \ldots, x_n) \in \mathcal{X}^n$ of size n. Specifically, for each $n \in \mathbb{N}$ the shattering coefficient is the maximum size of the set of vectors $\mathcal{F}_{\mathbf{x}} = \{(f(x_1), \ldots., f(x_n)) : f \in \mathcal{F}\} \subset \mathbb{R}^n$ that can be realized for some choice of $\mathbf{x} \in \mathcal{X}^n$. That is,

$$S_{\mathcal{F}}(n) = \sup_{\mathbf{x} \in \mathcal{X}^n} |\mathcal{F}_x|.$$

The shattering coefficient of a hypothesis class $\mathcal{H}$ is used in ▶ generalization bounds as an analogue to the class's size in the finite case.

Similarity Measures

Michail Vlachos
IBM Research, Zurich, Switzerland

Synonyms

Distance; Distance functions; Distance measures; Distance metrics

Introduction

The term similarity measure refers to a function that is used for comparing objects of any type. The objects can be data structures, database records, or even multimedia objects (audio, video, etc). Therefore the input of a similarity measure is two objects, and the output is, typically, a number between 0 and 1; "zero" meaning that the objects are completely dissimilar and "one" signifying that the two objects are identical. Similarity is related to distance, which is the inverse of similarity, that is, a similarity of 1 implies a distance of 0 between two objects.

Background

Similarity measures are typically used for quantifying the affinity between objects in search operations, in which the user presents an object (query) and requests other objects "similar" to the given query. Therefore, a similarity measure is a mathematical abstraction for comparing objects and it assigns a single number that indicates the affinity between the said pair of objects. The results of the search are customarily presented to the user in the order suggested by the similarity value returned. Objects with higher similarity value are presented first because they are deemed to be more relevant to the query posed by the user. For example, when searching for specific keywords on an internet search engine, internet pages that are more relevant/similar to the query posed are presented first. The selection of the proper similarity function is an important parameter in many applications, including ▸ instance-based learning, ▸ clustering, and ▸ anomaly detection.

Most similarity measures attempt to model (imitate) the human notion of similarity between objects. If a similarity function resembles very closely the similarity ranking between objects as returned by a human, then it is considered successful. This, however, is also where the difficulty lies because in general similarity is something that is very subjective.

Consider the case where a user poses the keyword query "crane" at a search engine while searching for images. The results returned would contain images of machinery, birds, or even origami creations. This is because when the similarity measure used is solely based on textual information then all such images are indeed proper answers to the query. If one were also interested in the semantics of an image, then perhaps additional features such as texture, color, or shape could have been used. Therefore, to define an effective similarity measure, one first has to extract the proper *object features* and then evaluate the similarity using an appropriate distance function.

Classes of Similarity Functions

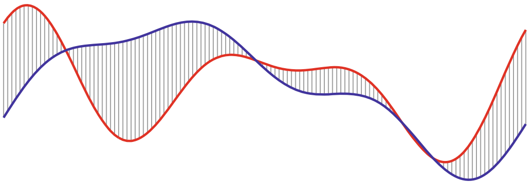
There are two major classes of similarity functions: metric and nonmetric functions. For a function d to be a metric, it has to satisfy all of the following three properties for any objects X, Y, Z:

1. $d(X,Y) = 0$ iff $X = Y$ (identity axiom)
2. $d(X,Y) = d(Y,X)$ (symmetry axiom)
3. $d(X,Y) + d(Y,Z) \geq d(X,Z)$ (triangle inequality)

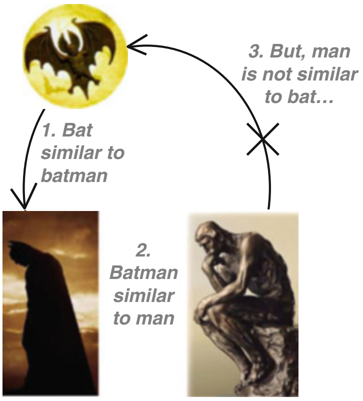
Metric similarity functions are very widely used in search operations because they support the triangle inequality. The triangle inequality can help prune much of the search space by eliminating objects from examination that are guaranteed to be distant to the given query (Agrawal et al. 1993; Zezula 2005). The most frequently used metric similarity function is the Euclidean distance. For two objects X and Y that are characterized by set of n features $X = (x_1, x_2, \ldots, x_n)$ and similarly $Y = (y_1, y_2, \ldots, y_n)$, the Euclidean distance is defined as

$$D = \sqrt{\sum_{i=1}^{n} (x_i - y_i)^2}$$

S



Similarity Measures, Fig. 1 Mapping achieved by the Euclidean distance between time-series data



Similarity Measures, Fig. 2 Nonmetric similarity that disobeys the triangle inequality

If we represent the objects X and Y as an ordered sequence of their features, we can visualize the linear mapping achieved by the Euclidean distance in Fig. 1.

Nonmetric similarity measures resemble more closely the human notion of similarity by allowing a more flexible matching between the objects examined, for example, by allowing nonlinear mappings or even by accommodating occlusion of points or features. The human visual system is in general considered to be nonmetric. Nonmetric measures typically disobey the triangle inequality. For example, consider the following nonmetric relationship: "Batman" is similar to "man," and "bat" is also similar to "batman," but this does not imply that "bat" is similar to "man." This is illustrated in Fig. 2.

Examples for Time-Series Data

Consider the case of time-series data. Widely used nonmetric similarity functions are the warping distance and the longest common subsequence (LCSS). The warping distance (also known as dynamic time warping or DTW) has been used very extensively in the past in voice-recognition tasks because of its ability to perform compression or decompression of the features, allowing flexible nonlinear mappings. In Fig. 3, we depict the outcome of the measures for time-series data mentioned above. The Euclidean distance performs a rigid linear mapping of points, the DTW can perform nonlinear one-to-many mappings, and the LCSS constructs a one-to-one nonlinear mapping.

Recently, similarity metrics based on information theory, and in specific, on Kolmogorov complexity, have been presented (Li 2004; Keogh 2004) and can also be considered as *compression-based* measures. A very simple and easily implementable version of a compression-based distance is

$$d_c(X,Y) = \frac{C(XY)}{C(X)+C(Y)}$$

where $C(X)$ is the compressed size (bytes) of X given a certain compression algorithm. The distance will be close to 1 if X and Y are dissimilar and less than 1 if X and Y are related. Therefore we exploit the fact that if X and Y are "similar," they should compress equally well (approximately same number of bytes) when considered either separately or together because the compression dictionaries will be similar when the two objects are related. In summary, the choice of similarity measure is highly dependent on the application at hand. The practitioner should also closely consider on which object features the similarity measure will be applied. Ultimately, the combination of both feature selection and similarity measure will define the quality of a search process.

Simple Recurrent Network

Risto Miikkulainen
Department of Computer Science, The University of Texas at Austin, Austin, TX, USA

Synonyms

Elman network; Feedforward recurrent network

Definition

The simple recurrent network is a specific version of the ▶ backpropagation neural network that makes it possible to process sequential input and output (Elman 1990). It is typically a three-layer network where a copy of the hidden layer activations is saved and used (in addition to the actual input) as input to the hidden layer in the next time step. The previous hidden layer is fully connected to the hidden layer. Because the network has no recurrent connections per se (only a copy of the activation values), the entire network (including the weights from the previous hidden layer to the hidden layer) can be trained with the backpropagation algorithm as usual. It can be trained to read a sequence of inputs into a target output pattern, to generate a sequence of outputs from a given input pattern, or to map an input sequence to an output sequence (as in predicting the next input). Simple recurrent networks have been particularly useful in ▶ time series prediction, as well as in modeling cognitive processes, such as language understanding and production.

Speedup Learning

Alan Fern
Science, Oregon State University, Corvallis, OR, USA

Definition

Speedup learning is a branch of machine learning that studies learning mechanisms for speeding up problem solvers based on problem-solving experience. The input to a speedup learner typically consists of observations of prior problem-solving experience, which may include traces of the problem solver's operations and/or solutions to solve the problems. The output is knowledge that the problem solver can exploit to find solutions more quickly than before learning without seriously effecting the solution quality. The most distinctive feature of speedup learning, compared with most branches of machine learning, is that the learned knowledge does not provide the problem solver with the ability to solve new problem instances. Rather, the learned knowledge is intended solely to facilitate faster solution times compared to the solver without the knowledge.

Motivation and Background

Much of the work in computer science and especially artificial intelligence aims at developing practically efficient problem solvers for combinatorially hard problem classes such as automated planning, logical and probabilistic reasoning, game playing, constraint satisfaction, and combinatorial optimization. While it is often straightforward to develop optimal problem solvers for these problems using brute-force, exponential-time search procedures, it is generally much more difficult to develop solvers that are efficient across a wide range of problem instances. The main motivation behind speedup learning is to create adaptive problem solvers that can learn patterns from problem-solving experience that can be exploited for efficiency gains. Such adaptive solvers have the potential to significantly outperform traditional static solvers by specializing their behavior to the characteristics of a single problem instance or to an entire class of related problem instances. The exact form of knowledge and learning mechanism is tightly tied to the problem class and the problem-solver architecture.

Most branches of machine learning, such as ▶ supervised classification, aim to learn fundamentally new problem-solving capabilities that are not easily programmed by hand even when ignoring efficiency issues – for example, learning to recognize handwritten digits. Speedup learning is distinct in that it is typically applied in situations where hand-coding an optimal, but inefficient, problem solver is straightforward – for example, solving satisfiability problems. Rather, learning is aimed exclusively at finding solutions in a more practical time frame.

Work in speedup learning grew out of various subfields of artificial intelligence and more generally computer science. An early example, from automated planning, involved learning knowledge for speeding up the original STRIPS planner (Fikes et al. 1972) via the learning of triangle tables or macros that could later be exploited by the problem solver. Throughout the 1980s and early 1990s, there was a great deal of additional work on speedup learning in the area of automated planning as overviewed in Minton (1993) and Zimmerman and Kambhampati (2003).

Another major source of speedup learning research has originated from the areas of AI search and constraint satisfaction. Many of the ▶ intelligent backtracking mechanisms from these areas, which are critical to perform, can be viewed as speedup learning techniques (Kambhampati 1998) where knowledge is learned, while solving a problem instance that better informs later search decisions. Such methods have also come out of the area of logic programming (Kumar and Lin 1988), where search efficiency plays a central role.

In addition, various branches of AI have developed speedup learning approaches based on learning-improved heuristic evaluation functions. Samuel's checker player (Samuel 1959) was one such early example, where learned evaluation functions allowed for the performance of deep game tree search to be approximated by a shallower, less expensive search.

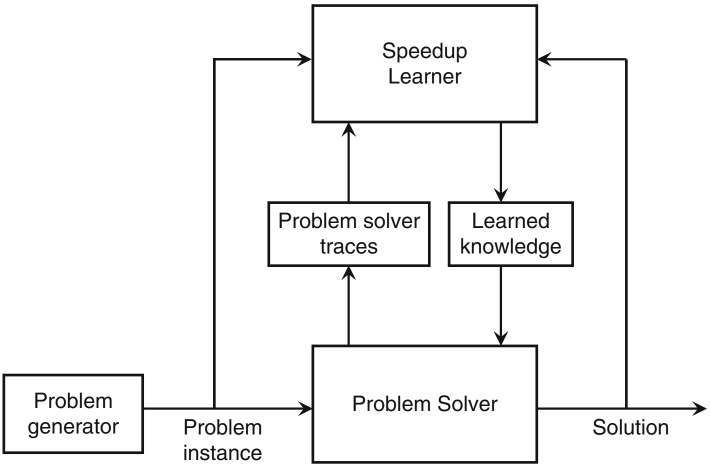
Structure of Learning System

Figure 1 shows a generic diagram of a speedup learning system. The main components are the problem solver and the speedup learner. The role of the problem solver is to receive problem instances from a problem generator and to produce solutions for those instances. For example, problem solvers might include constraint-satisfaction engines, automated planners, or A^* search. The role of the speedup learner is to produce knowledge that the problem solver can use to improve its solution time. The input to the speedup learner, which is analyzed in order to produce the knowledge, can include one or more of the following data sources: (1) the input problem instances, (2) traces of the problem solver's decisions while solving the input problems, and (3) solutions to solved problems.

Clearly there is a large space of possible speedup learning systems that result from different problem solvers, forms of learned knowledge, learning methods, and intended mode of applicability. Some of the main dimensions are described in the following section in which speedup learning approaches can be characterized. Examples of typical learners that span this space are provided, noting that the examples are far from an exhaustive list.

Dimensions of Speedup Learning

Intra-problem Versus Inter-problem Speedup. Intra-problem speedup learning is when knowledge is learned during the solution of the current problem instance and is only applicable to speeding up the solution of the current instance. After a solution is found, the knowledge is discarded as it is not applicable for the future instances. Inter-problem speedup learning is when the learned knowledge is applicable not only to the problem(s) it was learned on but also to new problems



Speedup Learning, Fig. 1 Schematic diagram of a speedup learning system. The problem solver receives problem instances from a problem generator and produces solutions. The speedup learner can observe the input problem instances, traces of the problem solver while solving the problem instances, and sometimes also the solutions to previously solved problem instances. The speedup learner outputs knowledge that can be used by the problem solver to speed up its solution time either on the current problem instance (intra-problem speedup) or future related instances (inter-problem speedup)

to be encountered in the future. In this sense, the learned knowledge can be viewed as a generalized knowledge about how to find solutions more quickly for an entire class of problems.

Typically in the inter-problem learning, the problem generator produces instances that are related in some way and, thus, share common structure that can be learned from the earlier instances and exploited when solving the later instances. Rather intra-problem speedup learners treat each problem instance as completely distinct from the rest. Also note that inter-problem learners have the potential to benefit from the analysis of solutions to previous problem instances. Rather, intra-problem learners are unable to use this source of information, since once the current problem is solved, no further learning is warranted.

Types of Learned Knowledge. Most problem solvers can be viewed as search procedures, which is the view that will be taken when characterizing the various forms of learned knowledge in speedup learning. Four types of commonly used knowledge are listed below, noting that this is far from an exhaustive list. First, *pruning constraints* are the sets of constraints on search nodes that signal when certain branch of the search space can be safely pruned. Second, *macro operators* (macros) are sequences of search operators that are typically useful when executed in order. Problem solvers can often utilize macros in order to decrease the effective solution depth of the search space by treating macros as additional search operators. It is important that the decrease in effective depth is enough to compensate for the increase in number of operators, which increases the search complexity. Third, *search-control rules* are the sets of rules that typically test the current problem-solving state and suggest problem-solving actions such as rejecting, selecting, or preferring a particular search operator. In the extreme case, learned search-control rules can completely remove the need for search. Fourth, *heuristic evaluation functions* are used to measure the quality of a particular search node. Learning-improved heuristics can result in better directed search behavior.

Deductive Versus Inductive Learning. ▶ Deductive learning refers to a learning process for which the learned knowledge can be deductively proven to be correct. For example, in the case of learned pruning constraints, a deductive learning mechanism would provide a guarantee that the pruning was sound in the sense that the optimality of the problem solver would be unaffected. ▶ Inductive learning mechanisms rather are statistical in nature and typically do not produce knowledge with associated deductive guarantees. Rather, inductive methods focus on finding statistical regularities that are typically useful, though perhaps not correct in all cases. For example, an inductive learner may discover patterns that are strongly correlated to pruning opportunities, though these patterns may have a small probability of leading to unsound pruning.

In cases where one must guarantee a sound and complete problem solver, deductive learning approaches are always applicable, though their utility depends on the particular application. In certain cases, inductively learned knowledge can also be utilized in a way that does not affect the correctness of the problem solver. For example, inductively learned search-control rules that assert preferences, rather than prune nodes from the search, do not lead to incompleteness. Traditionally, the primary disadvantage of deductive learning, compared with inductive learning, is that the inductive methods typically produce knowledge that generalizes to a wider range of situations than deductive methods. In addition, deductive learning methods are often more costly in terms of learning time as they rely on expensive deductive reasoning mechanisms. Naturally, a number of speedup learning systems exist that utilize a combination of inductive and deductive learning techniques.

Examples of Intra-problem Speedup Learning

Much of the speedup learning work arising from research in AI search and constraint satisfaction falls into the intra-problem paradigm. The most common forms of learning are deductive and are based on computing explanations of "search failures" that occur during the solution of a particular problem. Here a search failure typically corresponds to a point where the problem solver must backtrack. By computing and forming such failure explanations, the problem solver is typically able to avoid similar types of failures in the future by detecting that a search path will lead to failure without fully exploring that path. ▶ Nogood learning is a very successful, and commonly used, example of the general failure-explanation approach (Schiex and Verfaillie 1994). Nogoods are combinations of variable values that lead to search failures. By computing and recording nogoods, it is possible to immediately prune search states that consider those value combinations. There are many variations of nogood learning, with different techniques utilizing different approaches to analyzing search failures to extract general nogoods.

Another example of the failure-explanation approach, which is commonly utilized in satisfiability solvers, is ▶ clause learning. The idea is similar to nogood learning. When a failure occurs during the systematic search, a proof of the failure is constructed and analyzed to extract implied constraints, or clauses, that the solution must satisfy. These learned clauses are then added to the set of clauses of the original satisfiability problem and in later search trigger early pruning when they, or their consequences, are violated. Efficient implementations of this idea have led to huge gains in satisfiability solvers. In addition, it has been shown theoretically that clause learning can improve solution times by an exponential factor (Beame et al. 2004).

Inductive techniques for learning heuristic evaluation functions have also been investigated in the intra-problem speedup paradigm. Here we discuss just two such approaches, where in both cases the key idea is to observe the problem solver and extract training examples that can be used to learn an accurate evaluation function. A particularly successful example of this approach is the STAGE system (Boyan and Moore 1998) for solving combinatorial optimization problems such as traveling salesman and circuit layout. The problem-solving architecture used by STAGE is based on repeated random restarts of a fast hill-climbing local optimizer, which, when given an initial configuration of the combinatorial object, performs a greedy search to a local minimum configuration. The speedup learning mechanism for STAGE is to learn an approximate function that maps initial configurations to the performance of the local optimizer when started at that configuration. Note that on each restart of the problem solver, the learning component gets a training example that can be used to improve the function. The problem solver uses the learned function in order to select promising configurations from which to restart, rather than choosing randomly. In particular, STAGE attempts to restart from a configuration that optimizes the learned function, which is the predicted best starting point for the hill climber. This overall approach has shown impressive performance gains in a number of combinatorial optimization domains.

As a second example of inductive learning of heuristics in the intra-problem paradigm, there has been work within the more traditional problem-solving paradigm of best-first search (Sarkar et al. 1998). Here the speedup learner observes the sequence of search nodes traversed by the problem solver. For any pair of nodes observed to be on the same search path, the learner creates a training example in an attempt to train a heuristic to better predict the distance between those two nodes. Ideally, this updated heuristic function better reflects the distance from nodes in the search queue to the goal node of the current problem instance and, hence, results in improved search performance.

Examples of Inter-problem Speedup Learning

Much of the work on inter-problem speedup learning came out of AI planning research, where researchers have long studied learning approaches for speeding up planners. Speedup in planning is focused in this chapter, noting that similar ideas have also been pursued in other research areas such as constraint satisfaction. For a collection and survey of work on speedup in planning, see Minton (1993) and Zimmerman and Kambhampati (2003). Typically in this work, one is interested in learning knowledge for an entire planning domain, which is a collection of problems that share the same set of actions. The Blocksworld is a classic example of such a planning domain. After experiencing and solving a number of problems from a target domain, such as the Blocksworld, the learned knowledge is then used to speed up performance on new problems from the same domain.

There have been a number of deductive learning approaches to speed up learning in planning, which are traditionally cited as ▸ explanation-based learning (EBL) approaches (Minton et al. 1989). EBL for AI planning is strongly related to the failure-explanation approaches developed for CSPs as characterized nicely by Kambhampati (1998). There are two main differences between the inter-problem EBL work in planning and the intra-problem EBL approaches for CSPs. First, EBL approaches in planning produce more general explanations that are applicable not only in the problem in which they were learned but also new problems. This is often made possible by introducing variables in the place of specific objects into the explanations derived from a particular problem. This allows the explanations to apply to contexts in new problems that share similar structure but involve different objects. The second difference is that inter-problem EBL approaches in planning often produce explanations of successes and not just of failures. These positive explanations are not possible in the context of intra-problem speedup since the intra-problem learner is only interested in solving a single problem.

Despite the relatively large effort invested in inter-problem EBL research, the best approaches typically did not consistently lead to significant gains and even hurt performance in many cases. A primary way that EBL can hurt performance is by learning too many explanations, which results in the problem solver spending too much time simply evaluating the explanations at the cost of reducing the number of search nodes considered. This problem is commonly referred to as the EBL utility problem (Minton 1988) as it is difficult to determine which explanations have high enough utility to be worth keeping.

In addition to EBL, there has also been work on inductive mechanisms for acquiring search-control rules to speed up AI planners. Typically, statistical learning mechanisms are used to find common patterns that can distinguish between good and bad search decisions. As one example, Huang et al. learn action-rejection and selection rules based on the solutions to planning problems from a common domain (Huang et al. 2000). The learned rules were then added as constraints to the constraint satisfaction engine, which served to guide the solver to solution plans more quickly. Another approach, which has been studied at a theoretical and empirical level, is to learn heuristic functions to guide a bounded search process (Xu and Fern 2009), in particular, breadth-first beam search. Results in a number of planning domains demonstrate significant improvements over planners that do not incorporate a learning component. One other class of approach is based on attempting to learn knowledge that removes the need for a problem solver altogether, in particular, to learn a reactive policy for quickly selecting actions in any given state of the environment. Such policies can be learned via statistical techniques by simply trying to learn an efficient function that maps planning states to the actions selected by the planner. Despite its simplicity, this approach has demonstrated considerable success (Khardon 1999) and has also been characterized at a theoretical level (Tadepalli and Natarajan 1996).

SMT

Definition

Statistical machine translation (SMT) deals with automatically mapping sentences in one human language (for example, French) into another human language (such as English). The first language is called the *source* and the second language is called the *target*. This process can be thought of as a stochastic process. There are many SMT variants, depending upon how translation is modeled. Some approaches are in terms of a string-to-string mapping, some use trees-to-strings, and some use tree-to-tree models. All share in common the central idea that translation is automatic, with models estimated from parallel corpora (source-target pairs) and also from monolingual corpora (examples of target sentences).

Motivation and Background

Machine Translation has widespread commercial, military, and political applications. For example, increasingly, the Web is accessed by non-English speakers reading non-English pages. The ability to find relevant information clearly should not be bounded by our language-speaking capabilities. Furthermore, we may not have sufficient linguists in some language of interest to cope with the sheer volume of documents that we would like translated. Enter automatic translation. Machine translation poses a number of interesting machine learning challenges: data sets are typically very large, as are the associated models; the training material used is often noisy and plagued with sparse statistics; the search space of possible translations is sufficiently large that exhaustive search is not possible. Advances in machine learning, such as maximum-margin methods, frequently appear in translation research. SMT systems are now sufficiently mature that they can be deployed in production systems. A good example of this is Google's online Arabic-English translation, which is based upon SMT techniques.

Structure of the Learning System

Modeling

Formally, translation can be described as finding the most likely target sentence e^* for some source sentence f:

$$e^* = \operatorname{argmax}_e P(f|e)P(e)$$

(e conventionally stands for English and f for French, but any language pairs can be substituted.)

This approach has three major aspects:

- A translation model ($P(f|e)$), which specifies the set of possible translations for some target sentence. The translation model also assigns probabilities to these translations, representing their relative correctness.
- A language model ($P(e)$), which models the fluency of the proposed target sentence. This assigns a distribution over strings, with higher probabilities being assigned to sentences which are more representative of natural language. Language models are usually smoothed n-gram models, typically conditioning on two (or more) previous words when predicting the probability of the current word.
- A search process (the argmax operation), which is concerned with navigating through the space of possible target translations. This is called *decoding*. Decoding for SMT is NP-hard, so most approaches use a beam search.

This is called the *Source-Channel* approach to translation (Brown et al. 1994). Most modern SMT systems instead use a ▸ log-linear model, as it is more flexible and allows for various aspects of translation to be balanced together (Och and Ney 2001):

$$e^* = \operatorname{argmax}_e \left(\sum_i fi(e, f)\lambda_i \right)$$

Here, feature functions $f_i(e, f)$ capture some aspect of translation and each feature function has an associated weight λ_i. When we have the two feature functions $P(f|e)$ and $P(e)$, we have the Source-Channel model. The weights are scaling factors (balancing the contributions that each feature function makes) and are optimized with respect to some ▸ loss function which evaluates translation quality. Frequently, this is in terms of the *BLEU* evaluation metric Papineni et al. (2001). Typically, the error surface is nonconvex and the loss function is nondifferentiable, so search techniques which do not use first-order derivatives must be employed. It is worth noting that machine translation evaluation is a complex problem and that methods such as BLEU are not without criticism.

SMT systems usually decompose entire sentences into a sequence of strings called *phrases* (Koehn et al. 2003). The modeling task then becomes one of determining how to break a source sentence into a sequence of contiguous phrases and how to specify which source phrase should be associated with each target phrase. Figure 1 shows an example English-French sentence pair. Figure 2 shows that sentence pair decomposed into phrase-pairs. Phrase-based systems represented an advance over previous word-based models, since phrase-based translation can capture local (within a phrase) word order. Furthermore, phrase-based translation approaches need to make fewer decisions than word-based models. This means there are fewer errors to make.

Those people have grown up, lived and worked for many years in a farming district.
Ces gens ont grandi, vécu et oeuvré des dizaines d'années dans le domain agricole.

oeuvré des dizaines d' années dizaines	worked many years
des dizaines d' années dans	many years in
années dans le	years in a
le domaine agricole	a farming districtle
domaine agricole .	farming district .

Statistical Machine Translation, Fig. 2 Example phrase pairs

A major aspect of any SMT approach is dealing with phrasal *reordering*. Typically, the translation of each source phrase need not follow the same temporal order in the target sentence. Simple approaches model the absolute distance a target phrase can "move" from the originating target phrase. More sophisticated reordering models condition this movement upon the aspects of the phrase pair.

Our description of SMT is in terms of a string-to-string model. There are numerous other SMT approaches, for example those which use notions of syntax (Chiang 2005). These models are now showing promising results, but are significantly more complex to describe.

Estimation

The translation model of a SMT system is estimated using *parallel corpora*. Because the search space is so large and that parallel corpora is not aligned at the word level, the estimation process is based upon a large-scale application of Expectation-Maximization, along with heuristics. This consists of the following steps:

- Determine how each source word translates to zero or more target words. The IBM models are used for this task, which are based upon the Expectation-Maximization algorithm for parameter estimation (Brown et al. 1994).
- Repeat this process, but instead determine how each target word translates to zero or more source words.
- Harmonize the previous two steps, creating a set of *word alignments* for each sentence pair. This process is designed to use the two directions as alternative views on how words should be translated. Figure 3 shows the sentence pair aligned at the word level.
- Heuristically, determine which sequence of source words translates to a sequence of target words. This produces a set of *phrase-pairs*: a snippet of text in the source sentence and

	Those	people	have	grown	up	,	lived	and	worked	many	years	in	a	farming	district	.

Statistical Machine Translation, Fig. 3 The sentence pair in Fig. 1 aligned at the word-level

the associated snippet of text in the target sentence.

- Relative frequency estimators can then be used to characterize how each source phrase translates to a given target phrase.

Parallel corpora varies in size tremendously; for language pairs such as Arabic to English, we have on the order of ten million sentence pairs. Most other language pairs (for example, Finnish to Irish) will have far smaller parallel corpora available. Parallel corpora exists for all European languages and for many other pairs, such as Mandarin to English.

The language model is instead estimated from monolingual corpora, typically using relative frequency estimates, which are then smoothed. For languages such as English, typically billion (and more) words are used. Deploying such large models can pose significant engineering challenges. This is because the language model can easily be so large that it will not fit into the memory of conventional machines. Also, the language model can be queried millions of times when translating sentences, which precludes storing it on disk.

Programs and Data

All of the code and data necessary to begin work on SMT is available either as public source, or for a small payment (in the case of corpora from the LDC):

- The standard software to estimate word-based translation models is Giza++: http://www.fjoch.com/GIZA++.html
- Converting word-based to phrase-based models and decoding can be achieved using the Moses decoder and associated sets of scripts: http://www.statmt.org/jhuws/?n=Moses.HomePage
- Translation performance can be evaluated using BLEU: http://www.nist.gov/speech/tests/mt/resources/scoring.htm
- The SRILM is the standard toolkit for building and using language models: http://www.speech.sri.com/projects/srilm/
- Europarl is a set of parallel corpora, dealing with European languages: http://www.statmt.org/europarl/
- The Linguistics Data Consortium (LDC) maintains corpora of various kinds, including large volumes of monolingual data which can be used to train language models: http://www.ldc.upenn.edu/

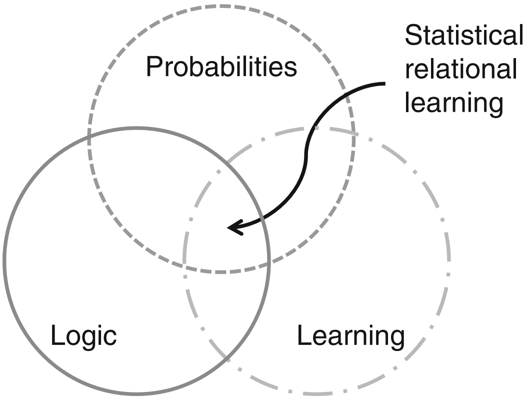
Definition

Statistical relational learning a.k.a. probabilistic inductive logic programming deals with machine learning and data mining in relational domains where observations may be missing, partially observed, or noisy. In doing so, it addresses one of the central questions of artificial intelligence – the integration of probabilistic reasoning with machine learning and first-order and relational representations – and deals with all related aspects such as reasoning, parameter estimation, and structure learning.

Motivation and Background

One of the central questions of artificial intelligence is concerned with combining expressive knowledge representation formalisms such as relational and first-order logic with principled probabilistic and statistical approaches to inference and learning. While traditionally relational and logical representations, probabilistic and statistical reasoning, and machine learning have been studied independently of one another, statistical relational learning investigates them jointly, cf. Fig. 1. A major driving force is the explosive growth in the amount of heterogeneous data that is being collected in the business and scientific world in domains such as bioinformatics, transportation systems, communication networks, social network analysis, citation analysis, and robotics. Characteristic for these domains is that they provide *uncertain* information about varying numbers of entities and relationships among the entities, that is, about *relational* domains. Traditional machine learning approaches are able to cope either with uncertainty or with relational representations but typically not with both.

Many formalisms and representations have been developed in statistical relational learning. For instance, Eisele (1994) has introduced a probabilistic variant of comprehensive unification for-



Statistical Relational Learning, Fig. 1 Statistical relational learning a.k.a. probabilistic inductive logic programming combines probability, logic, and learning malism (CUF). In a similar manner, Muggleton (1996) and Cussens (1999) have upgraded stochastic grammars toward *stochastic logic programs*. Sato (1995) has introduced *probabilistic distributional semantics* for logic programs. Taskar et al. (2002) have upgraded Markov networks toward *relational Markov networks*, and Richardson and Domingos (2006) toward *Markov logic networks*. Neville and Jensen (2004) have extended dependency networks toward *relational dependency networks*. Another research stream has investigated logical and relational extensions of Bayesian networks. It includes Poole's *independent choice logic* (Poole 1993), Ngo and Haddawy's *probabilistic logic programs* (Ngo and Haddawy 1997), Jäger's *relational Bayesian networks* (Jäger 1997), Koller, Getoor, and Pfeffer's *probabilistic relational models* (Getoor 2001; Pfeffer 2000), and Kersting and De Raedt's *Bayesian logic programs* (Kersting and De Raedt 2007).

The benefits of employing logical abstraction and relations within statistical learning are manyfold:

1. Relations among entities allow one to use information about one entity to help reach conclusions about other, related entities.
2. Variables, that is, placeholders for entities allow one to make abstraction of specific entities.
3. Unification allows one to share information among entities. Thus, instead of learning regularities for each single entity independently, statistical relational learning aims at finding general regularities among groups of entities.
4. The learned knowledge is often declarative and compact, which makes it easier for people to understand and to validate.
5. In many applications, there is a rich background theory available, which can efficiently and elegantly be represented as a set of general regularities. This is important because background knowledge may improve the quality of learning as it focuses the learning on the relevant patterns, that is, it restricts the search space.
6. When learning a model from data, relational and logical abstraction allow one to reuse experience in that *learning about one entity improves the prediction for other entities*; and this may even generalize to objects that have never been observed before.

Thus, relational and logical abstraction make statistical learning more robust and efficient. This has proven to be beneficial in many fascinating real-world applications in citation analysis, web mining, natural language processing, robotics, bio- and chemo-informatics, electronic games, and activity recognition.

Theory

Whereas most of the existing works on statistical relational learning have started from a statistical and probabilistic learning perspective and extended probabilistic formalisms with relational aspects, statistical relational learning can elegantly be introduced by starting from ▸ inductive logic programming (De Raedt 2008; Muggleton and De Raedt 1994), which is often also called *multi-relational data mining* (MRDM) (Džeroski and Lavrač 2001). Inductive logic programming is a research field at the intersection of machine learning and logic programming. It forms a formal framework and has introduced practical algorithms for inductively learning relational descriptions (in the form of logic programs) from examples and background knowledge. So, the only difference to statistical relational learning is that it does not explicitly deal with uncertainty.

Essentially, there are only two changes to apply to inductive logic programming approaches in order to arrive at statistical relational learning:

1. ▸ clauses (i.e., logical formulae that can be interpreted as rules; cf. below) are annotated with probabilistic information such as conditional probabilities; and
2. the covers relation (which states the conditions under which a hypothesis considers an example as positive) becomes probabilistic.

A probabilistic covers relation softens the hard covers relation employed in traditional inductive logic programming and is defined as the probability of an example given the hypothesis and the background theory.

Definition 1 (Probabilistic Covers Relation) A probabilistic covers relation takes as arguments an example e, a hypothesis H and possibly the background theory B, and returns the probability value $\mathbf{P}(e \mid H, B)$ between 0 and 1 of the example e given H and B, that is, covers$(e, H, B) = \mathbf{P}(e \mid H, B)$.

It specifies the likelihood of the example given the hypothesis and the background theory. Different choices of the probabilistic covers relation lead to different statistical relational learning approaches; this is akin to the learning settings in inductive logic programming.

Statistical Relational Languages

There is a multitude of different languages and formalisms for statistical relational learning. For an overview of these languages we refer to Getoor and Taskar (2007) and De Raedt et al. (2008). Here, we choose two formalisms that are representatives of the two main streams in statistical relational learning. First, we discuss Markov logic (Richardson and Domingos 2006), which upgrades Markov network toward first-order logic, and second, we discuss ProbLog (De Raedt et al. 2007), which is a probabilistic Prolog based on Sato's distribution semantics (Sato 1995). While Markov logic is a typical example of knowledge-based model construction, ProbLog is a probabilistic programming language.

Case Study: Markov Logic Networks

Markov logic combines first-order logic with ▶ Markov networks. The idea is to view logical formulae as soft constraints on the set of possible worlds, that is, on the interpretations (an interpretation is a set of facts). If an interpretation does not satisfy a logical formula, it becomes less probable, but not necessarily impossible as in traditional logic. Hence, the more formulae an interpretation satisfies, the more likely it becomes. In a Markov logic network, this is realized by associating a weight to each formula that reflects how strong the constraint is. More precisely, a Markov logic network consists of a set of weighted clauses $H = \{c_1, \ldots, c_m\}$. (Markov logic networks, in principle, also allow one to use arbitrary logical formulae, not just clauses. However, for reasons of simplicity, we only employ clauses and make some further simplifications.) The weights w_i of the clauses then specify the strength of the clausal constraint.

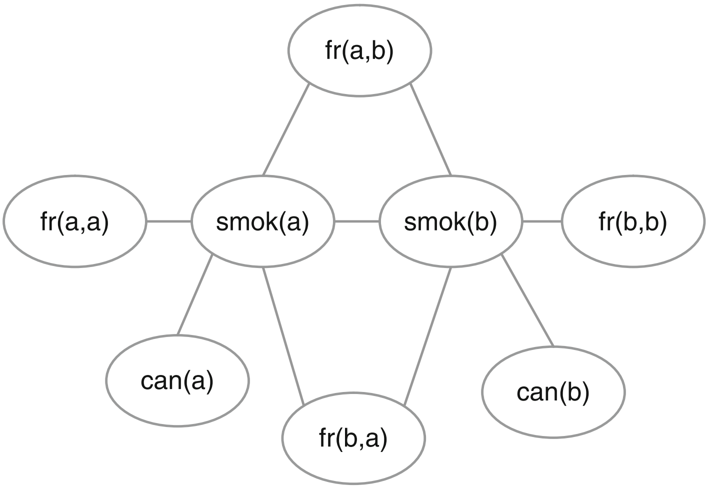
Example 1 Consider the following example (Adapted from Richardson and Domingos 2006). Friends & Smokers is a small Markov logic network that computes the probability of a person having lung cancer on the basis of her friends smoking. This can be encoded using the following weighted clauses:

1.5: cancer(P) ← smoking(P)
1.1: smoking(X) ← friends(X,Y), smoking(Y)
1.1: smoking(Y) ← friends(X,Y), smoking(X)

The first clause states the soft constraint that smoking causes cancer. So, interpretations in which persons that smoke have cancer are more likely than those where they do not (under the assumptions that other properties remain constant). The second and third clauses state that friends of smokers are typically also smokers.

A Markov logic network together with a Herbrand domain (in the form of a set of constants $\{d_1, \ldots, d_k\}$) then induces a grounded Markov network, which defines a probability distribution over the possible Herbrand interpretations.

The nodes, that is, the random variables in the grounded network, are the atoms in the Herbrand base, that is, the facts of the form $p(d'_1, \ldots, d'_n$ where p is a predicate or relation and the d'_i are constants. Furthermore, for every ground instance $c_i\theta$ of a clause c_i in H, there will be an edge between any pair of atoms $a\theta$, $b\theta$ that occurs in $c_i\theta$. The Markov network obtained for the constants anna and bob is shown in Fig. 2. To obtain a probability distribution over the Herbrand interpretations, we still need to define the potentials.



Statistical Relational Learning, Fig. 2 The Markov network for the constants ann and bob (Adapted from Richardson and Domingos 2006)

The probability distribution over interpretations I is

$$\mathbf{P}(I) = \frac{1}{Z} \prod_{c:clause} \mathbf{f}_c(I) \qquad (1)$$

where the f_c are defined as

$$f_c(I) = e^{n_c(I)w_c} \qquad (2)$$

and $n_c(I)$ denotes the number of substitutions θ for which $c\theta$ is satisfied by I, and Z is a normalization constant. The definition of a potential as an exponential function of a weighted feature of a clique is common in Markov networks; cf. ▶ graphical models. The reason is that the resulting probability distribution is easier to manipulate.

Note that for different (Herbrand) domains, different Markov networks will be produced. Therefore, one can view Markov logic networks as a kind of template for generating Markov networks, and, hence, Markov logic is based on knowledge-based model construction. Notice also that Markov logic networks define a probability distribution over interpretations, and nicely separate the qualitative from the quantitative component.

Case Study: ProbLog

Many formalisms do not explicitly encode a set of conditional independency assumptions, as in Bayesian or Markov networks, but rather extend a (logic) programming language with probabilistic choices. Stochastic logic programs (Cussens 2001; Muggleton 1996) directly upgrade stochastic context-free grammars toward definite clause logic, whereas Prism (Sato 1995), probabilistic Horn abduction (PHA) (Poole 1993), and the more recent independent choice logic (ICL) (Poole 1997) specify probabilities on facts from which further knowledge can be deduced. As a simple representative of this stream of work, we introduce the probabilistic Prolog called ProbLog (De Raedt et al. 2007).

The key idea underlying Problog is that some facts f for *probabilistic* predicates are annotated with a probability value. This value indicates the degree of belief, that is the probability, that any ground instance $f\theta$ of f is true. It is also assumed that the $f\theta$ are marginally independent. The probabilistic facts are then augmented with a set of definite clauses defining further predicates (which should be disjoint from the probabilistic ones). An example adapted from De Raedt et al. (2007) is given below.

Example 2 Consider the facts

```
0.9: edge(a,c) ←
0.7: edge(c,b) ←
0.6: edge(d,c) ←
0.9: edge(d,b) ←
```

which specify that with probability 0.9 there is an edge from *a* to *c*. Consider also the following (simplified) definition of *path/2*.

path(X,Y)edge(X,Y) ←
path(X,Y)edge(X,Z), path(Z,Y) ←

One can now define a probability distribution on (ground) proofs as follows. The probability of a ground proof is the product of the probabilities of the (ground) clauses (here, facts) used in the proof. For instance, the only proof for the goal ← path(a,b) employs the facts edge(a,c) and edge(c,b); these facts are marginally independent, and hence the probability of the proof is 0.9 × 0.7. The probabilistic facts used in a single proof are sometimes called an *explanation*.

It is now tempting to define the probability of a ground atom as the sum of the probabilities of the proofs for that atom. However, this does not work without additional restrictions, as shown in the following example.

Example 3 The fact path(d,b) has two explanations:

1. {edge(d,c), edge(c,b)} with probability $0.6 \times 0.7 = 0.42$, and
2. {edge(d,b)} with probability 0.9.

Summing the probabilities of these explanations gives a value of 1.32, which is clearly impossible.

The reason for this problem is that the different explanations are not mutually exclusive, and therefore their probabilities may not be summed. The probability $P(\text{path(d,b)} = \textit{true})$ is, however, equal to the probability that *a* proof succeeds, that is,

$$p(\text{path(d,b)} = true) = P[(\text{e(d,c)} \wedge \text{e(c,b)}) \vee \text{e(d,b)}]$$

which shows that computing the probability of a derived ground fact reduces to computing the probability of a boolean formula in disjunctive normal form (DNF), where all random variables are marginally independent of one another. Computing the probability of such formulae is an NP-hard problem, the *disjoint-sum* problem. Using the *inclusion-exclusion* principle from set theory, one can compute the probability as

$$\begin{aligned} p(\text{path(d,b)} = true) &= P[(\text{e(d,c)} \wedge \text{e(c,b)}) \\ &\quad \vee \text{e(d,b)}] \\ &= P(\text{e(d,c)} \wedge \text{e(c,b)}) \\ &+ P(\text{e(d,b)}) \\ &- P((\text{e(d,c)} \wedge \text{e(c,b)}) \\ &\quad \wedge \text{e(d,b)}) \\ &= 0.6 \times 0.7 + 0.9 - 0.6 \\ &\quad \times 0.7 \times 0.9 = 0.942 \end{aligned}$$

There exist more effective ways to compute the probability of such DNF formulae (De Raedt et al. 2007), where binary decision diagrams are employed to represent the DNF formulae.

The above example shows how the probability of a specific fact is defined and can be computed. The distribution at the level of individual facts (or goals) can easily be generalized to a possible world semantics, specifying a probability distribution on interpretations. It is formalized in the *distribution semantics* of Sato (1995), which is defined by starting from the set of all probabilistic ground facts F for the given program. For simplicity, we shall assume that this set is finite, though Sato's results also hold for the infinite case. The distribution semantics then starts from a probability distribution $P_F(S)$ defined on subsets $S \subseteq F$:

$$P_F(S) = \prod_{f \in s} P(f) \prod_{f \notin s} (1 - P(f)). \quad (3)$$

Each subset S is now interpreted as a set of logical facts and combined with the definite clause program R that specifies the logical part of the probabilistic logic program. Any such combination $S \cup R$ possesses a unique least Herbrand model $M(S \cup R)$, which corresponds to a possible world. The probability of such a possible world is then the sum of the probabilities of the subsets S yielding that possible world, that is,

$$P_W(M) = \sum_{s \subseteq F: M(S \cup R) = M} P_F(S) \quad (4)$$

For instance, in the path example, there are 16 possible worlds, which can be obtained from the 16 different truth assignments to the facts, and whose probabilities can be computed using Eq. (4). As for graphical models, the probability of any logical formula can be computed from a possible world semantics (specified here by P_W).

Because computing the probability of a fact or goal under the distribution semantics is hard, systems such as Prism (Sato 1995) and PHA (Poole 1993) impose additional restrictions that can be used to improve the efficiency of the inference procedure. The key assumption is that the explanations for a goal are *mutually exclusive*, which overcomes the disjoint-sum problem. If the different explanations of a goal do not overlap, then its probability is simply the sum of the probabilities of its explanations. This directly follows from the inclusion-exclusion formulae as under the exclusive-explanation assumption the conjunctions (or intersections) are empty.

Learning

Essentially, any statistical relational approach can be viewed as lifting a traditional inductive logic programming setting by associating probabilistic information to clauses and by replacing the deterministic coverage relation by a probabilistic one. In contrast to traditional graphical models such as Bayesian networks or Markov networks, however, we can also employ "counterexamples" for learning. Consider a simple kinship domain. Assume rex is a male person. Consequently, he cannot be the daughter of any other person, say ann. Thus, daughter(rex,ann) can be listed as a negative example although we will never observe it. "Counterexamples" conflict with the usual view on learning examples in statistical learning.

In statistical learning, we seek to find that hypothesis H^*, which is most likely given the learning examples:

$$\begin{aligned} H^* &= \arg\max_H P(H|E) \\ &= \arg\max_H \frac{P(E|H) \cdot P(F)}{P(E)} \\ &\quad \text{with } P(E) > 0. \end{aligned}$$

Thus, examples E in traditional statistical learning are always observable, that is, $P(E) > 0$. However, in statistical relational learning, as in inductive logic programming, we may also employ "counterexamples" such as daughter(rex,ann), which have probability "0," and that actually never can be observed.

Definition 2 (SRL Problem) **Given** a set $E = E_p \cup E_i$ of *positive* and *negative* examples E_p and E_i (with $E_p \cap E_i = \emptyset$) over some example language $\mathcal{L}_E$, a probabilistic covers relation $covers(e, H, B) = P(e \mid H, B)$, a probabilistic logical language $\mathcal{L}_H$ for hypotheses, and a background theory B, **find** a hypothesis H^* in $\mathcal{L}_H$ such that $H^* = \text{argmax}_H\ score(E, H, B)$ and the following constraints hold: $\forall\ e_p \in E_p\ :\ covers(e_p, H^*, B) > 0$ and $\forall\ e_i \in E_i\ :\ covers(ei, H^*, B) = 0$. The score is some objective function, usually involving the probabilistic covers relation of the observed examples such as the observed likelihood $\prod_{e_p \in E_p} covers(e_p, H^*, B)$ or some penalized variant thereof.

This learning setting unifies inductive logic programming and statistical learning in the following sense: using a deterministic covers relation (either 1 or 0), it yields the classical inductive logic programming learning problem; sticking to propositional logic and learning from *positive* examples, that is, $P(E) > 0$, only yields traditional statistical learning.

To come up with algorithms solving the SRL problem, say for density estimation, one typically distinguishes two subtasks because $H = (L, \lambda)$ is essentially a logical theory L annotated with probabilistic parameters λ:

1. *Parameter estimation* where it is assumed that the underlying logic program L is fixed, and

the learning task consists of estimating the parameters λ that maximize the likelihood.

2. *Structure learning* where both L and λ have to be learned from the data.

In the following paragraphs, we will sketch the basic parameter estimation and structure learning techniques, and illustrate them for each setting.

Parameter Estimation

The problem of parameter estimation is concerned with estimating the values of the parameters λ of a fixed probabilistic program $H = (L, \lambda)$ that best explains the examples E. So, λ is a set of parameters and can be represented as a vector. As already indicated above, to measure the extent to which a model fits the data, one usually employs the likelihood of the data, that is, $P(E|L, \lambda)$, though other scores or variants could be used as well.

When all examples are fully observable, maximum likelihood reduces to frequency counting. In the presence of missing data, however, the maximum likelihood estimate typically cannot be written in closed form. It is a numerical optimization problem, and all known algorithms involve nonlinear optimization. The most commonly adopted technique for probabilistic logic learning is the expectation-maximization (EM) algorithm (Dempster et al. 1977; McLachlan and Krishnan 1997). EM is based on the observation that learning would be easy (i.e., correspond to frequency counting), if the values of all the random variables would be known. Therefore, it estimates these values, maximizes the likelihood based on the estimates, and then iterates. More specifically, EM assumes that the parameters have been initialized (e.g., at random) and then iteratively performs the following two steps until convergence:

(E-Step) On the basis of the observed data and the present parameters of the model, it computes a distribution over all possible completions of each partially observed data case.

(M-Step) Treating each completion as a fully observed data case weighted by its probability, it computes the improved parameter values using (weighted) frequency counting.

The frequencies over the completions are called the *expected counts*. Examples for parameter estimation of probabilistic relational models can be found in Getoor and Taskar (2007) and De Raedt et al. (2008).

Structure Learning

The problem is now to learn both the structure L and the parameters λ of the probabilistic program $H = (L, \lambda)$ from data. Often, further information is given as well. As in inductive logic programming, the additional knowledge can take various different forms, including a ▸ *language bias* that imposes restrictions on the syntax of L, and an *initial hypothesis* (L, λ) from which the learning process can start.

Nearly all (score-based) approaches to structure learning perform a heuristic search through the space of possible hypotheses. Typically, hill-climbing or beam-search is applied until the hypothesis satisfies the logical constraints and the *score*(H, E) is no longer improving. The steps in the search-space are typically made using refinement operators, which make small, syntactic modifications to the (underlying) logic program.

At this point, it is interesting to observe that the logical constraints often require that the positive examples are covered in the logical sense. For instance, when learning ProbLog programs from entailment, the observed example clauses must be entailed by the logic program. Thus, for a probabilistic program $H = (L_H, \lambda_H)$ and a background theory $B = (L_B, \lambda_B)$ it holds that $\forall e_p \in E_p: P(e|H, B) > 0$ if and only if *covers*$(e, L_H, L_B) = 1$, where L_H (respectively L_B) is the underlying logic program (logical background theory) and *covers*(e, L_H, L_B) is the purely logical *covers* relation, which is either 0 or 1.

Applications

Applications of statistical relational learning can be found in many areas such as web search and mining, text mining, bioinformatics, natural language processing, robotics, and social network analysis, among others. Due to space restrictions, we will only name a few of these exciting applications.

For instance, Getoor et al. (2001) have used statistical relational models to estimate the result size of complex database queries. Segal et al. have employed probabilistic relational models to cluster gene expression data (Segal et al. 2001) and to discover cellular processes from gene expression data (Segal et al. 2003). Getoor et al. have used probabilistic relational models to understand tuberculosis epidemiology (Getoor et al. 2004). McGovern et al. (2003) have estimated probabilistic relational trees to discover publication patterns in high-energy physics. Probabilistic relational trees have also been used to learn to rank brokers with respect to the probability that they would commit a serious violation of securities regulations in the near future (Neville et al. 2005). Anguelov et al. (2005) have used relational Markov networks for segmentation of 3D scan data. Markov networks have also been used to compactly represent object maps and to estimate trajectories of people (Limketkai et al. 2005). Kersting et al. have employed relational hidden Markov models for protein fold recognition (Kersting et al. 2006). Poon and Domingos (2008) have shown how to use Markov logic to perform joint unsupervised coreference resolution. Xu et al. have used nonparametric relational models for analyzing social networks (Xu et al. 2010). Kersting and Xu (2009) have used relational Gaussian processes for learning to rank search results. Recently, Poon and Domingos (2009) have shown how to perform unsupervised semantic parsing using Markov logic networks.

Future Directions

We have provided an overview of the new and exciting area of statistical relational learning. It combines principles of probabilistic reasoning, logical representation, and statistical learning into a coherent whole. The techniques of probabilistic logic learning were analyzed starting from an inductive logic programming perspective by lifting the coverage relation to a probabilistic one and annotating the logical formulae. Different choices of the probabilistic coverage relation lead to different representational formalisms, two of which were introduced.

Statistical relational learning is an active area of research within the machine learning and the artificial intelligence community. First, there is the issue of *efficient inference* and learning. Most current inference algorithms for statistical relational models require explicit state enumeration, which is often impractical: the number of states grows very quickly with the number of domain objects and relations. *Lifted* inference algorithms seek to avoid explicit state enumeration and directly work at the level of groups of atoms, eliminating all the instantiations of a set of atoms in a single step, in some cases independently of the number of these instantiations. Despite various approaches to lifted inference (de Salvo Braz et al. 2005; Jaimovich et al. 2007; Kersting et al. 2009; Kisynski and Poole 2009; Milch et al. 2008; Poole 2003; Sen et al. 2008; Singla and Domingos 2008), it largely remains a challenging problem. For what concerns learning, advanced principles of both statistical learning and logical and relational learning can be employed for learning the parameters and the structure of probabilistic logics such as statistical *predicate invention* (Kok and Domingos 2007) and *boosting* (Gutmann and Kersting 2006). Recently, people started to investigate *learning from weighted examples* (see e.g., Chen et al. 2008) and to link statistical relational learning to support vector machines (see e.g., Passerini et al. 2006). Second, there is the issue of *closed-world versus open-world* assumption that is, do we know how many objects there are (see e.g., Milch et al. 2005). Third, there is interest in dealing with *continuous values* within statistical relational learning (see e.g., Chu et al. 2006; Silva et al. 2007; Wang and Domingos 2008; Xu et al. 2009). This is mainly motivated by the fact that most real-world applications actually contain continuous values. *Nonparametric Bayesian* approaches to statistical relational learning have also been developed (see e.g., Kemp et al. 2006; Xu et al. 2006; Yu and

Chu 2007; Yu et al. 2006), to overcome the typically strong parametric assumptions underlying current statistical relational learning. People have also started to investigate *relational variants of classical statistical learning tasks* such as matrix factorizations (see e.g., Singh and Gordon 2008). Finally, while statistical relational learning approaches have been used successfully in a number of applications, they do not yet cope with the *dynamic environments* in an effective way.

Stochastic Finite Learning

Thomas Zeugmann
Hokkaido University, Sapporo, Japan

Motivation and Background

Assume that we are given a concept class $\mathcal{C}$ and should design a learner for it. Next, suppose we already know or could prove $\mathcal{C}$ not to be learnable in the model of ▶ PAC learning. But it can be shown that $\mathcal{C}$ is learnable within Gold's (1967) model of ▶ inductive inference or learning in the limit. Thus, we can design a learner behaving as follows. When fed any of the data sequences allowed in this model, it converges in the limit to a hypothesis correctly describing the target concept. Nothing more is known. Let M be any fixed learner. If $(d_n)_{n \geq 0}$ is any data sequence, then the *stage of convergence* is the least integer m such that $M(d_m) = M(d_n)$ for all $n \geq m$ provided such an n exists (and infinite, otherwise). In general, it is undecidable whether or not the learner has already reached the stage of convergence, but even if it is decidable for a particular concept class, it may be practically infeasible to do so. This *uncertainty* may not be tolerable in many applications.

When we tried to overcome this uncertainty, the idea of stochastic finite learning emerged. Clearly, in general nothing can be done, since in Gold's (1967) model the learner has to learn from any data sequence. So for every concept that needs more than one datum to converge, one can easily construct a sequence where the first datum is repeated very often and where therefore the learner does not find the right hypothesis within the given bound. However, such data sequences seem unnatural. Therefore, we looked at data sequences that are generated with respect to some probability distribution taken from a prespecified class of probability distributions and computed the expected *total learning time*, i.e., the expected time until the learner reaches the stage of convergence (cf. Erlebach et al. 2001; Zeugmann 1998). Clearly, one is then also interested in knowing how often the expected total learning time is exceeded. In general, Markov's inequality can be applied to obtain the relevant tail bounds. However, if the learner is known to be rearrangement-independent and conservative, then we always get *exponentially* shrinking tail bounds (cf. Rossmanith and Zeugmann 2001). A learner is said to be *rearrangement-independent* if its output depends exclusively on the range and length of its input (but not on the order) (cf., e.g., Lange and Zeugmann (1996) and the references therein). Furthermore, a learner is *conservative*, if it exclusively performs mind changes that can be justified by an inconsistency of the abandoned hypothesis with the data received so far (see Angluin (1980b) for a formal definition).

Combining these ideas results in stochastic finite learning. A stochastic finite learner is successively fed data about the target concept. Note that these data are generated randomly with respect to one of the probability distributions from the class of underlying probability distributions. Additionally, the learner takes a confidence parameter δ as input. But in contrast to learning in the limit,

S

the learner itself decides how many examples it wants to read. Then it computes a hypothesis, outputs it, and stops. The hypothesis output is correct for the target with probability at least $1 - \delta$.

The description given above explains how it works, but not why it does. Intuitively, the stochastic finite learner simulates the limit learner until an upper bound for twice the expected total number of examples needed until convergence has been met. Assuming this to be true, by Markov's inequality the limit learner has now converged with probability $1/2$. All what is left is to decrease the probability of failure. This can be done by using again Markov's inequality, i.e., increasing the sample complexity by a factor of $1/\delta$ results in a confidence of $1 - \delta$ for having reached the stage of convergence.

Note that the stochastic finite learner has to calculate an upper bound for the stage of convergence. This is precisely the point where we need the parameterization of the class $\mathcal{D}$ of underlying probability distributions. Then a bit of *prior knowledge* must be provided in the form of suitable upper and/or lower bounds for the parameters involved. A more serious difficulty is to incorporate the unknown target concept into this estimate. This step depends on the concrete learning problem on hand and requires some extra effort.

It should also be noted that our approach may be beneficial even in case that the considered concept class is PAC learnable.

Definition

Let $\mathcal{D}$ be a set of probability distributions on the learning domain, let $\mathcal{C}$ be a concept class, $\mathcal{H}$ a hypothesis space for $\mathcal{C}$, and let $\delta \in (0, 1)$. The pair $(\mathcal{C}, \mathcal{D})$ is said to be *stochastically finitely learnable with δ-confidence* with respect to $\mathcal{H}$ iff there is a learner M that for every $c \in \mathcal{C}$ and every $D \in \mathcal{D}$ performs as follows. Given any random data sequence θ for c generated according to D, M stops after having seen a finite number of examples and outputs a single hypothesis $h \in \mathcal{H}$. With probability at least $1 - \delta$ (with respect to distribution D), h has to be correct, i.e., $c = h$.

If stochastic finite learning can be achieved with δ-confidence for every $\delta > 0$, then we say that $(\mathcal{C}, \mathcal{D})$ can be learned stochastically finite *with high confidence*.

Detail

Note that there are subtle differences between our model and PAC learning. By its definition, stochastic finite learning is not completely distribution independent. A bit of *additional knowledge* concerning the underlying probability distributions is required. Thus, from that perspective, stochastic finite learning is weaker than the PAC model. On the other hand, we do *not* measure the quality of the hypothesis with respect to the underlying probability distribution. Instead, we require the hypothesis computed to be exactly correct with high probability. Note that exact identification with high confidence has been considered within the PAC paradigm, too (cf., e.g., Goldman et al. 1993). Conversely, we also can easily relax the requirement to learn *probably exactly correct* but whenever possible we shall not do it.

Furthermore, in the uniform PAC model as introduced in Valiant (1984), the sample complexity depends exclusively on the VC dimension of the target concept class and the error and confidence parameters ε and δ, respectively. This model has been generalized by allowing the sample size to depend on the concept complexity, too (cf., e.g., Blumer et al. 1989; Haussler et al. 1991). Provided no upper bound for the concept complexity of the target concept is given, such PAC learners decide themselves how many examples they wish to read (cf. Haussler et al. 1991). This feature is also adopted to our setting of stochastic finite learning. However, all variants of efficient ▶ PAC learning we are aware of require that all hypotheses from the relevant hypothesis space are uniformly polynomially evaluable. Though this requirement may be necessary in some cases to achieve (efficient) stochastic finite learning, it is not necessary in general as we shall see below.

In the following, we provide two sample applications of stochastic finite learning. We always choose as hypothesis space the concept class $\mathcal{C}$ itself.

Learning Monomials

Let $X_n = \{0,1\}^n$ be the learning domain, let $\mathcal{L}_n = \{x_1, \bar{x}_1, x_2, \bar{x}_2, \ldots, x_n, \bar{x}_n\}$ (set of literals) and consider the class $\mathcal{C}_n$ of all concepts describable by a conjunction of literals. As usual, we refer to any conjunction of literals as a *monomial*. A monomial m describes a concept $c \subseteq X_n$ in the obvious way: the concept contains exactly those binary vectors for which the monomial evaluates to 1. For a monomial m, let $\#(m)$ denote its length, i.e., the number of literals in it.

The basic ingredient to the stochastic finite learner is Haussler's (1987) Wholist algorithm, and thus the main emphasis is on the resulting complexity. The Wholist algorithm can also be used to achieve ▸PAC learning of the class $\mathcal{C}_n$, and the resulting sample complexity is $O(1/\varepsilon \cdot (n + \ln(1/\delta)))$ for all $\varepsilon, \delta \in (0,1]$. Since the Wholist algorithm learns from positive examples only, it is meaningful to study the learnability of $\mathcal{C}_n$ from positive examples only. So, the stage of convergence is *not* decidable.

Since the Wholist algorithm immediately converges for the empty concept, we exclude it from our considerations. That is, we consider concepts $c \in \mathcal{C}_n$ described by a monomial $m = \bigwedge_{j=1}^{\#(m)} \ell_{i_j}$ such that $k = k(m) = n - \#(m) > 0$. A literal not contained in m is said to be irrelevant. Bit i is said to be irrelevant for monomial m if neither x_i nor $\bar{x}_i$ appears in m. There are 2^k positive examples for c. For the sake of presentation, we assume these examples to be *binomially distributed* with parameter p. So, in a random positive example, all entries corresponding to irrelevant bits are selected independently to one another. With some probability p, this will be a 1, and with probability $1-p$, this will be a 0. Only distributions where $0 < p < 1$ are considered, since otherwise exact identification is impossible. Now, one can show that the expected number of examples needed by the Wholist algorithm until convergence is bounded by $\lceil \log_\psi k(m) \rceil + \tau + 2$, where $\psi := \min\left\{\frac{1}{1-p}, \frac{1}{p}\right\}$ and $\tau := \max\left\{\frac{p}{1-p}, \frac{1-p}{p}\right\}$.

Let *CON* denote a random variable for the stage of convergence. Since the Wholist algorithm is rearrangement-independent and conservative, we can conclude (cf. Rossmanith and Zeugmann 2001)

$$\Pr(\mathrm{CON} > 2t \cdot \mathrm{E}[\mathrm{CON}]) \leq 2^{-t} \quad \text{for all natural numbers } t \geq 1\,. \tag{1}$$

Finally, in order to obtain a stochastic finite learner, we reasonably assume that *prior knowledge* is provided by parameters p_{low} and p_{up} such that $p_{\text{low}} \leq p \leq p_{\text{up}}$ for the true parameter p. Binomial distributions fulfilling this requirement are called $(p_{\text{low}}, p_{\text{up}})$*-admissible distributions*. Let $\mathcal{D}_n[p_{\text{low}}, p_{\text{up}}]$ denote the set of such distributions on X_n. Then one can show *Let* $0 < p_{\text{low}} \leq p_{\text{up}} < 1$ *and* $\psi := \min\{\frac{1}{1-p_{\text{low}}}, \frac{1}{p_{\text{up}}}\}$. *Then* $(\mathcal{C}_n, \mathcal{D}_n[p_{\text{low}}, p_{\text{up}}])$ *is stochastically finitely learnable with high confidence from positive examples. To achieve* δ*-confidence no more than* $O\left(\log_2 1/\delta \cdot \log_\psi n\right)$*, many examples are necessary.*

Therefore, we have achieved an exponential improvement on the number of examples needed for learning (compared to the PAC bound displayed above), and, in addition, our stochastic finite learner exactly identifies the target. Note that this result is due to Reischuk and Zeugmann; however, we refer the reader to Zeugmann (2006) for the relevant proofs.

The results obtained for learnability from positive examples only can be extended *mutatis mutandis* to the case when the learner is fed positive and negative examples (cf. Zeugmann (2006) for details).

Learning Pattern Languages

The pattern languages have been introduced by Angluin (1980a) and can be informally defined as follows. Let $\Sigma = \{0, 1, \ldots\}$ be any finite alphabet containing at least two elements. Let $X = \{x_0, x_1, \ldots\}$ be a countably infinite set of variables such that $\Sigma \cap X = \emptyset$. *Patterns* are nonempty strings over $\Sigma \cup X$, e.g., 01, $0x_0111$, $1x_0x_00x_1x_2x_0$ are patterns. The length of a string $s \in \Sigma^*$ and of a pattern π is denoted by $|s|$ and $|\pi|$, respectively. A pattern π is in *canonical form* provided that if k is the number of different variables in π then the variables occurring in π are precisely $x_0, \ldots, x_{k-1}$. Moreover, for every j with $0 \leq j < k - 1$, the leftmost occurrence of x_j in π is left to the leftmost occurrence of x_{j+1}. The examples given above are patterns in canonical form.

If k is the number of different variables in π, then we refer to π as to a *k-variable pattern*. For example, $x0xx$ is a one-variable pattern, and $x_010x_1x_0$ is a two-variable pattern. If π is a pattern, then the language generated by π is the set of all strings that can be obtained from π by substituting a *nonnull* element $s_i \in \Sigma^*$ for each occurrence of the variable symbol x_i in π, for all $i \geq 0$. We use $L(\pi)$ to denote the language generated by pattern π. So, 1011, 1001010 belong to $L(x0xx)$ (by substituting 1 and 10 for x, respectively) and 010110 is an element of $L(x_010x_1x_0)$ (by substituting 0 for x_0 and 11 for x_1). Note that even the class of all one-variable patterns has infinite ▸ VC dimension (cf. Mitchell et al. 1999).

Reischuk and Zeugmann (2000) designed a stochastic finite learner for the class of all one-variable pattern languages that runs in time $O(|\pi| \log(1/\delta))$ for all meaningful distributions and learns from positive data only. That is, all data fed to the learner belong to the target pattern language. Furthermore, by meaningful distribution essentially the following is meant. The expected length of an example should be finite and the distribution should allow to learn the target pattern. This is then expressed by fixing some suitable parameters. It should be noted that the algorithm is highly practical, and a modification of it also works for the case that *empty* substitutions are allowed. Though this seems to be a minor modification, it is *not*. The learnability results for pattern languages resulting from a definition that also allows for empty substitutions considerably differ from the case, where only nonnull substitutions are admitted (cf. Reidenbach 2006, 2008).

For the class of all pattern languages, one can also provide a stochastic finite learner identifying the whole class from positive data. In order to arrive at a suitable class of distributions, essentially three requirements are made. The first one is the same as in the one-variable case, i.e., the expected length $\mathrm{E}[\Lambda]$ of a generated string should be finite. Second, the class of distributions is restricted to regular product distributions, i.e., for all variables the substitutions are identically distributed.

Third, two parameters α and β are introduced. The parameter α is the probability that a string of length 1 is substituted, and β is the conditional probability that two random strings that get substituted into π are identical under the condition that both have length 1. These two parameters ensure that the target pattern language is learnable at all. The stochastic finite learner is then using as *a priori knowledge* a lower bound α^* for α and an upper bound β^* for β. The basic ingredient to this stochastic finite learner is Lange and Wiehagen's (1991) pattern language learning algorithm. Rossmanith and Zeugmann's (2001) stochastic finite learner for the pattern languages runs in time $O\left((1/\alpha_*^k)\mathrm{E}[\Lambda] \log_{1/\beta_*}(k) \log_2(1/\delta)\right)$, where k is the number of different variables in the target pattern. So, with increasing k it becomes impractical.

Note that the two stochastic finite learners for the pattern languages can compute the expected stage of convergence, since the first string seen provides an upper bound for the length of the target pattern.

For further information, we refer the reader to Zeugmann (2006) and the references therein. More research is needed to explore the potential of stochastic finite learning. Such investigations should extend the learnable classes, should study the incorporation of noise, and should explore further possible classes of meaningful probability distributions.

Stratified Cross Validation is a form of ▶ cross validation in which the class distribution is kept as close as possible to being the same across all folds.

Stream Classification

Jerzy Stefanowski and Dariusz Brzezinski
Institute of Computing Science, Poznan
University of Technology, Poznan, Poland

Abstract

Compared to batch learning from static data, constructing classifiers from data streams implies new requirements for algorithms, such as constraints on memory usage, restricted processing time, and one scan of incoming examples. Additionally, streams classifiers have to adapt to concept drifts. The entry discusses the following stream classification issues: data stream specific requirements, processing schemes, categorization of concept drifts, classifier evaluation criteria and procedures, forgetting mechanisms, change detection methods, main algorithms for

supervised learning of single classifiers and ensembles, open problems, areas of application.

Definition

Stream classification is a variant of incremental learning of classifiers that has to satisfy requirements specific for massive streams of data: restrictive processing time, limited memory, and one scan of incoming examples. Additionally, stream classifiers often have to be adaptive, as they usually act in dynamic, non-stationary environments where data and target concepts can change over time. To fulfill these requirements, new solutions include dedicated data management and forgetting mechanisms, concept drift detectors that monitor the underlying changes in the stream, effective online single classifiers, and adaptive ensembles that continuously react to changes in the stream.

Motivation and Background

In many data-intensive applications, like sensor networks, traffic control, market analysis, Web user tracking, and social media, massive volumes of data are continuously generated in the form of data streams. A data stream is a potentially unbounded, ordered sequence of data items, which arrive continuously at high speeds. These data elements can be simple attribute-value pairs like relational database tuples or more complex structures such as graphs.

The main characteristics of streams include:

- continuous flow (elements arrive one after another),
- huge data volumes (possibly of an infinite length),
- rapid arrival rate (relatively high with respect to processing power of the system),
- susceptibility to change (data distributions generating examples may change on the fly).

Due to the above characteristics, learning from data streams differs from ▶ batch learning, where data are stored in finite, persistent data repositories. The main dissimilarities include the sequential nature of the data, massive volumes, processing speed restrictions, and the fact that data elements cannot be accessed multiple times as it is in the case of learning from static repositories. Moreover, contrary to ▶ online learning, stream classification does not assume adversarial actions from the instance generating process, but rather focuses on computational restrictions.

One of the most widely studied tasks in data stream mining is ▶ supervised classification. Apart from the aforementioned general difficulties connected with learning from streams, classification is also often performed in non-stationary environments, where the data distribution and target concepts can change over time. This phenomenon, called ▶ concept drift, deteriorates the predictive accuracy of classifiers as the instances they were trained on differ from the current data. Typical examples of real-life concept drifts include content changes in unwanted emails in spam categorization or evolving customer preferences.

Several researchers imply the following requirements on algorithms learning classifiers from streams (Bifet et al. 2010):

1. Process one example at a time and inspect it only once.
2. Use a limited amount of memory.
3. Be ready to predict at any time.
4. Be able to react to concept drift in case of evolving data streams.

Typical batch learning algorithms for supervised classification are not capable of fulfilling all of the listed data stream requirements. ▶ Incremental learning is also insufficient, as it does not meet tight computational demands and does not tackle concept drift. Therefore, several new learning algorithms have been introduced. Surveys on stream classification, such as Ditzler et al. (2015), Gama (2010), and Kuncheva (2004), showcase research on using sliding windows to manage memory and provide a forgetting mechanism, sampling techniques, drift detectors, and new online algorithms.

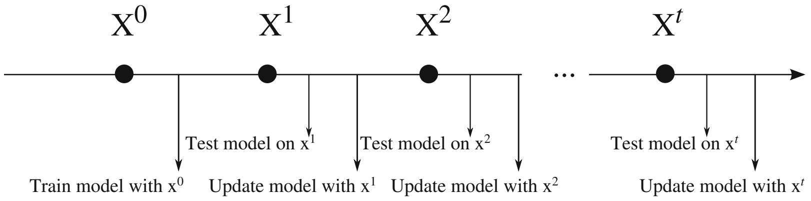
Structure of the Learning System

Stream classification can be formalized as follows. Learning instances from a stream $\mathcal{S}$ appear incrementally as a sequence of labeled ▸ examples $\{\mathbf{x}^t, y^t\}$ for $t = 1, 2, \ldots, T$, where $\mathbf{x}$ is a vector of ▸ attribute values and y is a ▸ class label ($y \in \{K_1, \ldots, K_l\}$). A new example $\mathbf{x}^t$ is classified by a classifier C, which predicts its class label. Here, we consider a completely supervised framework where after some time the true class label y^t is available and can be used to update the classifier.

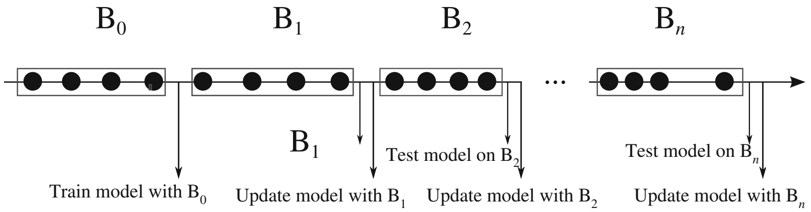
Examples from the data stream can be provided either *online*, i.e., instance by instance, or in portions (*blocks*). In the first approach, presented in Fig. 1, algorithms process single examples appearing one by one in consecutive moments in time, while in the other approach, presented in Fig. 2, examples are available only in larger sets called data blocks (or data chunks) $B_1, B_2, \ldots, B_n$, where n denotes the last element of the stream up to the current timepoint. Blocks are usually of equal size and the construction, evaluation, or updating of classifiers is done when all examples from a new block are available. This distinction also refers to the availability of class labels. For instance, in some problems data elements are naturally accumulated through some time and labeled in blocks. However, with class labels appearing online with single instances, algorithms have the possibility of reacting to concept drift much faster than in block-based environments.

Two basic models of data streams are considered: *stationary*, where examples are drawn from a fixed although unknown probability distribution, and *non-stationary*, where data can evolve over time. As process changes occur in many real-world problems (Zliobaite et al. 2015), most stream classification algorithms are capable of predicting, detecting, and adapting to concept drifts.

Concept drift can be defined from the perspective of hidden data contexts, which are unknown to the learning algorithm. However, in case of evolving streams, a more probabilistic view on the matter can be presented (Gama 2010). In each point in time t, every example is generated by a source with a joint distribution $P^t(\mathbf{x}, y)$ over the data. Concepts in data are *stable* if all examples are generated by the same distribution. If for two distinct points in time t and $t + \Delta$ an $\mathbf{x}$ exists such that $P^t(\mathbf{x}, y) \neq P^{t+\Delta}(\mathbf{x}, y)$, then concept drift



Stream Classification, Fig. 1 Online processing



Stream Classification, Fig. 2 Block processing occurs. Although different component probabilities of $P^t(\mathbf{x}, y)$ may change (Gama et al. 2014), in case of supervised classification, one is mainly interested in *real drift*, i.e., changes in posterior probabilities of classes $P(y|\mathbf{x})$.

Usually two basic types of concept drifts are distinguished: *sudden* (abrupt) and *gradual*. The first type of drift occurs when at a moment in time t, the source data distribution in S^t is suddenly replaced by a different distribution in S^{t+1}. Gradual drifts are not so radical and they are connected with a slower rate of changes that can be noticed while observing a data stream for a longer period of time. In some domains, situations when previous concepts reappear after some time are separately treated and analyzed as *recurring* drifts (Gomes et al. 2014). Moreover, data streams can contain outliers and ▶ noise, but these are not considered as concept drifts and stream classifiers should be robust to these random changes.

Evaluation

Stream classification requirements make *processing time*, *memory usage*, *predictive performance*, and the *ability to adapt* key evaluation criteria.

The time required to process a single instance and the average memory usage should remain constant throughout the life of a stream classifier. That is why training and testing time as well as model size have to be periodically monitored during stream classification. Additionally, processor time and memory are also considered key costs when deploying a stream classification system and are sometimes measured in a single metric called RAM hours.

The predictive performance of stream classifiers is usually assessed using evaluation measures known from static supervised classification, such as ▶ accuracy or ▶ error rate. However, contrary to batch learning scenarios, it is assumed that due to the size and speed of data streams, repeated runs over the data are not necessary to estimate these measures on labeled testing examples. Due to their computational costs, resampling techniques such as ▶ cross-validation or ▶ bootstrapping are deemed too expensive for streams. As a result, simpler error-estimation procedures are used, yet ones that build a picture of performance over time.

One of such evaluation procedures involves using a ▶ holdout test set to periodically evaluate the classifier's performance. An alternate scheme of estimating the performance of stream classifiers involves interleaving testing with training. Each individual example is first used to test the classifier before it is used for training (see Fig. 1). This evaluation procedure, often called *test-then-train*, has the advantage that it makes maximum use of the available data. A similar procedure of interleaving testing with training can also be performed with blocks of examples instead of single instances (see Fig. 2). However, for evolving streams the prequential evaluation procedure is suggested (Gama 2010). The term *prequential* (blend of predictive and sequential) stems from online learning and is used in data stream mining literature to denote algorithms that base their functioning only on the most recent data rather than the entire stream. Such a procedure highlights the current rather than overall performance and, as a result, showcases changes in the stream more clearly, which is especially important for drift detection. All three of the aforementioned evaluation procedures (holdout, test-then-train, prequential) are usually used to periodically calculate a selected metric, e.g., accuracy, and plot its value creating a line chart depicting classifier performance over time.

Finally, an important criterion when comparing stream classifiers is their ability to react to various types of concept changes. Adaptability can be evaluated by comparing drift reaction times. This is done by measuring the time between the start of a drift and the moment when the tested classifier's accuracy recovers to a level from before the drift. More elaborate methods of assessing the classifier's ability to adapt include *recovery analysis* and *controlled permutations* (Krempl et al. 2014). Nevertheless, in order to calculate reaction times and other adaptability measures, usually a human expert needs to determine moments when a drift starts and when a classifier recovers from it. Alternately, such evaluations are carried out with synthetic data generators.

Algorithms

The simplest categorization of algorithms for learning stream classifiers makes a distinction between *single classifiers* and *ensembles*. Additionally, from the perspective of learning from drifting environments, most of researchers distinguish *active* approaches, which trigger changes in classifiers when drifts are detected, and *passive* approaches, which continuously update the classifier regardless of whether drifts occur in the data stream or not (Gama et al. 2014). We discuss algorithms from the point of view of both of these taxonomies.

Data Management and Forgetting Mechanisms

Many approaches to dealing with time-changing streams involve the use of some sort of data management or forgetting mechanism. Data management strategies specify which data is used for learning, while forgetting strategies specify how old data are discarded. Both mechanisms are necessary to meet time and memory requirements posed by data streams and serve as a way of reacting to drifts by eliminating those examples that come from an old concept.

Online classifiers decide if an example will be included in the learning model on a per-instance basis. Such an approach promotes gradual adaptation to evolving concepts mainly by continuously updating the model with new examples. As an alternative, several classifiers apply *sliding windows* to keep the classifier consistent only with the most recent data. As sliding windows encompass a larger set of examples, they can be used to periodically build classifiers by conventional batch algorithms. From this point of view, this data management mechanism can be viewed as a general approach to transforming batch learners into classifiers for concept-drifting data streams.

The basic windowing algorithm is straightforward. Each example updates the window and later the classifier is updated by that window. The key part of this algorithm lies in the definition of the window, i.e., in the way it models the forgetting process. In the simplest approach, sliding windows are of fixed size and include only the most recent examples from the data stream. With each new data point, the oldest example that does not fit in the window is discarded. More complex approaches vary the window size depending on, e.g., the indications of a drift detector (Bifet and Gavaldà 2007).

Sliding windows are also one of the most popular forgetting mechanisms – examples that fall outside of the window are instantly excluded from the model. From this perspective, two basic types of windows are defined: *sequence based*, where the size of a window is characterized by the number of instances, and *timestamp based*, where the size is defined by duration time.

There are two common alternatives to forgetting using sliding windows: *sampling* and *fading factors*. The first alternative aims at summarizing the characteristics of the data stream over a long period of time using a limited number of examples. One of the best known data stream sampling algorithms is reservoir sampling, which keeps a fixed-size sample of the stream that is updated with randomly selected instances (Aggarwal 2007). Fading factors, on the other hand, provide a way of gradually forgetting examples. This is usually done with a decay function that assigns a weight to each example in the entire stream or a large window. Older examples receive smaller weights and are gradually treated as less important by the learner. Popular fading factors include linear, exponential, polynomial, and chordal functions.

Drift Detectors

Apart from sliding windows, another group of techniques that allow to construct a stream classifier are *drift detectors*. Their task is to detect concept drift and alarm a base learner that its classifier should be rebuilt or updated. For example, when a detector signals a sudden change, an existing classifier can be discarded and replaced by a new one trained only on the most recent data.

Drift detectors are usually implemented using statistical tests based on *sequential analysis*, *process control charts*, or *monitoring differences between two distributions*. Detectors based on sequential analysis check whether the classification error calculated on the most recent instances is significantly different from its value calculated for range of older instances. Examples of sequential tests include CUSUM and the Page-Hinkley test (Gama 2010). Drift detectors based on control charts take inspiration from statistical techniques used in quality control during product manufacturing. In these approaches, each prediction a classifier makes is treated as a Bernoulli trail. Then, the number of classification errors can be modeled with a Binomial distribution, which in turn can be tested for significantly improbable changes. Examples from this group include algorithms such as DDM, EDDM, and EWMA (Gama et al. 2014). Finally, several detection methods use two subsets of the stream: a reference window and a sliding window of the most recent examples. If the distributions over these two windows are significantly different, a change is signaled, suggesting that only examples from the sliding window should be used to create a new model.

Single Classifiers

First proposals of stream classifiers concentrated on processing massive stationary data sets in constant time per example. Decision trees were one of the first algorithms to be adapted to meet these requirements using the Hoeffding bound. This bound states that with probability $1 - \delta$, the true mean of a random variable of range R will not differ from the estimated mean after n independent observations by more than:

$$\epsilon = \sqrt{\frac{R^2 ln(1/\delta)}{2n}}. \tag{1}$$

Using the Hoeffding bound, Domingos and Hulten (2000) proposed a classifier called very fast decision tree (VFDT). This algorithm incrementally induces a tree from a massive data stream, without the need for storing examples after they have been used to update the tree. Its key idea is the selection of the split attribute, which is realized differently than in static trees (e.g., C4.5). Instead of selecting the best attribute (in terms of a split evaluation function) after viewing all the examples, VFDT uses the Hoeffding bound to calculate the number of examples necessary to select the right split node with probability $1 - \delta$. From the theoretical point of view, recent studies have shown that other bounds, as the ▸ McDiarmid inequality, are more suitable depending on the assumptions made about the distribution of values of the split evaluation function.

Many enhancements to the basic VFDT algorithm, often called the Hoeffding tree, have been proposed. They include methods of limiting memory usage, the use of alternative bounds which requires less examples for each split node, approaches to dealing with numerical attributes, pruning mechanisms, and the use of sliding windows or drift detectors to adapt the algorithm to non-stationary settings (Gama 2010). Nevertheless, the VFDT algorithm paved the way for many other learning algorithms that use the Hoeffding bound to incrementally process massive datasets (Ditzler et al. 2015).

Several traditional incremental classifiers were also adapted to computational and concept drift requirements. An illustrative example could be learning neural networks. By abandoning the epoch protocol and presenting examples in a single pass, neural networks can be adapted to changing data streams. Bayesian methods can also learn incrementally and require constant memory. To add a forgetting mechanism to this group of algorithms, sliding windows are usually employed to “unlearn” the oldest examples. Similarly, nearest neighbor classifiers are naturally transformed to incremental versions with different techniques for selecting the limited subset of the most “useful” examples for accurate predictions. Rule-based algorithms were also adjusted to data stream environments, in fact, FLORA algorithms developed by Kubat and Widmer were one of the first classifiers to cope with concept drift (Deckert 2013). Other algorithms use a structure similar to a decision tree to create rules and rule-specific drift detectors to react to changes (Kosina and Gama 2015).

Ensembles

▶ Ensembles are easily adapted to non-stationary data streams. Due to their modular construction, they are capable of incorporating new data elements by introducing a new component into the ensemble, updating existing component classifiers, or changing weights in the aggregation phase. Ensembles are usually categorized into block-based and online approaches.

Most block-based ensembles periodically evaluate component classifiers with the newest data block and substitute the worst ensemble member with a new (candidate) classifier. Additionally, practically all proposed approaches work with fixed-sized blocks. A generic block-based ensemble scheme is presented in Algorithm 1.

For each block B_i, the weights of current component classifiers $C_j \in \mathcal{E}$ are calculated by a quality measure $Q()$, which depends on the particular algorithm. For instance, in Accuracy Weighted Ensemble (AWE), $Q()$ is realized as a version of the mean square error of the component classifier C_j calculated on the recent block B_i, which is compared to the error of a random classifier on the same block (Wang et al. 2003). In addition to component re-weighting, a candidate classifier C_c is built from the recent block B_i and added to the ensemble if the ensemble's size is not exceeded. If the ensemble is full, the candidate classifier C_c substitutes the weakest ensemble member. It is worth noting that some algorithms, e.g., Learn++.NSE (Ditzler et al. 2015), do not limit the number of component classifiers in order to react to recurring concepts. The label prediction for new examples is usually based on a weighted majority vote of component classifiers. Most block-based ensembles take advantage of batch learning algorithms as component classifiers. This is not the case for hybrid algorithms, like the Accuracy Updated Ensemble (Brzezinski and Stefanowski 2014), which updates classifiers after processing each block.

Algorithm 1 Generic block-based ensemble

Input: $\mathcal{S}$, data stream of examples partitioned into blocks of size d; k, number of ensemble members; $Q()$, classifier quality measure;
Output: $\mathcal{E}$, ensemble of k weighted classifiers

```
for all blocks $B_i \in \mathcal{S}$ do
    build and weight candidate classifier $C_c$ using $B_i$ and $Q()$;
    weight all classifiers $C_j$ in ensemble $\mathcal{E}$ using $B_i$ and $Q()$;
    if $|\mathcal{E}| < k$ then
        $\mathcal{E} \leftarrow \mathcal{E} \cup \{C_c\}$;
    else if $\exists j : Q(C_c) > Q(C_j)$ then
        replace weakest ensemble member with $C_c$;
    end if
end for
```

The origins of online stationary ensembles come from research on the Winnow algorithm and the Weighted Majority Algorithm (Littlestone and Warmuth 1994), which combine the predictions of several experts (classifiers) by majority voting. When the ensemble misclassifies an instance, the weights of the wrong experts are decreased by a user-specified coefficient. The Dynamic Weighted Majority (DWM) is an extension of this idea for drifting data streams (Kolter and Maloof 2007). It uses a set of incremental classifiers, which are generated by the same learning algorithm. When a new example is available, the final prediction is obtained as a weighted vote of all classifiers. The weights of all classifiers that misclassify the example are decreased in the same way as in the Weighted Majority Algorithm. However, DWM dynamically creates and deletes component classifiers in response to changes in classification performance. If the ensemble's overall prediction is incorrect, a new classifier is added to the ensemble.

Another group of online ensembles includes generalizations of static ensembles. The most well known are online versions of ▶ bagging and ▶ boosting (Oza and Russell 2001). In case of online bagging, the key idea is to adapt the ▶ bootstrap sampling step to a streaming setting. This is done by using single examples multiple times according to the Poisson distribution.

This proposal of randomly updating training sets was an inspiration to develop several other approaches, e.g., leveraging bagging, online boosting, or the DDD ensemble (Ditzler et al. 2015).

Comprehensive reviews of various ensembles can be found in Ditzler et al. (2015), Gama (2010), and Kuncheva (2004).

Other Approaches

Although developing classifiers for concept-drifting streams is in itself a nontrivial task, some other characteristics of learning problems can make this task even more difficult. In most current algorithms, it is assumed that all information, in particular class labels of instances, are complete, immediately available, and received for free (Krempl et al. 2014). However, these assumptions may not hold true in some real-world problems, e.g., in fraud detection or patient health monitoring, where the labeling of examples is scarce or missing. In the case of static data, these problems are studied with ▸ semi-supervised learning. For adapting such techniques to streams, the availability of at least some labeled data from the most recent distribution is required. For instance, Masud et al. (2008) divide the stream into blocks containing partly labeled examples and then propose various approaches to combine learning ensemble classifiers with semi-supervised clustering. ▸ Active learning is also often related to semi-supervised frameworks. However, many sampling techniques developed for static data are not well suited for non-stationary streams (Spiliopoulou and Krempl 2013). A review of recent active learning strategies is presented in Žliobaitė et al. (2011).

A particularly challenging problem is learning classifiers from initially labeled non-stationary streams, where completely labeled examples are available for the first period only, followed by unlabeled data which may be drawn from a different distribution. Research on this topic is still at an early stage. Yet another problem is dealing with delayed information. In the case of *verification latency*, the class labels of preceding examples are not available before the subsequent instance has to be predicted. Therefore, feedback from correct predictions cannot be instantly used to improve the classifier. For a review of approaches that try to deal with this problem, see Ditzler et al. (2015).

Dealing with the ▸ class imbalance problem in non-stationary streams also introduces additional difficulties. Recent proposals to this problem pay attention to drifts of the minority class and specialized evaluation methods (Wang et al. 2015). The problem of class imbalance is also related to an increasing interest in studying other types of changes (Gama et al. 2014). Finally, other research concerns more complex representations of instances in streams, as graphs, semi-structured documents, or text messages, as well as complex target outputs, like multi-labeled or ordinal classification. Other open issues are discussed in Ditzler et al. (2015) and Krempl et al. (2014).

Applications

Applications of stream classification can be organized into three groups: monitoring and control, information management, and analytics and diagnostics (Zliobaite et al. 2015).

Monitoring and control mostly relates to the detection of abnormal events. Domains from this group include sensor networks, telecommunications, traffic control, and fraud detection. Information management encompasses applications such as product recommendation, crime prediction, personalized search, and customer profiling. Analytics and diagnostics address domains like evaluation of creditworthiness, budget planning, or drug resistance prediction.

Each of the aforementioned groups differs also in the way stream classification is modeled. Monitoring and control usually involves sequential data where the task is to detect sudden changes. Information management is mostly based on relational data and gradual rather than abrupt changes are to be expected. Finally, diagnostic applications often involve recurring concepts. For an in-depth analysis of different application settings, see Zliobaite et al. (2015).

Stream Mining

A subfield of knowledge discovery called *stream mining* addresses the issue of rapidly changing data. The idea is to be able to deal with the stream of incoming data quickly enough to be able to simultaneously update the corresponding models (e.g., ontologies), as the amount of data is too large to be stored: new evidence from the incoming data is incorporated into the model without storing the data. For instance, modeling ontology changes and evolution over time using text mining methods (TextMining for Semantic Web). The underlying methods are based on the machine learning methods of ▶ Online Learning, where the model is built from the initially available data and updated regularly as more data become available.

Examples of data streams include computer network traffic, phone conversations, ATM transactions, web searches, and sensor data.

String Kernel

A *string kernel* is a function from any of various families of kernel functions (see ▶ kernel methods) that operate over strings and sequences. The most typical example is as follows. Suppose that we are dealing with strings over a finite alphabet Σ. Given a string $a = a_1a_2\ldots a_n \in \Sigma^*$, we say that a substring $p = p_1p_2\ldots p_k$ *occurs* in a on positions $i_1i_2\ldots i_k$ iff $1 \leq i_1 < i_2 < \ldots < i_k \leq n$ and $a_{i_j} = p_j$ for all $j = 1,\ldots,k$. We define the *weight* of this occurrence as $\lambda^{i_k - i_i - k + 1}$, where $\lambda \in [0,\ 1]$ is a constant chosen in advance; in other words, an occurrence weighs less if characters of p are separated by other characters. Let $\phi_p(a)$ be the sum of the weights of all occurrences of p in a, and let $\phi(a) = (\phi_p(a))_{p\in\sum^*}$ be an infinite-dimensional feature vector consisting of $\phi_p(a)$ for all possible substrings $p \in \Sigma^*$. It turns out that the dot product of two such infinite-length vectors, $K(a,a') = \phi(a)^T\phi(a')$, can be computed in time polynomial in the length of a and a', e.g., using dynamic programming. The function K defined in this way can be used as a kernel with various kernel methods. See also ▶ feature construction in text mining.

String Matching Algorithm

A string matching algorithm returns parts of text matching a given pattern, such as a *regular expression*. Such algorithms have countless applications, from file editing to bioinformatics. Many algorithms compute deterministic finite automata, which can be expensive to build, but are usually efficient to use; they include the *Knuth–Morris–Pratt* algorithm and the *Boyer–Moore* algorithm, that build the automaton in time $O(m)$ and $O(m + s)$, respectively, where m is the length of the pattern and s the size of the alphabet, and match a text of length n in time $O(n)$ in the worst case.

Australia

Abstract

Structural risk minimization is an inductive principle used to combat overfitting. It seeks a tradeoff between model complexity and fitness of the model on the training data.

Definition

The goal of learning is usually to find a model which delivers good generalization performance over an underlying distribution of the data. Consider an input space $\mathcal{X}$ and output space $\mathcal{Y}$. Assume the pairs $(X \times Y) \in \mathcal{X} \times \mathcal{Y}$ are random variables whose (unknown) joint distribution is

P_{XY}. It is our goal to find a predictor $f : \mathcal{X} \mapsto \mathcal{Y}$ which minimizes the expected risk:

$$P(f(X) \neq Y) = \mathbb{E}_{(X,Y)\sim P_{XY}}[\delta(f(X) \neq Y)],$$

where $\delta(z) = 1$ if z is true, and 0 otherwise.

In practice we only have n pairs of training examples (X_i, Y_i) drawn identically and independently from P_{XY}. Based on these samples, the ▶ Empirical Risk can be defined as

$$\frac{1}{n}\sum_{i=1}^{n}\delta(f(X_i) \neq Y_i).$$

Choosing a function f by minimizing the empirical risk often leads to ▶ Overfitting. To alleviate this problem, the idea of structural risk minimization (SRM) is to employ an infinite sequence of models $\mathcal{F}_1, \mathcal{F}_2, \ldots$ with increasing capacity. Here each $\mathcal{F}_i$ is a set of functions, e.g., polynomials with degree 3. We minimize the empirical risk in each model with a penalty for the capacity of the model:

$$f_n := \text{argmin}_{f\in\mathcal{F}_i, i\in\mathbb{N}} \frac{1}{n}\sum_{i=1}^{n}\delta(f(X_i) \neq Y_i)$$
$$+ \text{capacity}(\mathcal{F}_i, n),$$

where capacity$(\mathcal{F}_i, n)$ quantifies the complexity of model $\mathcal{F}_i$ in the context of the given training set. For example, it equals 2 when $\mathcal{F}_i$ is the set of polynomials with degree 2. In other words, when trying to reduce the risk on the training set, we prefer a predictor from a simple model.

Note the penalty is measured on the model $\mathcal{F}_i$, *not* the predictor f. This is different from the regularization framework, e.g., support vector machines, which penalizes the complexity of the *classifier*.

More details about SRM can be found in Vapnik (1998).

Structured Induction

Michael Bain
University of New South Wales, Sydney, NSW, Australia

Definition

Structured induction is a method of applying machine learning in which a model for a task is learned using a representation where some of the components are themselves the outputs of learned models for specified sub-tasks. The idea was inspired by structured programming (Dahl et al. 1972), in which a complex task is solved by repeated decomposition into simpler sub-tasks that can be easily analyzed and implemented. The approach was first developed by Alen Shapiro (1987) in the context of constructing expert systems by ▶ decision tree learning, but in principle it could be applied using other learning methods.

Motivation and Background

Structured induction is designed to solve complex learning tasks for which it is difficult a priori to obtain a set of attributes or features in which it is possible to represent an accurate approximation of the target hypothesis reasonably concisely. In Shapiro's approach, a hierarchy of ▶ decision trees is learned, where in each tree of the hierarchy the attributes can have values that are outputs computed by a lower-level ▶ decision tree. Shapiro showed in computer chess applications that structured induction could learn accurate models, while significantly reducing their complexity. Structured induction was first commercialized in the 1980s by a number of companies providing expert systems solutions and has since seen many applications (Razzak et al. 1984).

A key assumption is that human expertise is available to define the task structure. Several approaches have been proposed to address the problem of learning this structure (under headings such as ▸ constructive induction, representation change, ▸ feature construction, and ▸ predicate invention) although to date, none have received wide acceptance.

The identification of knowledge acquisition as the "bottleneck" in knowledge engineering by Feigenbaum (1977) sparked considerable interest in symbolic machine-learning methods as a potential solution. Early work on ▸ decision tree induction around this time was often driven by problems from computer chess, a challenging domain by the standards of the time due to relatively large data sets and the complexity of the target hypotheses. In a landmark paper on his ID3 ▸ decision tree learning algorithm, Quinlan (1983) reported experiments on learning to classify positions in a four-piece chess endgame as winnable (or not) within a certain number of moves ("lost N-ply"). A set of attributes was defined as *inadequate* for a classification task if two objects belonging to different classes had identical values for each attribute. He concluded that "almost all the effort (for a non chess-player, at least) must be devoted to finding attributes that are adequate for the classification problem being tackled".

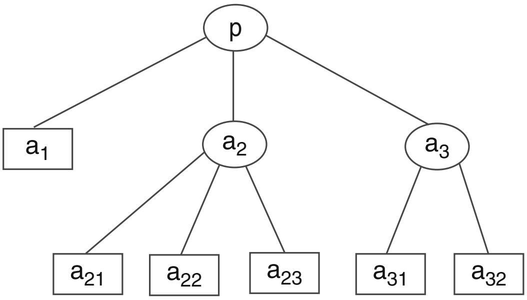
The problem is that the effort of developing the set of attributes becomes disproportionate to the time taken to do the induction. Quinlan (1983) reported durations of three weeks and two man-months, respectively, to define an adequate set of attributes for the "lost 2-ply" and "lost 3-ply" experiments. In contrast, the implementation of ID3 used in that work induced the ▸ decision trees in 3 s and 34 s, respectively. It is worth noting that the more complex problem of "lost 4-ply" was abandoned due to the difficulty of developing an adequate set of attributes.

Although Quinlan's experiments with ID3 produced exact ▸ classifiers for his chess problems, the resulting ▸ decision trees were too large to be comprehensible to domain experts. This is a serious drawback when machine learning is used with the goal of installing learned rules in an expert system, since the system cannot provide understandable explanations. Shapiro and Niblett (1982) proposed structured induction as a solution to this problem, and the method was developed in Shapiro's PhD thesis (Shapiro 1987) motivated by expert systems development.

Structure of Learning System

Structured induction is essentially a two-stage process, comprising a top-down decomposition of the problem into a solution structure, followed by a bottom-up series of ▸ classifier learning steps, one for each of the subproblems. A knowledge engineer and a domain expert are required to collaborate at each stage, with the latter acting as a source of examples. The use of machine learning to avoid the knowledge acquisition bottleneck is based on the finding that although domain experts find it difficult to express general and accurate rules for a problem, they are usually able to generate tutorial examples in an attribute-value formalism from which rules can be generalized automatically. The key insight of structured induction is that the task of specifying an attribute and its value set can be treated as a subproblem of the learning task, and solved in the same way.

The approach can be illustrated by a simple example using the structure shown in Fig. 1. Suppose the task is to learn a model for some concept $\mathbf{p}$. Suppose further that the domain expert proposes three attributes $\mathbf{a_1}$, $\mathbf{a_2}$, and $\mathbf{a_3}$ as adequate for the classification of $\mathbf{p}$. Now the domain expert consults with the knowledge engineer and it is decided that while attribute $\mathbf{a_1}$ is directly implementable, the other two are not. An attribute that is directly implementable by a knowledge engineer is referred to as *primitive* for the domain. The other attributes become sub-concepts $\mathbf{a_2}$ and $\mathbf{a_3}$, and each in turn is addressed by the domain expert. In this case, three attributes are proposed



Structured Induction, Fig. 1 A schematic diagram of a model learned by structured induction (after Shapiro 1987). Concepts to be learned are shown in ovals, and primitive attributes in boxes. The top-level concept **p** is defined in terms of the primitive attribute $\mathbf{a_1}$ and two sub-concepts $\mathbf{a_2}$ and $\mathbf{a_3}$. Each of the two sub-concepts are further decomposed into sets of primitive attributes, $\mathbf{a_{21\ldots3}}$ and $\mathbf{a_{31\ldots2}}$

as most relevant to the solution of $\mathbf{a_2}$, and two for $\mathbf{a_3}$. Since all of these attributes are found to be primitive, the top-down problem decomposition stage is therefore complete.

The domain expert, having proposed a set of primitive attributes for a sub-concept, say $\mathbf{a_3}$, is now required to provide a set of classified examples defined in terms of values for attributes $\mathbf{a_{31}}$ and $\mathbf{a_{32}}$. Given these examples, the knowledge engineer will run a learning algorithm to induce a ▸ classifier such as a ▸ decision tree. The domain expert will then inspect the ▸ classifier and can optionally refine it by supplying further examples, until they are satisfied that it completely and correctly defines the sub-concept $\mathbf{a_3}$. This process is repeated in a bottom-up fashion for all sub-concepts. At every level of the hierarchy, once all sub-concepts have been defined, they are now directly executable ▸ classifiers and can be treated in the same way as primitive attributes and used for learning. The structured induction solution is complete once an acceptable ▸ classifier has been learned for the top-level concept, **p** in this example.

Structured Versus Unstructured Induction

On two chess end-game domains, Shapiro (1987) showed that structured induction could generate more compact trees from fewer examples compared with an unstructured approach. To quantify this improvement, Shapiro made an analysis based on Michie's finite message information theory (Michie 1982). This showed that on one of the domains, the information gain contributed by the structured induction approach over learning unstructured trees from the same set of examples was 84 %. Essentially, this is because the structure devised by the domain expert in collaboration with the knowledge engineer provides a context for each of the induction tasks required. Since within this context only a subset of the complete attribute set is used to specify a sub-concept, it suffices to obtain only sufficient examples to learn a model for that sub-concept. However, without the benefit of such contextual restrictions the task of learning a complete solution can require considerably more examples. Shapiro's analysis is an attempt to quantify the relative increase in information per example in structured versus unstructured induction.

Related Work

While induction can bypass the knowledge acquisition bottleneck, in structured induction the process of acquiring the structure in collaboration with a domain expert can become a new bottleneck. In an attempt to avoid this, a number of researchers have attempted to develop methods whereby the structure, as well as the sub-concept models can be learned automatically.

Muggleton (1987) introduced ▶ inverse resolution as an approach to learning structured ▶ rule sets in a system called Duce. As part of this process, a domain expert is required to provide names for new sub-concepts or *predicates* that are proposed by the learning algorithm. A domain expert is also required to confirm learned rules. Both these roles are similar to those required of the expert in constructive induction, but the key difference is that the learning algorithm is now the source of both the structure and the rules. Duce was applied to one of the chess end-game domains used in Shapiro's study (Shapiro 1987) and found a solution that was less compact, but still accepted as comprehensible by a chess expert.

The Duce system searches for commonly occurring subsets of attribute-value pairs within rules, and uses these to construct new sub-concept definitions. Many approaches have been developed using related methods to learn new sub-concepts in the context of ▶ decision tree or ▶ rule learning; some examples include Pagallo and Haussler (1990), Zheng (1995), and Zhang and Honavar (2003). Gaines (1996) proposed EDAGs (exception directed acyclic graphs) as a generalization of both ▶ decision trees and rules with exceptions, and reported EDAG representations of chess end-game ▶ classifiers that were more comprehensible than either rules or ▶ decision trees. Zupan et al. (1999) developed a system named HINT designed to learn a model represented as a concept hierarchy based on methods of function decomposition. Inverse resolution as used in Duce has been generalized to first-order logic representations in the field of inductive logic programming. In this framework, the construction of new intermediate concepts is referred to as ▶ *predicate invention*, but to date this remains a largely open problem. More recently, much of the interest in representation change has focused on approaches like support vector machines, where the so-called kernel trick enables the use of *implicit* ▶ feature construction (Shawe-Taylor and Cristianini 2004).

Subgroup Discovery

Definition

Subgroup discovery (Klösgen 1996; Lavrač et al. 2004) is an area of ► supervised descriptive rule induction. The subgroup discovery task is defined as given a population of individuals and a property of those individuals that we are interested in, find population subgroups that are statistically "most interesting," for example, are as large as possible and have the most unusual statistical (distributional) characteristics with respect to the property of interest.

Sublinear Clustering

Artur Czumaj[1] and Christian Sohler[2]
[1]University of Warwick, Coventry, UK
[2]University of Paderborn, Paderborn, Germany

Definition

Sublinear clustering describes the process of clustering a given set of input objects using only a small subset of the input set, which is typically selected by a random process. A solution computed by a sublinear clustering algorithm is an implicit description of the clustering (rather than a partition of the input objects), for example in the form of cluster centers. Sublinear clustering is usually applied when the input set is too large to be processed with standard clustering algorithms.

Motivation and Background

► Clustering is the process of partitioning a set of objects into subsets of similar objects. In machine learning, it is, for example, used in unsupervised learning to fit input data to a density model. In many modern applications of clustering, the input sets consist of billions of objects to be clustered. Typical examples include web search, analysis of web traffic, and spam detection. Therefore, even though many relatively efficient clustering algorithms are known, they are often too slow to cluster such huge inputs.

Since in some applications it is even not possible to cluster the entire input set, a new approach is needed to cope with very large data sets. The approach used in many different areas of science and engineering in this context is to *sample* a subset of the data and to analyze this sample instead of the whole data set. This is also the underlying method used in sublinear clustering. The main challenge and innovation in this area lies in the qualitative analysis of random sampling (in the form of approximation guarantees) and the design of *non uniform sampling* strategies that approximate the input set provably better than *uniform random sampling*.

Structure of the Learning System

In sublinear clustering a large input set of objects is to be partitioned into subsets of similar objects. Usually, this input is a point set P either in the Euclidean space or in the metric space. The clustering problem is specified by an objective function that determines the quality or cost of every possible clustering. The goal is to find a clustering of minimum cost/maximum quality. For example, given a set P of points in the Euclidean space the objective of ▶ *k-means clustering* is to find a set C of k centers that minimizes $\sum_{p \in P}(d(p, C))^2$, where $d(p, C)$ denotes the distance of p to the nearest center from C. Since usually the clustering problems are computationally hard ($\mathcal{NP}$-hard), one typically considers *approximate* solutions: instead of finding a clustering that optimizes the cost of the solution, one aims at a solution whose cost is close to the optimal one.

In sublinear algorithms a solution is computed for a small representative subset of objects, for example a random sample. The solution is represented implicitly, for example, in the form of cluster centers and it can be easily extended to the whole input point set. The quality of the output is analyzed *with respect to the original point set*. The challenge is to *design and analyzefast (sublinear-time) algorithms* that select a subset of objects that very well represent the entire input, such that the solution computed for this subset will also be a good solution for the original point set. This can be achieved by uniform and non uniform *random sampling* and the computation of *core-sets*, i.e., small weighted subsets of the input that approximate the input with respect to a clustering objective function.

Theory/Solution

Clustering Problems

For any point p and any set Q in a metric space (X, d), let $d(p, Q) = \min_{q \in Q} d(p, q)$. A point set P is *weighted* if there is a function w assigning a positive weight to each point in P.

Radius k-Clustering: Given a weighted set P of points in a metric space (X, d), find a set $C \subseteq P$ of k centers minimizing $\max_{p \in P} d(p, C)$.

Diameter k-Clustering: Given a weighted set P of points in a metric space (X, d), find a partition of P into k subsets $P_1, \ldots, P_k$, such that $\max_{i=1}^{k} \max_{p,q \in P_i} d(p, q)$ is minimized.

k-Median: Given a weighted set P of points in a metric space (X, d), find a set $C \subseteq P$ of k centers that minimizes $\mathit{median}(P, C) = \sum_{p \in P} w(p) \cdot d(p, C)$.

k-Means: Given a weighted set of points P in a metric space (X, d), find a set $C \subseteq P$ of k centers that minimizes $\mathit{mean}(P, C) = \sum_{p \in P} w(p) \cdot (d(p, C))^2$.

Random Sampling and Sublinear-Time Algorithms

Random sampling is perhaps the most natural approach to design sublinear-time algorithms for clustering. For the input set P, random sampling algorithm follows the following scheme:

1. Pick a random sample S of points
2. Run an algorithm (possibly an approximation one) for (given kind of) clustering for S
3. Return the clustering induced by the solution for S

The running time and the quality of this algorithm depends on the size of the random sample S and of the running time and the quality of the algorithm for clustering of S. Because almost all interesting clustering problems are computationally intractable ($\mathcal{NP}$-hard), usually the second step of the sampling scheme uses an approximation algorithm. (An algorithm for a minimization problem is called a λ-approximation if it always returns a solution whose cost is at most λ times the optimum.)

While random sampling approach gives very simple algorithms, depending on the clustering problem at hand, it often finds a clustering of poor quality and it is usually difficult to analyze. Indeed, it is easy to see that random sampling has some serious limitations to obtain clustering of good quality. Even the standard assumption that the input is in metric space is not sufficient to obtain good quality of clustering because of the small clusters which are "hidden" for random sampling approach. (If there is a cluster of size $o(|P|/|S|)$ then with high probability the random sample set S will contain no point from that cluster.) Therefore, another important parameters used in the analysis is the *diameter* of the metric space Δ, which is $\Delta = \max_{p,q \in P} d(p, q)$.

Quality of Uniformly Random Sampling: The quality of random sampling for three basic clustering problems (k-means, k-median, and min-sum k-clustering) have been analyzed in Ben-David (2004), Czumaj and Sohler (2007), and Mishra et al. (2001). In these papers, generic methods of analyzing uniform random sampling have been obtained. These results assume that the input point sets are in a metric space and are unweighted (i.e., when the weight function w is always 1).

Theorem 1 *Let* $\epsilon > 0$ *be an approximation parameter. Suppose that an* α*-approximation algorithm for the k-median problem in a metric space is used in step* (2) *of the uniform sampling, where* $\alpha \geq 1$ (Ben-David 2004; Czumaj and Sohler 2007; Mishra et al. 2001). *If we choose S to be of size at least*

$$c\alpha(K + \frac{\Delta}{\epsilon}(\alpha + k\ln(k\Delta\alpha/\epsilon)))$$

for an appropriate constant c, then the uniform sampling algorithm returns a clustering C^* *(of S) such that with probability at least 0.99 the normalized cost of clustering for S satisfies*

$$\frac{median(S, C^*)}{|S|} \leq \frac{2(\alpha + 0.01)OPT(P)}{|P|} + \epsilon,$$

where OPT(S) = min$_C$ *median(P,C) is the minimum cost of a solution for k-median for P.*

Similar results can be shown for the k-means problem, and also for min-sum k-clustering (cf. Czumaj and Sohler 2007). For example, for k-means, with a sample S of size at least $c\alpha(k + (\Delta^2/\epsilon)(\alpha + k\ln(k\Delta^2\alpha/\epsilon)))$, with probability at least 0. 99 the normalized cost of k-means clustering for S satisfy

$$\frac{mean(S, C^*)}{|S|^2} \leq \frac{4(\alpha + 0.01OPT(P))}{|P|^2} + \epsilon,$$

where $OPT(S) = \min_C\ mean(P, C)$ is the minimum cost of a solution for k-means for P.

Improvements of these bounds for the case when the input consists of points in Euclidean space are also discussed in Mishra et al. (2001) and Czumaj and Sohler (2007) discuss also. For example, for k-median, if one takes S of size at least $c\alpha(k + \Delta k\ln(\Delta/\epsilon)/\epsilon)$, then with probability at least 0.99 the normalized cost of k-median clustering for S satisfies

$$\frac{median(S, C^*)}{|S|} \leq \frac{(\alpha + 0.001)OPT(P)}{|P|} + \epsilon,$$

and hence the approximation ratio is better than that in Theorem 1 by factor of 2.

The results stated in Czumaj and Sohler (2007) allow to parameterize the constants 0.99 and 0.01 in the claims above.

Property Testing of the Quality of Clustering: Since most of the clustering problems are computationally quite expensive, in some situations it might be interesting not to find a clustering (or its succinct representation), but just to test if the input set has a good clustering.

Alon et al. (2003) introduced the notion of approximate testing of good clustering. A point set P is *c-clusterable* if it has a clustering of the cost at most c, that is, *OPT(P)* $\leq c$. To formalize the notion of having no good clustering, one says a point set is ε*-far from* $(1 + \beta)c$*-clusterable*, if more than an ε-fraction of the points in P must be removed (or moved) to make the input set $(1 + \beta)c$-clusterable. With these definitions, the goal is to design fast algorithms that accept the input point sets P, which are c-clusterable, and reject with probability at least 2/3 inputs are ε-far from $(1 + \beta)c$-clusterable. If neither holds, then the algorithms may either accept or reject. The bounds for the testing algorithms are phrased in terms of *sample complexity*, that is, the number of sampled input points which are considered by the algorithm (e.g., by using random sampling).

Alon et al. (2003) consider two classical clustering problems in this setting: radius and diameter k-clusterings. If the inputs are drawn from an arbitrary metric space, then they show that to distinguish between input points sets that are c-clusterable and are ε-far from $(1+\beta)c$-clusterable with $\beta < 1$, the sample complexity must be at least $\Omega(\sqrt{|P|/\epsilon})$. However, to distinguish between inputs that are c-clusterable and are ε-far from $2c$-clusterable, the sample complexity is only $O(\sqrt{k/\epsilon})$.

A more interesting situation is for the input points drawn from the Euclidean d-dimensional space. In that case, even a constant-time algorithms are possible.

Theorem 2 *For the radius k-clustering, one can distinguish between points sets in* R^d *that are c-clusterable from those ε-far from c-clusterable with the sample complexity* $\tilde{O}(dk/\epsilon)$ (Alon et al. 2003) *(The* $\tilde{O}$ *-notation ignores logarithms in the largest occurrence of a variable;* $\tilde{O}(f(n)) = O(f(n)\cdot(\log f(n))^{o(1)})$.*)*

Furthermore, for any $\beta > 0$*, one can distinguish between points sets in* R^d *that are c-clusterable from those ε-far from* $(1+\beta)c$*-clusterable with the sample complexity* $\tilde{O}(k^2/(\beta^2\epsilon))$.

Theorem 3 *For the diameter k-clustering, one can distinguish between points sets in* R^d *that are c-clusterable from those ε-far from* $(1+\beta)c$*-clusterable with the sample complexity* $\tilde{O}(k^2 d(2/\beta)^{2d}/\epsilon)$ (Alon et al. 2003).

Core-Sets: Sublinear Space Representations with Applications

A *core-set* is a small weighted set of points S that provably approximates another point set P with respect to a given clustering problem (Bădoiu et al. 2002). The precise definition of a core-set depends on the clustering objective function and the notion of approximation. For example, a coreset for the k-median problem can be defined as follows:

Definition 4 A weighted point set S is called ε-coreset for a point set P for the k-median problem, if for every set C of k centers, we have $(1-\epsilon)\cdot$ median $(P, C) \leq$ median $(S, C) \geq (1+\epsilon)\cdot$ median (P, C) (Har-Peled and Mazumdar 2004).

A core-set as defined above is also sometimes called a *strong* core-set, because the cost of the objective function is approximately preserved for any set of cluster centers. In some cases it can be helpful to only require a weaker notion of approximation. For example, for some applications it is sufficient that the cost is preserved for a certain discrete set of candidate solutions. Such a core-set is usually called a *weak* core-set. In high-dimensional applications it is sometimes sufficient that the solution is contained in the low-dimensional subspace spanned by the core-set points.

Constructing a Core-Set: There are deterministic and randomized constructions for core-sets of an unweighted set P of n points in the R^d. Deterministic core-set constructions are usually based on the *movement paradigm*. The input points are moved to a set of few locations such that the overall movement is at most ε times the cost of an optimal solution. Then the set of points at the same location are replaced by a single point whose weight equals the number of these points. Since for the k-median problem the cost of any solution changes by at most the overall movement, this immediately implies that the constructed weighted set is an ε-core-set. For other similar problems more involved arguments can be used to prove the core-set property. Based on the movement paradigm, for k-median a core-set of size $O(k \log n/\epsilon^d)$ can be constructed efficiently (Har-Peled and Mazumdar 2004).

Randomized core-set constructions are based on non uniform sampling. The challenge is to define a randomized process for which the resulting weighted point set is with high probability a core-set. Most randomized coreset constructions first compute a bi-criteria approximation C'. Then every point is sampled with probability proportional to its distance to the nearest center of C'. A point q is assigned a weight proportional to $1/p_q$, where p_q is the probability that p is sampled. For every fixed set C of k centers, the resulting sample is an unbiased estimator for *median*(P, C). If the sample set is large enough, it approximates the cost of every possible set of k centers within a factor of $(1 \pm \epsilon)$. The above approach can be used to obtain a weak core-set of size independent of the size of the input point set and the dimension of the input space (Feldman et al. 2007). A related construction has been previously used to obtain a strong core-set of size $\tilde{O}(k^2 \cdot d \cdot \log n/\epsilon^2)$. Both constructions have constant success probability that can be improved by increasing the size of the core-set.

Applications Core-sets have been used to obtain improved approximation algorithms for different variants of clustering problems. Since the core-sets are of sublinear size and they can be constructed in sublinear time, they can be used to obtain sublinear-time approximation algorithms for a number of clustering problems.

Another important application is clustering of data streams. A data stream is a long sequence of data that typically does not fit into main memory, for example, a sequence of packet headers in IP traffic monitoring. To analyze data streams we need algorithms that extract information from a stream without storing all of the observed data. Therefore, in the data streaming model algorithms are required to use $\log^{O(1)} n$ bits of memory. For core-sets, a simple but rather general technique is known, which turns a given construction of a strong core-set into a data streaming algorithm, i.e., an algorithm that processes the input points sequentially and uses only $\log^{O(1)}$ space (for constant k and ϵ) and computes a $(1 + \epsilon)$-approximation for the optimal set of centers of the k-median clustering (Har-Peled and Mazumdar 2004). Core-sets can also be used to improve the running time and stability of clustering algorithms like the k-means algorithm (Frahling and Sohler 2006).

Subsumption

Claude Sammut
The University of New South Wales, Sydney,
NSW, Australia

Subsumption provides a syntactic notion of generality. Generality can simply be defined in terms of the cover of a concept. That is, a concept, C, is more general than a concept, C', if C covers at least as many examples as C' (see ▶ Learning as Search). However, this does not tell us how to determine, from their syntax, if one sentence in a concept description language is more general than another. When we define a *subsumption* relation for a language, we provide a syntactic analogue of generality (Lavrač and Džeroski 1994). For example, θ*-subsumption* (Plotkin 1970) is the basis for constructing generalization lattices in ▶ inductive logic programming (Shapiro 1981). See ▶ Generality of Logic for a definition of θ*-subsumption*. An example of defining a subsumption relation for a domain specific language is in the LEX program (Mitchell et al. 1983), where an ordering on mathematical expressions is given.

SDRI

Definition

Supervised descriptive rule induction (SDRI) is a machine learning task in which individual patterns in the form of rules (see ▶ classification rule) intended for interpretation are induced from data, labeled by a predefined property of interest. In contrast to standard ▶ supervised rule induction, which aims at learning a set of rules defining a classification/prediction model, the goal of SDRI is to induce individual descriptive patterns. In this respect, SDRI is similar to ▶ association rule discovery, but the consequents of the rules are restricted to a single variable – the property of interest – and, except for the discrete target attribute, the data is not necessarily assumed to be discrete.

Supervised descriptive rule induction assumes a set of training examples, described by attributes and their values and a selected attribute of interest (called the target attribute). Supervised descriptive rule induction induces rules that may each be interpreted independently of the others. Each rule is a local model, covering a subset of training examples, that captures a local relationship between the target attribute and the other attributes.

Induced descriptive rules are mainly aimed at human interpretation. More specifically, the purposes of supervised descriptive rule induction are to allow the user to gain insights into the data domain and to better understand the phenomena underlying the data.

Motivation and Background

Symbolic data analysis techniques aim at discovering comprehensible patterns or models in data. They can be divided into techniques for *predictive induction*, where models, typically induced from class-labeled data, are used to predict the class value of previously unseen examples, and *descriptive induction*, where the aim is to find comprehensible patterns, typically induced from unlabeled data. Until recently, these techniques have been investigated by two different research communities: predictive induction mainly by the machine learning community and descriptive induction mainly by the data mining community.

Data mining tasks where the goal is to find comprehensible patterns from labeled data have been addressed by both the machine learning and the data mining community independently. The data mining community, using the ▸ association rule learning perspective, adapted association rule learners like ▸ Apriori (Agrawal et al. 1996) to perform tasks on labeled data, like class association rule learning (Liu et al. 1998; Fürnkranz et al. 2012), as well as ▸ contrast set mining (Bay and Pazzani 2001) and ▸ emerging pattern mining (Dong and Li 1999). On the other hand, the machine learning community, which traditionally focused on the induction of ▸ rule sets from labeled data for the purposes of classification, turned to building individual rules for exploratory data analysis and interpretation. This is the goal of the task named ▸ subgroup discovery (Wrobel 1997). These are the main areas of supervised descriptive rule induction. All deal with finding comprehensible rules from class-labeled data. However, the methods used and the interpretation of the results differ slightly from approach to approach. Other related approaches include change mining, mining of closed sets for labeled data, exception rule mining, bump hunting, quantitative association rules, and impact rules. See Kralj Novak et al. (2009) for a more detailed survey of supervised descriptive rule induction.

Structure of the Learning System

Supervised descriptive rule induction assumes that there is data with the property of interest defined by the user. Let us illustrate supervised descriptive rule induction using data from Table 1, a very small artificial sample data set, adapted from Ross Quinlan (1986), which contains the results of a survey on 14 individuals, concerning the approval or disproval of an issue analyzed in the survey. Each individual is characterized by four attributes that encode rudimentary information about the sociodemographic background. The last column (Approved) is the designated property of interest, encoding whether the individual approved or disproved the issue. Unlike predictive induction, where the aim is to find a predictive model, the goal of supervised descriptive rule induction is to find local patterns in the form of individual rules describing individuals that are likely to approve or disprove the issue, based on the four demographic characteristics.

Figure 1 shows six descriptive rules, found for the sample data using the Magnum Opus (Webb 1995) rule learning software. These rules were found using the default settings except that the critical value for the statistical test was relaxed. This set of descriptive rules differs from a typical predictive rule set in several ways. The first rule

Supervised Descriptive Rule Induction, Fig. 1 Selected descriptive rules, describing individual patterns in the data of Table 1

is redundant with respect to the second. The first rule is included as a strong pattern (all three single males do not approve), whereas the second is weaker but more general (four out of seven males do not approve, which is not highly predictive, but accounts for four out of all five respondents who do not approve). Most predictive systems would include only one of these rules, but either or both of them may be of interest to someone trying to understand the data, depending on the specific application. This particular approach to descriptive pattern discovery does not attempt to guess which of the more specific or more general patterns will be more useful to the end user. Another difference between predictive and descriptive rules is that the predictive approach often includes rules for the sake of completeness, while some descriptive approaches make no attempt at completeness, as they assess each pattern on its individual merits.

Exactly which rules will be induced by a supervised descriptive rule induction algorithm depends on the task definition, the selected algorithm, as well as the user-defined constraints concerning minimal rule support, precision, etc. Different learning approaches and heuristics have been proposed to induce supervised descriptive rules.

Applications

Applications of supervised descriptive rule induction are widely spread. See Kralj Novak et al. (2009) for a detailed survey.

Subgroup discovery has been used in numerous real-life applications Herrera et al. (2011). Medical applications include the analysis of coronary heart disease, brain ischemia data analysis, the analysis of cervical cancer, and psychiatric emergency, as well as profiling examiners for sonographic examinations. Spatial subgroup mining applications include mining of census data, mining of vegetation data and mining of demographic data. There are also applications in marketing, traffic accidents, production control, election analysis, and social data.

▶ Contrast set mining has been used with retail sales data and for designing customized insurance programs. It has also been used in medical applications to identify patterns in synchrotron x-ray data that distinguish tissue samples of different forms of cancerous tumor and for distinguishing between groups of brain ischemia patients.

▶ Emerging pattern mining has been mainly applied to the field of bioinformatics, more specifically to microarray data analysis. For example, an interpretable classifier based on simple rules that is competitive to the state of the art black-box classifiers on the acute lymphoblastic leukemia (ALL) microarray data set was built from emerging patterns. Another application was about finding groups of genes by emerging patterns in a ALL/AML data set and a colon tumor data set. Emerging patterns were also used together with the unexpected change approach and the added/perished rule to mine customer behavior.

Future Directions

A direction for further research is to decompose SDRI algorithms and preprocessing and evaluation methods into basic components and to reimplement them as connectable web services, which include the definition of interfaces between SDRI services. For instance, this can include the adaptation and implementation of subgroup discovery techniques to solving open problems in the area of contrast set mining and emerging patterns. This would allow for the improvement of algorithms due to the cross-fertilization of ideas from different SDRI subareas.

Another direction for further research concerns complex data types and the use of background knowledge. The SDRI attempts in this direction include relational subgroup discovery approaches like algorithms Midos (Wrobel 2001), RSD (relational subgroup discovery) (Železný and Lavrač 2006), and SubgroupMiner (Klösgen and May 2002), which is designed for spatial data mining in relational space databases. When ontologies are used as background knowledge to define the hypothesis search space and data are used to constrain and guide the hypothesis search and evolution, and this is called semantic subgroup discovery (Vavpetič and Lavrač 2013).

Supervised Learning

Definition

Supervised learning refers to any machine learning process that learns a function from an input type to an output type using data comprising examples that have both input and output values. Two typical examples of supervised learning are ▶ classification learning and ▶ regression. In these cases, the output types are respectively categorical (the classes) and numeric. Supervised learning stands in contrast to ▶ unsupervised learning, which seeks to learn structure in data, and to ▶ reinforcement learning in which sequential decision-making policies are learned from reward with no examples of "correct" behavior.

Abstract

Support vector machines (SVMs) are a class of linear algorithms which can be used for classification, regression, density estimation, novelty detection, etc. In the simplest case of two-class classification, SVMs find a hyperplane that separates the two classes of data with as wide a margin as possible. This leads to good generalization accuracy on unseen data and supports specialized optimization methods that allow SVM to learn from a large amount of data.

Motivation and Background

Over the past decade, maximum margin models especially SVMs have become popular in machine learning. This technique was developed in three major steps. First, assuming that the two classes of training examples can be separated by a hyperplane, Vapnik and Lerner proposed in 1963 that the optimal hyperplane is the one that separates the training examples with the widest margin. From the 1960s to 1990s, Vapnik and Chervonenkis developed the Vapnik-Chervonenkis theory, which justifies the maximum margin principle from a statistical point of view. Similar algorithms and optimization techniques were proposed by Mangasarian in (1965).

Second, Boser et al. (1992) incorporated kernel function into the maximum margin models, and their formulation is close to the currently popular form of SVMs. Before that, Wahba (1990) also discussed the use of kernels. Kernels allow SVM to implicitly construct the optimal hyperplane in the feature space, and the resulting nonlinear model is important for modeling real data.

Finally, in case the training examples are not linearly separable, Cortes and Vapnik (1995) showed that the soft margin can be applied, allowing some examples to violate the margin condition.

On the theoretical side, Shawe-Taylor et al. (1998) gave the first rigorous statistical bound on the generalization of hard-margin SVMs. Shawe-Taylor and Cristianini (2000) gave statistical bounds on the generalization of soft-margin algorithms and for the regression case.

In reality, SVMs became popular thanks to its significantly better empirical performance than the neural networks. By incorporating transform invariances, the SVMs developed at AT&T achieved the highest accuracy on the MNIST benchmark set (a handwritten digit recognition problem). Joachims (1998) also showed clear superiority of SVMs on text categorization. Afterwards, SVMs have been shown effective in many applications including computer vision, natural language, bioinformatics, finance, etc.

Theory

SVM has a stronger mathematical basis than some machine learning methods such as neural networks and is closely related to some well-established theories in statistics. As a linear model, it not only tries to correctly classify the training data but also maximizes the margin for better generalization performance. This formulation leads to a separating hyperplane that depends only on the (usually small fraction of) data points that lie on the margin, which are called support vectors. Hence the whole algorithm is called support vector machine. In addition, since real-world data analysis problems often involve nonlinear dependencies, SVMs can be easily extended to model such nonlinearity by means of positive semi-definite kernels. Moreover, SVMs can be trained via quadratic programming, which (a) makes theoretical analysis easier and (b) provides much convenience in designing efficient solvers that scale for large datasets. Finally, when applied to real-world data, SVMs often deliver state-of-the-art performance in accuracy, flexibility, robustness, and efficiency.

Optimal Hyperplane for Linearly Separable Examples

Consider the training set $\{(\mathbf{x}_i, y_i)\}_{i=1}^n$ where $\mathbf{x}_i \in \mathbb{R}^p$ is the input feature vector for the i-th example and $y_i \in \{1, -1\}$ is its corresponding label indicating whether the example is positive ($y_i = +1$) or negative ($y_i = -1$). To begin with, we assume that the set of positive and negative examples are linearly separable, i.e., there exists a function $f(\mathbf{x}) = \langle \mathbf{w}, \mathbf{x} \rangle + b$ where $\mathbf{w} \in \mathbb{R}^p$ (called the weight vector) and $b \in \mathbb{R}$ (called bias) such that

$$\langle \mathbf{w}, \mathbf{x}_i \rangle + b > 0 \quad \text{for } y_i = +1$$

$$\langle \mathbf{w}, \mathbf{x}_i \rangle + b < 0 \quad \text{for } y_i = -1.$$

We call $\langle \mathbf{w}, \mathbf{x} \rangle + b = 0$ the decision hyperplane, and in fact, there can exist multiple hyperplanes that separate the positive and negative examples; see Fig. 1. However, they are not created equal. Associated with each such hyperplane is a notion called *margin*, defined as the distance between the hyperplane and the closest example. SVM aims to find the particular hyperplane that maximizes the margin.

Mathematically, it is easy to check that the distance from a point $\mathbf{x}_i$ to a hyperplane $\langle \mathbf{w}, \mathbf{x} \rangle + b = 0$ is $\|\mathbf{w}\|^{-1} |\langle \mathbf{w}, \mathbf{x}_i \rangle + b|$. Therefore, SVM seeks for the optimal $\mathbf{w}, b$ of the following optimization problem:

$$\underset{\mathbf{w}\in\mathbb{R}^p,\, b\in\mathbb{R}}{\text{maximize}} \ \min_{1\le i\le n} \frac{|\langle \mathbf{w}, \mathbf{x}_i \rangle + b|}{\|\mathbf{w}\|}, \quad s.t. \begin{cases} \langle \mathbf{w}, \mathbf{x}_i \rangle + b > 0 \text{ if } y_i = +1 \\ \langle \mathbf{w}, \mathbf{x}_i \rangle + b < 0 \text{ if } y_i = -1 \end{cases} \quad \forall i \ .$$

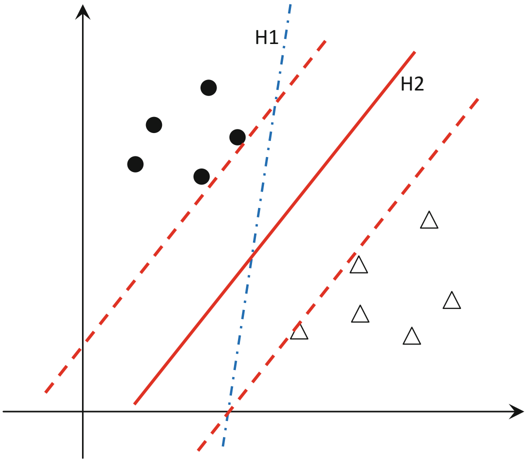
It is clear that if $(\mathbf{w}, b)$ is an optimal solution, then $(\alpha\mathbf{w}, \alpha b)$ is also an optimal solution for any $\alpha > 0$. Therefore, to fix the scale, we can equivalently set the numerator of the objective $\min_{1\le i\le n} |\langle \mathbf{w}, \mathbf{x}_i \rangle + b|$ to 1 and minimize the denominator $\|\mathbf{w}\|$:

$$\underset{\mathbf{w}\in\mathbb{R}^p,\, b\in\mathbb{R}}{\text{minimize}} \ \|\mathbf{w}\|^2, \quad s.t. \begin{cases} \langle \mathbf{w}, \mathbf{x}_i \rangle + b > 1 \quad \text{if } y_i = +1 \\ \langle \mathbf{w}, \mathbf{x}_i \rangle + b < -1 \text{ if } y_i = -1. \end{cases} \quad \forall i \ . \tag{1}$$

This is a linearly constrained quadratic program, which can be solved efficiently. Hence, it becomes the most commonly used (primal) form of SVM for the linearly separable case.

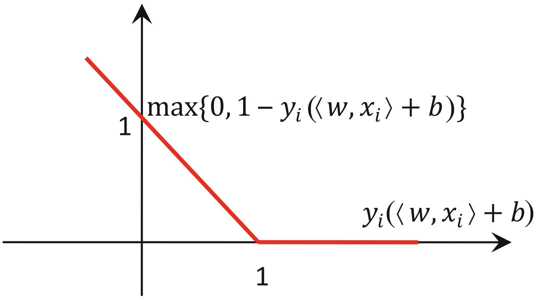
Soft Margins

In practice, most, if not all, datasets are not linearly separable, i.e., no $\mathbf{w}$ and b can satisfy the constraints of the optimization problem (1). In this case, we will allow some data points



Support Vector Machines, Fig. 1 Example of maximum margin separator. Both H1 and H2 correctly separate the examples from the two classes. But H2 has a wider margin than H1

to violate the margin condition and penalize it accordingly. Mathematically, notice that the constraints in (1) can be equivalently written as $y_i(\langle \mathbf{w}, \mathbf{x}_i \rangle + b) > 1$. Now we introduce a new set of nonnegative slack variables ξ_i into the constraints:



Support Vector Machines, Fig. 2 Graph of hinge loss

$$y_i(\langle \mathbf{w}, \mathbf{x}_i \rangle + b) > 1 - \xi_i \ ,$$

and incorporate a penalty into the original objective to derive the soft-margin SVM:

$$\underset{\mathbf{w}, b, \xi_i}{\text{minimize}} \ \lambda \|\mathbf{w}\|^2 + \frac{1}{n} \sum_{i=1}^{n} \xi_i \quad s.t. \ y_i(\langle \mathbf{w}, \mathbf{x}_i \rangle + b) > 1 - \xi_i, \text{and } \xi_i > 0 \ \ \forall i \ . \tag{2}$$

$\lambda > 0$ is a tradeoff factor. It is important to note that ξ_i can be written as $\xi_i = \max\{0, 1 - y_i(\langle \mathbf{w}, \mathbf{x}_i \rangle + b)\}$, which is called hinge loss and is depicted in Fig. 2. This way, the optimization problem can be reformulated into an unconstrained non-smooth problem:

$$\underset{\mathbf{w} \in \mathbb{R}^p, \, b \in \mathbb{R}}{\text{minimize}} \ \frac{\lambda}{2} \|\mathbf{w}\|^2 + \frac{1}{n} \sum_{i=1}^{n} \max\{0, 1 - y_i(\langle \mathbf{w}, \mathbf{x}_i \rangle + b)\} \ . \tag{3}$$

Notice that $\max\{0, 1 - y_i(\langle \mathbf{w}, \mathbf{x}_i \rangle + b)\}$ is also a convex upper bound of $\delta(y_i(\langle \mathbf{w}, \mathbf{x}_i \rangle + b) > 0)$, where $\delta(x) = 1$ if x is true and 0 otherwise. Therefore, the penalty we use is a convex upper bound of the average training error. When the training set is actually separable, the soft-margin problem (2) automatically recovers the hard-margin problem (1) when λ is sufficiently large.

Dual Forms and Kernelization

As the constraints in the primal form (2) are not convenient to handle, people have conventionally resorted to the dual problem of (2). Following the standard procedures, one can derive the Lagrangian dual

$$\frac{1}{2\lambda} \sum_{i,j} y_i y_j \alpha_i \alpha_j \langle \mathbf{x}_i, \mathbf{x}_j \rangle - \sum_i \alpha_i, \quad s.t. \ \alpha_i \in [0, n^{-1}], \ \text{and} \ \sum_i y_i \alpha_i = 0 \ . \tag{4}$$

which is again a quadratic program but with much simpler constraints: box constraints plus a single linear equality constraint. To recover the primal solution $\mathbf{w}^*$ from the dual solution α_i^*, we have

$$\mathbf{w}^* = \sum_{i=1}^{n} \alpha_i^* y_i \mathbf{x}_i \ ,$$

and the optimal bias b can be determined by using the duality conditions.

The training examples can be divided into three categories according to the value of α_i^*. If $\alpha_i^* = 0$, it means the corresponding training example does not affect the decision boundary, and in fact it lies beyond the margin, i.e., $y_i(\langle \mathbf{w}, \mathbf{x}_i \rangle + b) > 1$. If $\alpha_i^* \in (0, n^{-1})$, then the training example lies on the margin, i.e., $y_i(\langle \mathbf{w}, \mathbf{x}_i \rangle + b) = 1$. If $\alpha_i^* = n^{-1}$, it means the training example violates the margin, i.e., $y_i(\langle \mathbf{w}, \mathbf{x}_i \rangle + b) < 1$. In the latter two cases where $\alpha_i^* > 0$, the i-th training example is called a support vector.

In many applications, most α_i^* in the optimal solution are 0, which gives a sparse solution. As the final classifier depends only on those support vectors, the whole algorithm is named support vector machines.

From the dual problem (4), a key observation can be drawn that the feature of the training examples $\{\mathbf{x}_i\}$ influences training only via the inner product $\langle \mathbf{x}_i, \mathbf{x}_j \rangle$. Therefore, we can redefine the feature by mapping $\mathbf{x}_i$ to a richer feature space via $\phi(\mathbf{x}_i)$ and then compute the inner product there: $k(\mathbf{x}_i, \mathbf{x}_j) := \langle \phi(\mathbf{x}_i), \phi(\mathbf{x}_j) \rangle$. Furthermore, one can even directly define k without explicitly specifying ϕ. This allows us to (a) implicitly use a rich feature space whose dimension can be infinitely high and (b) apply SVM to non-Euclidean spaces as long as a kernel $k(\mathbf{x}_i, \mathbf{x}_j)$ can be defined on it. Examples include strings and graphs (Haussler 1999), which have been widely applied in bioinformatics (Schölkopf et al. 2004). Mathematically, the objective (4) can be kernelized into

$$\frac{1}{2\lambda} \sum_{i,j} y_i y_j \alpha_i \alpha_j k(\mathbf{x}_i, \mathbf{x}_j) - \sum_i \alpha_i, \quad s.t.\ \alpha_i \in [0, n^{-1}], \text{ and } \sum_i y_i \alpha_i = 0 \ . \tag{5}$$

However, now the $\mathbf{w}$ cannot be expressed just in terms of kernels because $\mathbf{w}^* = \sum_{i=1}^{n} \alpha_i^* y_i \phi(\mathbf{x}_i)$. Fortunately, when predicting on a new example $\mathbf{x}$, we again only require the inner product and hence use kernel only:

$$\begin{aligned} \langle \mathbf{w}^*, \mathbf{x} \rangle &= \sum_{i=1}^{n} \alpha_i^* y_i \langle \phi(\mathbf{x}_i), \phi(\mathbf{x}) \rangle \\ &= \sum_{i=1}^{n} \alpha_i^* y_i k(\mathbf{x}_i, \mathbf{x}) \ . \end{aligned}$$

Commonly used kernels on $\mathbb{R}^n$ include polynomial kernels $(1 + \langle \mathbf{x}_i, \mathbf{x}_j \rangle)^d$, Gaussian RBF kernels $\exp(-\gamma \left\| \mathbf{x}_i - \mathbf{x}_j \right\|^2)$, Laplace RBF kernels $\exp(-\gamma \left\| \mathbf{x}_i - \mathbf{x}_j \right\|)$, etc. Kernels on strings and trees are usually based on convolution which requires involved algorithms for efficient evaluation (Haussler 1999; Borgwardt 2007). More details can be found in the kernel section.

Optimization Techniques and Toolkits

The main challenge of optimization lies in scaling for large datasets, i.e., n and p are large. Decomposition methods based on the dual problem is the first popularly used method for solving large-scale SVMs. For example, sequential minimal optimization (SMO) optimizes two dual variables α_i, α_j analytically in each iteration (Platt 1999a). An SMO-type implementation is available in the LibSVM package http://www.csie.ntu.edu.tw/~cjlin/libsvm. Another popular package using decomposition methods is the SVM-light, available at http://svmlight.joachims.org. Coordinate descent in the dual is also effective and converges at linear rate. An implementation can be downloaded from http://www.csie.ntu.edu.tw/~cjlin/liblinear.

Primal methods are also popular, most of which are based on formulating the objective as a non-smooth objective function like (3). An important type is the subgradient descent method, which is similar to gradient descent but uses a subgradient due to the non-smooth objective. When the dataset is large, one can further use a random subset of training examples to efficiently compute the (approximate) subgradient, and algorithms exist that guarantee the convergence in probability. This is called stochastic subgradient descent, and in practice, it can often quickly find a reasonably good solution. A package that implements this idea can be found at http://leon.bottou.org/projects/sgd.

Finally, cutting plane and bundle methods are also effective (Tsochantaridis et al. 2005; Smola et al. 2007), and they are especially useful for generalized SVMs with structured outputs. An implementation is the bundle method for risk minimization (BMRM), available for download at http://users.rsise.anu.edu.au/~chteo/BMRM.html.

Applications

The above description of SVM focused on binary class classification. In fact, SVMs, or the ideas of maximum margin and kernel, have been widely used in many other learning problems such as regression, ranking and ordinal regression, density estimation, novelty detection, quantile regression, etc. Even in classification, SVM has been extended to the case of multi-class, multi-label, and structured output (Tsochantaridis et al. 2005; Taskar 2004).

For multi-class classification and structured output classification where the possible label set $\mathcal{Y}$ can be large, maximum margin machines can be formulated by introducing a joint feature map ϕ on pairs of (x_i, y) $(y \in \mathcal{Y})$. Letting $\Delta(y_i, y)$ be the discrepancy between the true label y_i and the candidate label y, the primal form can be written as

$$\underset{w,\xi_i}{\text{minimize}} \frac{\lambda}{2}\|w\|^2 + \frac{1}{n}\sum_{i=1}^{n}\xi_i, \quad s.t.\ \langle w, \phi(x_i, y_i) - \phi(x_i, y)\rangle \geq \Delta(y_i, y) - \xi_i,\ \forall\, i, y,$$

and the dual form is

$$\underset{\alpha_{i,y}}{\text{minimize}} \frac{1}{2\lambda} \sum_{(i,y),(i',y')} \alpha_{i,y}\alpha_{i',y'} \left\langle \phi(x_i, y_i) - \phi(x_i, y), \phi(x_{i'}, y_{i'}) - \phi(x_{i'}, y')\right\rangle - \sum_{i,y} \Delta(y_i, y)\alpha_{i,y}$$

$$s.t. \quad \alpha_{i,y} \geq 0,\ \forall\, i, y; \quad \sum_{y} \alpha_{i,y} = \frac{1}{n},\ \forall i.$$

Again kernelization is convenient, by simply replacing all the inner products $\langle \phi(x_i, y), \phi(x_{i'}, y')\rangle$ with a joint kernel $k((x_i, y), (x_{i'}, y'))$. Further factorization using graphical models is possible; see (Taskar 2004). Notice when $\mathcal{Y} = \{1, -1\}$, setting $\phi(x_i, y) = y\phi(x_i)$ recovers the binary SVM formulation. Effective methods to optimize the dual objective include SMO, exponentiated gradient descent, mirror descent, cutting plane, or bundle methods.

In general, SVMs are not trained to output the odds of class membership, although the posterior probability is desired to enable post-processing. Platt (1999b) proposed training an SVM and then training the parameters of an additional sigmoid function to map the SVM outputs into probabilities. A more principled approach is the relevance vector machine, which has an identical functional form to the SVMs and uses Bayesian inference to obtain sparse solutions for probabilistic classification.

As mentioned above, the hinge loss used in SVM is essentially a convex surrogate of the misclassification loss, i.e., 1 if the current weight **w** misclassifies the training example and 0 otherwise. Minimizing the misclassification loss is proved NP-hard, so for computational convenience, continuous convex surrogates are used, including hinge loss, exponential loss, and logistic loss. Their statistical properties are studied by Jordan et al. (2003). For hinge loss, it has the significant merit of sparsity in the dual, which leads to robustness and good generalization performance.

SVMs have been widely applied in real-world problems. In history, its first practical success was gained in handwritten digit recognition. By incorporating transform invariances, the SVMs developed at AT&T achieved the highest accuracy on the MNIST benchmark set. It has also been very effective in computer vision applications such as object recognition and detection. With the special advantage in handling high-dimensional data, SVMs have witnessed wide application in bioinformatics such as microarray processing (Schölkopf et al. 2004) and natural language processing like named entity recognition, part-of-speech tagging, parsing, and chunking (Taskar 2004; Joachims 1998).

Swarm Intelligence

Swarm intelligence is the discipline that studies the collective behavior of systems composed of many individuals that interact locally with each other and with their environment and that rely on forms of decentralized control and self-organization. Examples of such systems are colonies of ants and termites, schools of fish, flocks of birds, herds of land animals, and also some artifacts, including swarm robotic systems and some computer programs for tackling optimization problems such as ▶ ant colony optimization and ▶ particle swarm optimization.

Symbolic Dynamic Programming

Synonyms

Dynamic programming for relational domains; Relational dynamic programming; Relational value iteration; SDP

Definition

Symbolic dynamic programming (SDP) is a generalization of the ▶ dynamic programming technique for solving ▶ Markov decision processes (MDPs) that exploits the symbolic structure in the solution of relational and first-order logical MDPs through a lifted version of dynamic programming.

Motivation and Background

Decision-theoretic planning aims at constructing a policy for acting in an uncertain environment that maximizes an agent's expected utility along a sequence of steps. For this task, Markov decision processes (MDPs) have become the standard model. However, classical dynamic programming algorithms for solving MDPs require explicit state and action enumeration, which is often impractical: the number of states and actions grows very quickly with the number of domain objects and relations. In contrast, SDP algorithms seek to avoid explicit state and action enumeration through the symbolic representation of an MDP and a corresponding symbolic derivation of its solution, such as a value function. In essence, SDP algorithms exploit the symbolic structure of the MDP representation to construct a minimal logical partition of the state space required to make all necessary value distinctions.

Theory and Solution

Consider an agent acting in a simple variant of the BoxWorld problem. There are several cities such as *London*, *Paris* etc., trucks $truck_1$, $truck_2$ etc., and boxes box_1, box_2 etc. The agent can load a box onto a truck or unload it and can drive a truck from one city to another. Only when a particular box, say box box_1, is in a particular city, say *Paris*, the agent receives a positive reward. The agent's learning task is now to find a policy for action selection that maximizes its reward over the long term.

A great variety of techniques for solving such decision-theoretic planning tasks have been developed over the last decades. Most of them assume atomic representations, which essentially

- *Domain Object Types (i.e., sorts)*: $Box, Truck, City = \{paris, \ldots\}$
- *Relations (with parameter sorts)*:
  $BoxIn(Box, City), TruckIn(Truck, City), BoxOn(Box, Truck)$
- *Reward*: if $\exists b.BoxIn(b, paris)$ 10 else 0
- *Actions (with parameter sorts)*:
  - $load(Box : b, Truck : t, City : c)$:
    - Success Probability: if $(BoxIn(b, c) \wedge TruckIn(t, c))$ then .9 else 0
    - Add Effects on Success: $\{BoxOn(b, t)\}$
    - Delete Effects on Success: $\{BoxIn(b, c)\}$
  - $unload(Box : b, Truck : t, City : c)$:
    - Success Probability: if $(BoxOn(b, t) \wedge TruckIn(t, c))$ then .9 else 0
    - Add Effects on Success: $\{BoxIn(b, c)\}$
    - Delete Effects on Success: $\{BoxOn(b, t)\}$
  - $drive(Truck : t, City : c_1, City : c_2)$:
    - Success Probability: if $(TruckIn(t, c_1))$ then 1 else 0
    - Add Effects on Success: $\{TruckIn(t, c_2)\}$
    - Delete Effects on Success: $\{TruckIn(t, c_1)\}$
  - *noop*
    - Success Probability: 1
    - Add Effects on Success: $\emptyset$
    - Delete Effects on Success: $\emptyset$

Symbolic Dynamic Programming, Fig. 1 A formal description of the BoxWorld adapted from Boutilier et al. (2001). We use a simple STRIPS (Fikes and Nilsson 1971) add and delete list representation of actions and, as a simple probabilistic extension in the spirit of PSTRIPS (Kushmerick et al. 1995), we assign probabilities that an action successfully executes conditioned on various state properties

amounts to enumerating all unique configurations of trucks, cities, and boxes. It might then be possible to learn, for example, that taking action *action234* in state *state42* is worth 6. 2 and leads to state *state654321*. Atomic representations are simple, and learning can be implemented using simple lookup tables. These lookup tables, however, can be intractably large as atomic representations easily explode. Furthermore, they do not easily generalize across different numbers of domain objects (We use the term *domain* in the first-order logical sense of an object universe. The term should not be confused with a planning *problem* such as BoxWorld or BlocksWorld.).

In contrast, SDP assumes a relational or first-order logical representation of an MDP (as given in Fig. 1) to exploit the existence of domain objects, relations over these objects, and the ability to express objectives and action effects using quantification.

It is then possible to learn that to get box b to *paris*, the agent drives a truck to the city of b, loads box_1 on the truck, drives the truck to *Paris*, and finally unloads the box box_1 in *Paris*. This is essentially encoded in the symbolic value function shown in Fig. 2, which was computed by discounting rewards t time steps into the future by 0. 9t. The key features to note here are the state and action abstraction in the value and policy representation that are afforded by the first-order specification and solution of the problem. That is, this solution does not refer to any specific set of domain objects, such as $City = \{paris, berlin, london\}$, but rather it provides a solution for *all possible domain ob-*

else do *noop* (value = 0.0)

Symbolic Dynamic Programming, Fig. 2 A decision-list representation of the optimal policy and expected discounted reward value for the BoxWorld problem

ject instantiations. And while classical dynamic programming techniques could never solve these problems for large domain instantiations (since they would have to enumerate all states and actions), a domain-independent SDP solution to this particular problem is quite simple due to the power of state and action abstraction.

Background: Markov Decision Processes (MDPs)

In the MDP (Puterman 1994) model, an agent is assumed to fully observe the current state and choose an action to execute from that state. Based on that state and action, nature then chooses a next state according to some fixed probability distribution. In an infinite-horizon MDP, this process repeats itself indefinitely. Assuming there is a reward associated with each state and action, the goal of the agent is to maximize the expected sum of discounted rewards received over an infinite horizon (Although we do not discuss it here, there are other alternatives to discounting such as averaging the reward received over an infinite horizon.). This criterion assumes that a reward received t steps in the future is discounted by γ^t, where γ is a discount factor satisfying $0 \leq \gamma < 1$. The goal of the agent is to choose its actions in order to maximize the expected, discounted future reward in this model.

Formally, a finite state and action MDP is a tuple: $\langle S, A, T, R \rangle$, where S is a finite state space, A is a finite set of actions, T is a transition function: $T : S \times A \times S \rightarrow [0, 1]$, where $T(s, a, \cdot)$ is a probability distribution over S for any $s \in S$ and $a \in A$, and R is a bounded reward function $R : S \times A \rightarrow \mathbb{R}$.

As stated earlier, our goal is to find a policy that maximizes the infinite horizon, discounted reward criterion: $E_\pi[\sum_{t=0}^{\infty} \gamma^t \cdot r_t | s_0]$, where r_t is a reward obtained at time t, γ is a discount factor as defined earlier, π is the policy being executed, and s_0 is the initial starting state. Based on this reward criterion, we define the value function for a policy π as the following:

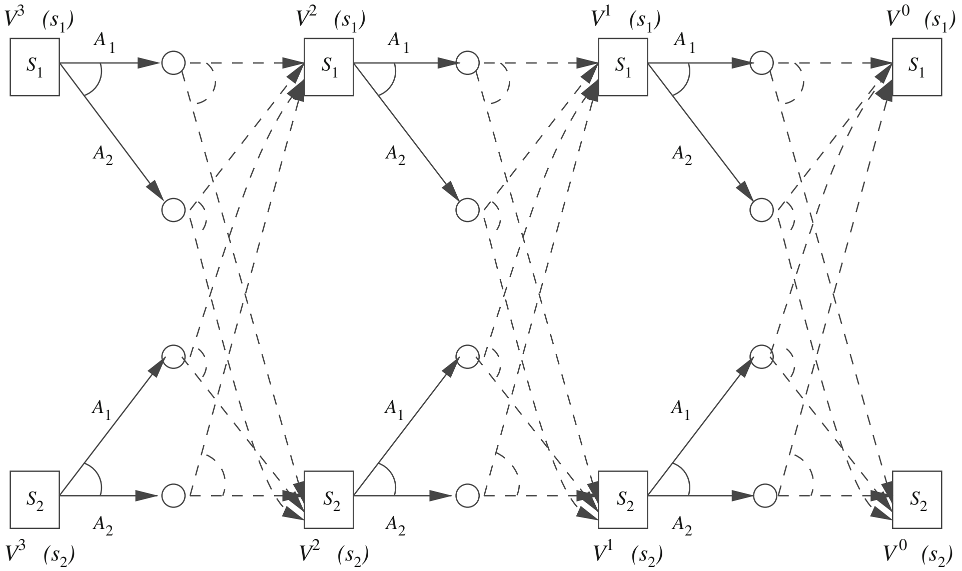
$$V_\pi(s) = E_\pi\left[\sum_{t=0}^{\infty} \gamma^t \cdot r_t | s_0 = s\right] \qquad (1)$$

Intuitively, the value function for a policy π is the expected sum of discounted rewards accumulated while executing that policy when starting from state s.

For the MDP model discussed here, the optimal policy can be shown to be stationary (Puterman 1994). Consequently, we use a stationary policy representation of the form $\pi : S \rightarrow A$, with $\pi(s)$ denoting the action to be executed in state s. An optimal policy π^* is the policy that maximizes the value function for all states. We denote the optimal value function over an indefinite horizon as $V^*(s)$ and note that it satisfies the following equality:

$$V^*(s) = \max_{a \in A}\Big\{R(s,a) + \gamma \sum_{s' \in s} T(s,a,s') \cdot V^*(s')\Big\} \qquad (2)$$

Bellman's *principle of optimality* (Bellman 1957) establishes the following relationship between



Symbolic Dynamic Programming, Fig. 3 A diagram demonstrating a *dynamic programming* regression-based evaluation of the MDP value function. *Dashed lines* are used in the expectation computation of the Q-function: for each action, take the expectation over the values of possible successor states. *Solid lines* are used in the max computation: determine the highest valued action to be taken in each state

the optimal value function $V^t(s)$ with a finite horizon of t steps remaining and the optimal value function $V^{t-1}(s)$ with a finite horizon of $t-1$ steps remaining:

$$V^t(s) = \max_{a \in A}\Big\{R(s,a) + \gamma \sum_{s' \in S} T(s,a,s') \cdot V^{t-1}(s')\Big\} \qquad (3)$$

A *dynamic programming* approach for computing the optimal value function over an indefinite horizon is known as value iteration and directly implements (3) to compute 1 by successive approximation. As sketched in Fig. 3, we start with arbitrary $V^0(s)$ (e.g., $\forall s V^0(s) = 0$) and perform the Bellman backup given in (3) for each state $V^1(s)$ using the value of $V^0(s)$. We repeat this process for each t to compute $V^t(s)$ from the memorized values for $V^{t-1}(s)$ until we have computed the intended t-stages-to-go value function. $V^t(s)$ will converge to $V^*(s)$ as $t \to \infty$ (Puterman 1994).

Often, the Bellman backup is rewritten in two steps to separate out the action regression and maximization steps. In this case, we first compute the t-stages-to-go Q-function for every action and state:

$$Q^t(s,a) = R(s,a) + \gamma \cdot \sum_{s' \in S} T(s,a,s') \cdot V^{t-1}(s') \qquad (4)$$

Then we maximize over each action to determine the value of the regressed state:

$$V^t(s) = \max_{a \in A}\{Q^t(s,a)\} \qquad (5)$$

This is clearly equivalent to (3) but is in a form that we refer to later, since it separates the algorithm into its two conceptual components: decision-theoretic regression and maximization.

First-Order Markov Decision Processes

A first-order MDP (FOMDP) can be thought of as a universal MDP that abstractly defines the state, action, transition, and reward tuple $\langle S, A, T, R\rangle$ for an infinite number of ground MDPs. To make this idea more concrete, consider the BoxWorld problem defined earlier. While we have not yet formalized the details of the FOMDP representation, it should be clear that the BoxWorld dynamics hold for any instantiation of the domain objects: *Box*, *Truck*, and *City*. For instance, assume that the domain instantiation consists of two boxes $Box = \{box_1, box_2\}$, two trucks $Truck = \{truck_1, truck_2\}$ and two cities $City = \{paris, berlin\}$. Then the resulting ground MDP has 12 state-variable atoms (each atom being *true* or *false* in a state), four atoms for *BoxIn* such as $BoxIn(box_1, paris)$, $BoxIn(box_2, paris)$, ..., four atoms for *TruckIn* such as $TruckIn(truck_2, paris)$, ...and four atoms for *BoxOn* such as $BoxOn(box_2, truck_1)$, ... There are also 24 possible actions (eight for each of *load*,*unload*, and *drive*) such as $load(box_1, truck_1, paris)$, $load(box_1, truck_1, berlin)$, $drive(truck_2, paris, paris)$, $drive(truck_2, paris, berlin)$, etc., where the transition function directly follows from the ground instantions of the corresponding PSTRIPS operators. The reward function looks like: if $(BoxIn(box_1, paris) \vee BoxIn(box\,_2, paris))$ 10 else 0.

Therefore, to solve an FOMDP, we could ground it for a specific domain instantiation to obtain a corresponding ground MDP. Then we could apply classical MDP solution techniques to solve this ground MDP. However, the obvious drawback to this approach is that the number of state variables and actions in the ground MDP grow at least linearly as the domain size increases. And even if the ground MDP could be represented within memory constraints, the number of distinct ground states grows exponentially with the number of state variables, thus rendering solutions that scale with state size intractable even for moderately small numbers of domain objects.

An alternative idea to solving an FOMDP at the ground level is to solve the FOMDP directly at the first-order level using symbolic dynamic programming, thereby obtaining a solution that applies universally to all possible domain instantiations. While the exact representation and SDP solution of FOMDPs differ among the variant formalisms, they all share the same basic first-order representation of rewards, probabilities, and values that we outline next. To highlight this, we introduce a graphical *case notation* to allow first-order specifications of the rewards, probabilities, and values required for FOMDPs:

$$case = \begin{array}{|l|}\hline \phi_1 \ : t_1 \\ \hline : \quad : : \\ \hline \phi_n \ : t_n \\ \hline \end{array}$$

Here the φ_i are *state formulae* and the t_i are terms. Often the t_i are constants and the φ_i partition state space. To make this concrete, we represent our BoxWorld FOMDP reward function as the following *rCase* statement:

$$rCase \ = \begin{array}{|l|}\hline \exists b.BoxIn(b, paris) : 10 \\ \hline \neg\exists b.BoxIn(b, paris) : 0 \\ \hline \end{array}$$

Here we see that the first-order formulae in the case statement divide all possible ground states into two regions of constant value: when there exists a box in Paris, a reward of 10 is achieved, otherwise a reward of 0 is achieved. Likewise, the value function *case* that we derive through SDP can be represented in exactly the same manner. Indeed, as we will see shortly, $case^0 = rCase$ in the first-order version of value iteration.

To state the FOMDP transition function for an action, we decompose stochastic "agent" actions into a *collection* of deterministic actions, each corresponding to a possible outcome of the stochastic action. We then specify a distribution according to which "nature" may choose a deterministic action from this set whenever the stochastic action is executed.

Letting $A(\vec{x})$ be a stochastic action with nature's choices (i.e., deterministic actions) $n_1(\vec{x}), \ldots n_k(\vec{x})$, we represent the distribution over $n_i(\vec{x})$ given $A(\vec{x})$ using the notation $pCase(n_j(\vec{x}), A(\vec{x}))$. Continuing our logistics example, if the success of driving a truck depends on whether the destination city is *paris* (perhaps due to known traffic delays), then we decompose the stochastic *drive* action into two deterministic actions *driveS* and *driveF*, respectively denoting success and failure. Then we can specify a distribution over nature's choice deterministic outcome for this stochastic action:

$$pCase(driveS(t,c_1,c_2)), drive(t,c_1,c_2)) = \begin{array}{|l|}\hline c_2 = paris : 0.6 \\ \hline c_2 \neq paris : 0.9 \\ \hline \end{array}$$

$$pCase(driveF(t,c_1,c_2)), drive(t,c_1,c_2)) = \begin{array}{|l|}\hline c_2 = paris : 0.4 \\ \hline c_2 \neq paris : 0.1 \\ \hline \end{array}$$

Intuitively, to perform an operation on case statements, we simply perform the corresponding operation on the intersection of all case partitions of the operands. Letting each φ_i and ψ_j denote generic first-order formula, we can perform the "cross-sum" $\oplus$ of case statements in the following manner:

$$\begin{array}{|l|}\hline \phi_1 : 10 \\ \hline \phi_2 : 20 \\ \hline \end{array} \oplus \begin{array}{|l|}\hline \psi_1 : 1 \\ \hline \psi_2 : 2 \\ \hline \end{array} = \begin{array}{|l|}\hline \phi_1 \wedge \psi_1 : 11 \\ \hline \phi_1 \wedge \psi_2 : 12 \\ \hline \phi_2 \wedge \psi_1 : 21 \\ \hline \phi_2 \wedge \psi_2 : 22 \\ \hline \end{array}$$

Likewise, we can perform $\ominus$, $\otimes$, and max operations by respectively subtracting, multiplying, or taking the max of partition values (as opposed to adding them) to obtain the result. Some partitions resulting from the application of the $\oplus$, $\ominus$, and $\otimes$ operators may be inconsistent; we simply discard such partitions (since they can obviously never correspond to any world state).

We define another operation on case statements max $\exists\vec{x}$ that is crucial for SDP. Intuitively, the meaning of max $\exists\vec{x}$ $case(\vec{x})$ is a case statement where the maximal value is assigned to each region of state space where there exists a satisfying instantiation of $\vec{x}$. To make these ideas concrete, following is an exposition of how the max $\exists\vec{x}$ may be explicitly computed:

$$\max \exists\vec{x} \begin{array}{|l|}\hline \psi_1(\vec{x}) : 1 \\ \hline \psi_2(\vec{x}) : 2 \\ \hline \psi_3(\vec{x}) : 3 \\ \hline \end{array}$$

$$= \begin{array}{|ll|}\hline \exists\vec{x}\psi_3(\vec{x}) & : 3 \\ \hline \neg(\exists\vec{x}\psi_3(\vec{x})) \wedge \exists\vec{x}\psi_2(\vec{x}) & : 2 \\ \hline \neg(\exists\vec{x}\psi_3(\vec{x})) \wedge \neg(\exists\vec{x}\psi_2(\vec{x})) \wedge \exists\vec{x}\psi_1(\vec{x}) & : 1 \\ \hline \end{array}$$

Here we have simply sorted partitions in order of values and have ensured that the highest value is assigned to partitions in which there exists a satisfying instantiation of $\vec{x}$ by rendering lower value partitions disjoint from their higher-value antecedents.

Symbolic Dynamic Programming

SDP is a dynamic programming solution to FOMDPs that produces a logical case description of the optimal value function. This is achieved through the operations of first-order decision-theoretic regression (FODTR) and symbolic maximization that perform the traditional dynamic programming Bellman backup at an abstract level without explicit enumeration of either the state or action spaces of the FOMDP. Among many uses, the application of SDP leads to a domain-independent value iteration solution to FOMDPs.

Suppose that we are given a value function in the form *case*. The FODTR (Boutilier et al. 2001) of this value function through an action $A(\vec{x})$ yields a case statement containing the logical description of states and values that would give rise to *case* after doing action $A(\vec{x})$. This is analogous to classical goal regression, the key difference being that action $A(\vec{x})$ is stochastic. In MDP terms, the result of FODTR is a case statement representing a Q-function.

We define the *FODTR* operator in the following manner:

$$FODTR[vcase, A(\vec{x})] = rcase \oplus \gamma[\oplus_j\{pCase(n_j(\vec{x})) \otimes \; Regr[vcase, A(\vec{x})]\}] \quad (6)$$

Note that we have not yet defined the regression operator $Regr[vcase, A(\vec{x})]$. As it turns out, the implementation of this operator is specific to a given FOMDP language and SDP implementation. We simply remark that the regression of a formula ψ through an action $A(\vec{x})$ is a formula ψ' that holds prior to $A(\vec{x})$ being performed iff ψ holds after $A(\vec{x})$. However, regression is a deterministic operator and thus FODTR takes the expectation of the regression over all possible outcomes of a stochastic action according to their respective probabilities.

It is important to note that the case statement resulting from FODTR contains free variables for the action parameters $\vec{x}$. That is, for any constant binding $\vec{c}$ of these action parameters such that $\vec{x} = \vec{c}$, the case statement specifies a well-defined logical description of the value that can be obtained by taking action $A(\vec{c})$ and following a policy so as to obtain the value given by *v*{ *case* thereafter. However, what we really need for symbolic dynamic programming is a logical description of a Q-function that tells us the highest value that can be achieved for *any* action instantiation. This leads us to the following $qCase(A(\vec{x}))$ definition of a first-order Q-function that makes use of the previously defined $\exists\vec{x}$ operator:

$$qCase^t(A(\vec{x})) \\ = \max \exists\vec{x}.FODTR[vcase^{t-1}, A(\vec{x})] \quad (7)$$

Intuitively, $qCase^t(A(\vec{x}))$ is a logical description of the Q-function for action $A(\vec{x})$ indicating the best value that could be achieved by *any* instantiation of $A(\vec{x})$. And by using the case representation and action quantification in the $\max \exists\vec{x}$ operation, FODTR effectively achieves *both* action and state abstraction.

At this point, we can regress the value function through a *single* action, but to complete the dynamic programming step, we need to know the maximum value that can be achieved by *any* action (e.g., in the BoxWorld FOMDP, our possible action choices are *unload*(b, t, c), *load*(b, t, c), and *drive*(t, c_1, c_2)). Fortunately, this turns out to be quite easy. Assuming we have m actions $\{A_1(\vec{x}_1), \ldots, A_m(\vec{x}_m)\}$, we can complete the SDP step in the following manner using the previously defined max operator:

$$vcase^t = \max_{a \in \{A_1(\vec{x}_1),\ldots,A_m(\vec{x}_m)\}} qCase^t(a) \quad (8)$$

While the details of SDP may seem very abstract at the moment, there are several examples for specific FOMDP languages that implement SDP as described earlier, for which we provide references next. Nonetheless, one should note that the SDP equations given here are exactly the “lifted” versions of the traditional dynamic programming solution to MDPs given previously in (4) and (5). The reader may verify — on a conceptual level — that applying SDP to the 0-stages-to-go value function (i.e., *case*^{0} = *rCase*, given previously) yields the following 1- and 2-stages-to-go value functions in the BoxWorld domain (¬ “indicating the conjunction of the negation of all higher value partitions):

$$case^t = \begin{array}{|lr|}\hline \exists b.BoxIn(b, paris) : & 19.0 \\ \hline \neg\text{“} \wedge \exists b,t.TruckIn(t, paris) \wedge BoxOn(b,t) : & 9.0 \\ \hline \neg'' : & 0.0 \\ \hline \end{array}$$

$$case^2 = \begin{array}{|lr|}\hline \exists b.BoxIn(b, paris) : & 27.1 \\ \hline \neg\text{“} \wedge \exists b,t.TruckIn(t, paris) \wedge BoxOn(b,t) : & 17.1 \\ \hline \neg\text{“} \wedge \exists b,c.BoxOn(b,t) \wedge TruckIn(t,c) : & 8.1 \\ \hline \neg'' : & 0.0 \\ \hline \end{array}$$

After sufficient iterations of SDP, the t-stages-to-go value function converges, giving the optimal value function (and corresponding policy) from Fig. 2.

Applications

Variants of SDP have been successfully applied in decision-theoretic planning domains such as BLOCKSWORLD, BOXWORLD, ZENOWORLD, ELEVATORS, DRIVE, PITCHCATCH, and SCHEDULE. The first-order approximate linear programming (FOALP) system (Sanner and Boutilier 2005) was runner-up at the probabilistic track of the 5th International Planning Competition (IPC-6). Related techniques have been used to solve path planning problems within robotics and instances of real-time strategy games, Tetris, and Digger.

Future Directions

The original *SDP* (Boutilier et al. 2001) approach is a value iteration algorithm for solving FOMDPs based on Reiter's situations calculus. Since then, a variety of exact algorithms have been introduced to solve MDPs with relational (RMDP) and first-order (FOMDP) structure (We use the term *relational MDP* to refer to models that allow implicit existential quantification, and *FOMDP* for those with explicit existential and universal quantification.). *First-order value iteration (FOVIA)* (Hölldobler and Skvortsova 2004; Karabaev and Skvortsova 2005) and the *relational Bellman algorithm (ReBel)* (Kersting et al. 2004) are value iteration algorithms for solving RMDPs. In addition, *first-order decision diagrams (FODDs)* have been introduced to compactly represent case statements and to permit efficient application of SDP operations to solve RMDPs via value iteration (Wang et al. 2007) and policy iteration (Wang and Khardon 2007). All of these algorithms have some form of guarantee on convergence to the (ε-)optimal value function or policy. The expressiveness of FOMDPs has been extended to support indefinitely factored reward and transition functions in FOMDPs (Sanner and Boutilier 2007).

A class of linear-value approximation algorithms have been introduced to approximate the value function as a linear combination of weighted basis functions. FOALP (Sanner and Boutilier 2005) directly approximates the FOMDP value function using a linear program. *First-order approximate policy iteration (FOAPI)* (Sanner and Boutilier 2006) approximately solves for the FOMDP value function by iterating between policy and value updates in a policy-iteration style algorithm. Somewhat weak error bounds can be derived for a value function approximated via FOALP (Sanner and Boutilier 2005) while generally stronger bounds can be derived from the FOAPI solution (Sanner and Boutilier 2006).

Finally, there are a number of heuristic solutions to FOMDPs and RMDPs. *Approximate policy iteration* (Fern et al. 2003) induces rule-based policies from sampled experience in small-domain instantiations of RMDPs and generalizes these policies to larger domains. In a similar vein, *inductive policy selection using first-order regression* (Gretton and Thiebaux 2004) uses the action regression operator in the situation calculus to provide the first-order hypothesis space for an inductive policy learning algorithm. *Approximate linear programming (for RMDPs)* (Guestrin et al. 2003) is an approximation technique using linear program optimization to find a best-fit value function over a number of sampled RMDP domain instantiations.

Symmetrization Lemma

Synonyms

Basic lemma

Definition

Given a distribution P over a sample space $\mathcal{Z}$, a finite sample $\mathbf{z} = (z_1, \ldots, z_n)$ drawn i.i.d. from P and a function $f : \mathcal{Z} \to \mathbb{R}$ we define the shorthand $\mathbb{E}_P f = \mathbb{E}_P[f(z)]$ and $\mathbb{E}_{\mathbf{z}} f = \frac{1}{n} \sum_{i-1}^{n} f(z_i)$ to denote the true and empirical average of f. The symmetrization lemma is an important result in the learning theory as it allows the true average $\mathbb{E}_P f$ found in ▸ generalization bounds to be replaced by a second empirical average $\mathbb{E}_{\mathbf{z}'} f$ taken over an independent *ghost sample* $\mathbf{z}' = z'_1, \ldots z'_n$ drawn i.i.d. from P. Specifically, the symmetrization lemma states that for any $\epsilon > 0$ whenever $n\epsilon^2 \geq 2$

$$P^n \left(\sup_{f \in \mathbb{F}} |\mathbb{E}_P f - \mathbb{E}_{\mathbf{z}} f| > \epsilon \right) \leq 2P^{2n} \left(\sup_{f \in \mathbb{F}} |\mathbb{E}_{\mathbf{z}'} f - \mathbb{E}_{\mathbf{z}} f| > \frac{\epsilon}{2} \right). \quad (1)$$

This means the typically difficult to analyze behavior of $\mathbb{E}_P f$ – which involves the entire sample space $\mathcal{Z}$ – can be replaced by the evaluation of functions from $\mathbb{F}$ over the points in $\mathbf{z}$ and $\mathbf{z}'$.

Abstract

Tables appear in text documents in almost every form imaginable, from simple lists to nested, hierarchical, and multidimensional layouts. They are primarily designed for human consumption and therefore can require a wide variety of visual cues and interpretive capabilities to be fully understood. This chapter deals with the challenges machines face when attempting to process and understand tables, along with state-of-the-art methods and performance on this task.

Table extraction; Table parsing; Table understanding

Definition

The objective of table extraction is to convert human-focused notation, to a logical, machine-readable, and machine-understandable form. This task is closely related to and could be viewed as a subproblem of document structure extraction. It is generally considered a higher level natural language processing problem, requiring a pipeline of capabilities to address.

Motivation and Background

Tables appear in text documents in almost every form imaginable, from simple lists to nested, hierarchical, and multidimensional layouts. They are primarily designed for human consumption and therefore can require a wide variety of visual cues and interpretive capabilities to be fully understood. In fact, the assumption of human consumption allows for a breadth of content presentation that is practically limitless. Often, critical information that is relevant to the interpretation is assumed, provided in short-hand notation, or inferred from other aspects of the content or layout.

Given that the problem of table extraction is motivated by the presence of electronic documents, it has only been formally studied since the early 1990s, as the prevalence of computer-based document storage, editing, and retrieval increased (Laurentini et al. 1992; Guthrie et al. 1993). With hundreds of document formats,

C. Sammut, G.I. Webb (eds.), *Encyclopedia of Machine Learning and Data Mining*,
DOI 10.1007/978-1-4899-7687-1

layout preferences, and established customs for data interchange, the problem has only become worse at web-scale, with very few document originators choosing machine-readable syntax over visual layouts (i.e., drawing).

This article explores the genesis of the problem domain, how to formalize and break down the various tasks involved in building a table extraction solution, and the methodologies generally used.

There have been several attempts at formalizing the table model and notation. Some of these were designed independently of automatic table extraction research (Association of American Publishers 1986) and pertain to the best practices for tabular data design. Computationally driven table models generally refer to the widely used Augmented Wang Notation (Wang 1996) which specifies a hierarchical schema for describing types, classes, and relations among cells. Common table models are necessary for the interoperation of different stages of the extraction pipeline as well as the common evaluation of different approaches with the same gold standard reference data (Govindaraju et al. 2013). As in most machine learning pipelines, it is often convenient to isolate component parts for algorithmic development and testing.

Approaches to evaluation of table extraction techniques vary widely, and can be looked at from multiple perspectives document level, table level, access level, and cell level. Each stage of the extraction pipeline can be evaluated separately, or one can look at the overall goal achievement measures. Vanessa Long (2010) adopts a multilevel structural evaluation approach which can be particularly informative.

Recent work is part of a more sparse literature, with consistently decreased focus since the early 2000s. In spite of this, table extraction is not a problem that has any broadly adopted solution. It is a fragmented environment and often viewed as a practitioner's problem as part of larger systems. However, certain industries (e.g., finance) and the rise of web-scale information extraction have led to a renewed focus on these technologies in a research and applied setting (Mitchell et al. 2015).

Structure of the Learning System

We will consider each of the logical steps that form part of a complete table extraction system. Hurst (2000) and Fang et al. (2012) both propose pipelines that allow for the evaluation of discrete capabilities. Starting from a raw text document, each subsequent pass adds more and more structure, getting us closer to the final goal – a disambiguated relational table object. Approaches at each stage can consider not only textual features but also layout and other visual cues. In fact, it is often the case that table extraction techniques on text documents will use a variety of methodologies from the computer vision community.

Table Detection

Given a text document, the objective is to identify whether or not it contains a table object. It should be possible to signal when a document contains multiple such distinct objects and their rough contiguous location (Kornfeld and Wattecamps 1998). Often, this step is combined with the next (boundary detection) to perform joint detection and delineation of tabular areas.

In the case where detection is performed in isolation, it may be viewed as a binary classification, sequence labeling, or clustering task over the document. Lopresti et al. (2000) approached this problem from a text density/clustering perspective over single-columned ASCII text documents, though more recent efforts in industrial applications tend to benefit from cascading binary (SVM) classifiers or random forest approaches.

Table Boundary Identification

Table boundary identification recognizes the boundaries of detected tables such that they could be isolated from the surrounding information. Laurentini et al. (1992) makes use of the Hough transform to identify connected shapes and components that represent the margins of tables. These must be separated from charts, images, and other visual components, which is the aim of the table detection step mentioned above. The identification of table boundaries can also benefit the table detection task by providing additional structural features on which to predicate the distinction from other visual objects in a document.

Structural Inference

For each recognized table, identify the column and row structure, such that each cell could be uniquely identified. In practice, the methods applied to this task mirror those of table boundary identification. However, there are additional constraints that often make it worthwhile to consider this step separately. For example, tables are structurally constrained to maintain linear relationships among cells – rows and columns must remain broadly coherent. Furthermore, the task may be recursive, where tables contain tables, or other structural items as inserts. It is important that this step provide the most accurate microstructure possible. As such, it can often be beneficial to look at measures of content coherence for merging or splitting neighbors, at the same time as optimizing overall coherence.

Functional Classification

The logical definition of a table is that of a set of associated keys and values. Headers, or groupings of headers, represent keys, which intersect along the axes of a table. The intersects of these header cells represent the values of interest. Headers provide the information necessary to understand the type of data as well as uniquely pinpoint the location of each value. Functional classification, therefore, identifies for each cell, whether it represents a key or a value (Liu 2009).

Functional Interpretation

For each cell representing a value, classify its type (e.g., weight, location, distance, revenue), according to its associated headers. In addition, many tables rely on auxiliary information and interpretation, such as footnotes or implied coherence (e.g., all adjacent cells have the same property, but do not explicitly define it). These additional structures need to be identified and associated with each cell. Furthermore, cell values should be fully normalized according to the available information. If a header states that all values are in $M, all numbers should take this into account.

Disambiguation

In most cases, the reason for reading and extracting a table from text is to be able to work with the information held therein. Comparing values to prior years' numbers, reasoning about them, and filtering all require that the data fit into some logical representation of the domain of interest, whether implicitly or explicitly defined. Disambiguating the values allows them to be used consistently and stored uniformly for later querying (Liu 2009; Hurst 2000).

Disambiguation requires some desired final representation, whether a formal ontology or a relational database schema. Ideally the representation would cover the entire universe of interest, allowing every possible value type to be logically captured. However, it is often necessary to account for content that has not been encountered before.

Generally, disambiguation can be viewed as a supervised classification problem, whereby explicit or implicit (latent, structural) features are mapped probabilistically to available outcomes, constrained by meta-schemas such as length, primitive type, and relative position. Additionally, structural factors (number of values, etc.) can be used, within an iterative framework, to further limit the output space. That is, as more of the table has been disambiguated, fewer options remain that would be consistent with the prior results. As such, this can be viewed as a constrained optimization, where the schema is sufficiently well defined.

TD-Gammon

Definition

TD-Gammon is a world-champion strength backgammon program developed by Gerald Tesauro. Its development relied heavily on machine learning techniques, in particular on ▶ Temporal-Difference Learning. Contrary to successful game programs in domains such as chess, which can easily out-search their human opponents but still trail these ability of estimating the positional merits of the current board configuration, TD-GAMMON was able to excel in backgammon for the same reasons that humans play well: its grasp of the positional strengths and weaknesses was excellent. In 1998, it lost a 100-game competition against the world champion with only 8 points. Its sometimes unconventional but very solid evaluation of certain opening strategies had a strong impact on the backgammon community and was soon adapted by professional players.

Description of the Learning System

TD-Gammon is a conventional game-playing program that uses very shallow search (the first versions only searched one ply) for determining its move. Candidate moves are evaluated by a ▸ Neural Network, which is trained by TD(λ), a well-known algorithm for Temporal-Difference Learning (Tesauro 1992). This evaluation function is trained on millions of games that the program played against itself. At the end of each game, a reinforcement signal that indicates whether the game has been lost or won is passed through all moves of the game. TD-Gammon developed useful concepts in the hidden layer of its network. Tesauro (1992) shows examples for two hidden units of TD-Gammon that he interpreted as a race-oriented feature detector and an attack-oriented feature detector.

TD-Gammon clearly surpassed its predecessors, in particular the Computer Olympiad champion Neurogammon, which was trained with ▸ Preference Learning (Tesauro 1989). In fact, early versions of TD-Gammon, which only used the raw board information as features, already learned to play as well as Neurogammon, which used a sophisticated set of features. Adding more sophisticated features to the input representation further improved TD-Gammon's playing strength. Over time, TD-Gammon not only that increase the number of training games that it played against itself, but Tesauro also increased the search depth and changed the network architecture, so that TD-Gammon eventually reached world-championship strength (Tesauro 1995).

Temporal Difference Learning

William Uther
NICTA and The University of New South Wales,
Sydney, NSW, Australia

Definition

Temporal Difference Learning, also known as TD-Learning, is a method for computing the long term utility of a pattern of behavior from a series of intermediate rewards (Sutton 1984, 1988, 1998). It uses differences between successive utility estimates as a feedback signal for learning. The Temporal Differencing approach to model-free ▸ reinforcement learning was introduced by, and is often associated with, R.S. Sutton. It has ties to both the artificial intelligence and psychological theories of reinforcement learning as well as ▸ dynamic programming and operations research from economics (Bellman 1957; Samuel 1959; Watkins 1989; Puterman 1994; Bertsekas 1996).

While TD learning can be formalised using the theory of ▸ Markov Decision Processes, in many cases it has been used more as a heuristic technique and has achieved impressive results even in situations where the formal theory does not strictly apply, e.g., Tesauro's TD-Gammon (Tesauro 1995) achieved world champion performance in the game of backgammon. These heuristic results often did not transfer to other domains, but over time the theory behind TD learning has expanded to cover large areas of reinforcement learning.]

Formal Definitions

Consider an agent moving through a world in discrete time steps, $t_1,\ t_2, \ldots$. At each time step, t, the agent is informed of both the current state of the world, $s_t \in \mathcal{S}$, and its reward, or utility, for the previous time step, $r_{t-1} \in \mathbb{R}$.

As the expected long term utility of a pattern of behavior can change depending upon the state, the utility is a function of the state, V:$\mathcal{S} \to \mathbb{R}$. V is known as the *value function* or *state-value function*. The phrase "long term utility" can be formalized in multiple ways.

Undiscounted Sum of Reward

The simplest definition is that long term reward is the sum of all future rewards.

$$\begin{aligned} V(s_t) &= r_t + r_{t+1} + r_{t+2} + \ldots \\ &= \sum_{\delta=0}^{\infty} r_t + \delta \end{aligned}$$

Unfortunately, the undiscounted sum of reward is only well defined if this sum converges. Convergence is usually achieved by the addition of a constraint that the agent's experience terminates at some, finite, point in time and all rewards after that point are zero.

Discounted Sum of Reward

The *discounted* utility measure discounts rewards exponentially into the future.

$$\begin{aligned} V(s_t) &= r_t + \gamma r_{t+1} + \gamma^2 r_{t+2} + \ldots \quad \gamma \in [0,1] \\ &= \sum_{\delta=0}^{\infty} r_{t+\delta} \end{aligned}$$

Note that when $\gamma = 1$ the discounted and undiscounted regimes are identical. When $\gamma < 1$, the discounted reward scheme does not require that the agent experience terminates at some finite time for convergence. The *discount factor* γ can be interpreted as an inflation rate, a probability of failure for each time step, or simply as a mathematical trick to achieve convergence.

Average Reward

Rather than consider a sum of rewards, the *average reward* measure of utility estimates both the expected reward per future time step, also known as the *gain*, and the current difference from that long-term average, or *bias*.

$$G(s_t) = \lim_{n\to\infty} \frac{1}{n} \sum_{\delta=0}^{n} r_{t+\delta}$$

$$B(s_t) = \sum_{\delta=0}^{\infty} [r_{t+\delta} - G(s_{t+\delta})]$$

A system where any state has a nonzero probability of being reached from any other state is known as an ergodic system. For such a system the gain, $G(s)$, will have the same value for all states and the bias, $B(s)$, serves a similar purpose to $V(s)$ above in indicating the relative worth of different states. While average reward has a theoretical advantage in that there is no discount factor to choose, historically average reward has been considered more complex to use than the discounted reward regimes and so has been less used in practice. There is a strong theoretical relationship between average reward and discounted reward in the limit as the discount factor approaches one.

Here we focus on discounted reward.

Estimating Discounted Sum of Reward

The temporal differencing estimation procedure is based on recursive reformulation of the above definitions. For the discounted case:

$$\begin{aligned} V(s_t) &= r_t + \gamma r_{t+1} + \gamma^2 r_{t+2} + \gamma^3 r_{t+3} + \dots \\ &= r_t + \gamma[r_{t+1} + \gamma r_{t+2} + \gamma^2 r_{t+3} + ldots] \\ &= r_t + \gamma V(s_{t+1}) \end{aligned}$$

From the recursive formulation we can see that the long term utility for one time step is closely related to the long term utility at the next time step. If there is already an estimate of the long term utility at s_t, $V(s_t)$, then we could calculate a change in that value given a new trajectory as follows:

$$\Delta_t = [r_t + \gamma V(s_{t+1})] - V(s_t)$$

If we are dealing with a stochastic system, then we may not want to update $V(s_t)$ to the new value in one jump, but rather only move part way toward the new value:

$$\Delta_t = \alpha(r_t + \gamma V(s_{t+1}) - V(s_t))$$

where α is a learning rate between 0 and 1. As an assignment, this update can be written in a number of equivalent ways, the two most common being:

$$V(s_t) \leftarrow V(s_t) + \alpha(r_t + \gamma V(s_{t+1}) - V(s_t)) \ or,$$

$$V(s_t) \rightarrow (1-\alpha)V(s_t) + \alpha(r_t + \gamma V(s_{t+1}))$$

This *update*, *error*, *learning* or *delta* rule is the core of temporal difference learning. It is from this formulation, which computes a delta based on the difference in estimated long term utility of the world at two consecutive time steps, that we get the term temporal differencing.

Having derived this update rule, we can now apply it to finding the long term utility of a particular agent. In the simplest case we will assume that there are a finite number of Markov states of the world, and that these can be reliably detected by the agent at run time. We will store the function V as an array of real numbers, with one number for each world state.

After each time step, t, we will use the knowledge of the previous state, s_t, the instantaneous reward for the time step, r_t, and the resulting state, s_{t+1}, to update the value of the previous state, $V(s_t)$, using the delta rule above:

$$V(s_t) \leftarrow V(s_t) + \alpha(r_t + \gamma V(s_{t+1}) - V(s_t))$$

Eligibility Traces and TD (λ)

Basic temporal differencing as represented above can be quite slow to converge in many situations. Consider, for example, a simple corridor with a single reward at the end, and an agent that walks down the corridor. Assume that the value function was initialized to a uniform zero value. On each walk down the corridor, useful information is only pushed one step back toward the start of the corridor.

Eligibility traces try to alleviate this problem by pushing information further back along the trajectory of the agent with each update to V. An algorithm incorporating eligibility traces can be seen as a mixture of "pure" TD, as described above, and ▶ Monte-Carlo estimation of the long term utility. In particular, the λ parameter to the TD(λ) family of algorithms specifies where in the range from pure TD, when $\lambda = 0$, to pure Monte-Carlo, when $\lambda = 1$, a particular algorithm falls.

Eligibility traces are implemented by keeping a second function of the state space , $\epsilon : \mathcal{S} \rightarrow \mathbb{R}$. The ε function represents how much an experience now should affect the value of a state the agent has previously passed through. When the agent performs an update, the values of all states are changed according to their eligibility.

The standard definition of the eligibility of a particular state uses an exponential decay over time, but this is not a strict requirement and other definitions of eligibility could be used. In addition, each time a state is visited, its eligibility increases. Formally, on each time step,

$$\forall_{s \in \mathcal{S}} \varepsilon(s) \leftarrow \gamma\lambda\varepsilon(s) \quad \text{and then,}$$
$$\varepsilon(s_t) \leftarrow \varepsilon(s_t) + 1$$

This eligibility is used to update all state values by first calculating the delta for the current state as above, but then applying it to all states according to the eligibility values:

$$\delta_t = \alpha(r_t + \gamma V(s_{t+1}) - V(s_t))$$
$$\forall_{s \in \mathcal{S}} V(s) \leftarrow V(s) + \delta_t \varepsilon(s)$$

Convergence

TD value function estimation has been shown to converge under many conditions, but there are also well known examples where it does not converge at all, or does not converge to the correct long term reward (Tsitsiklis 1997).

In particular, temporal differencing has been shown to converge to the correct value of the long term discounted reward if,

- The world is finite.
- The world state representation is Markovian.
- The rewards are bounded.
- The representation of the V function has no constraints (e.g., a tabular representation with an entry for each state).
- The learning rate, α, is reduced according to the Robbins-Monro conditions: $\sum_{t=0}^{\infty} \alpha_t = \infty$, and $\sum_{t=0}^{\infty} \alpha_t^2 < \infty$.

Much of the further work in TD learning since its invention has been in finding algorithms that provably converge in more general cases.

These convergence results require that a Markovian representation of state be available to the agent. There has been research into how to acquire such a representation from a sequence of observations. The approach of the Temporal Differencing community has been to use TD-Networks (Sutton 2004).

Control of Systems

Temporal Difference Learning is used to estimate the long term reward of a pattern of behavior. This estimation of utility can then be used to improve that behavior, allowing TD to help solve a reinforcement learning problem. There are two common ways to achieve this: An *Actor-Critic* setup uses value function estimation as one component of a larger system, and the *Q-learning* and *SARSA* techniques can be viewed as slight modifications of the TD method which allow the extraction of control information more directly from the value function.

First we will formalise the concept of a pattern of behavior. In the preceding text it was left deliberately vague as TD can be applied to multiple definitions. Here we will focus on discrete action spaces.

Assume there is a set of allowed actions for the agent, $\mathcal{A}$. We define a *Markov policy* as a function from world states to actions, $\pi : \mathcal{S} \rightarrow \mathcal{A}$. We also define a *stochastic* or *mixed* Markov policy as a function from world states to probability distributions over actions, $\pi : \mathcal{S} \rightarrow \mathcal{A} \rightarrow [0, 1]$. The goal of the control algorithm is to find an optimal policy: a policy that maximises long term reward in each state. (When function approximation is used (see section "Approximation"), this definition of an optimal policy no longer suffices. One can then either move to average reward if the system is ergodic, or give a, possibly implicit, weighting function specifying the relative importance of different states.)

Actor-Critic Control Systems

Actor-Critic control is closely related to *mixed policy iteration* from Markov Decision Process theory. There are two parts to an actor-critic system; the *actor* holds the current policy for the agent, and the *critic* evaluates the actor and suggests improvements to the current policy.

There are a number of approaches that fall under this model. One early approach stores a preference value for each world state and action pair, $p : \mathcal{S} \times \mathcal{A} \rightarrow \mathbb{R}$. The actor then uses a stochastic policy based on the Gibbs softmax function applied to the preferences:

$$\pi(s,a) = \frac{e^{p(s,a)}}{\sum_{x \in \mathcal{A}} e^{P(s,x)}}$$

The critic then uses TD to estimate the long term utility of the current policy, and also uses the TD update to change the preference values. When the agent is positively surprised it increases the preference for an action, when negatively surprised it decreases the preference for an action. The size of the increase or decrease is modulated by a parameter, β:

$$p(s_t, a_t) \leftarrow p(s_t, a_t) + \beta\delta_t$$

Convergence of this algorithm to an optimal policy is not guaranteed.

A second approach requires the agent to have an accurate model of its environment. In this approach the critic uses TD to learn a value function for the current behavior. The actor uses model based forward search to choose an action likely to lead to a state with a high expected long term utility. This approach is common in two player, zero sum, alternating move games such as Chess or Checkers where the forward search is a deterministic game tree search.

More modern approaches which guarantee convergence are related to *policy gradient* approaches to reinforcement learning (Di 2010). These store a stochastic policy in addition to the value function, and then use the TD updates to estimate the gradient of the long term utility with respect to that policy. This allows the critic to adjust the policy in the direction of the negative gradient with respect to long term value, and thus improve the policy.

Other Value Functions

The second class of approaches to using TD for control relies upon extending the value function to estimate the value of multiple actions. Instead of V we use a *state-action value function*, $Q : \mathcal{S} \times \mathcal{A} \rightarrow \mathbb{R}$. The update rule for this function is minimally modified from the TD update defined for V above.

Once these state-action value functions have been estimated, a policy can be selected by choosing for each state the action that maximizes the state-action value function, and then adding some exploration.

In order for this extended value function to be learned, the agent must explore each action in each state infinitely often. Traditionally this has been assured by making the agent select random actions occasionally, even when the agent believes that action would be sub-optimal. In general the choice of when to explore using a sub-optimal action, the *exploration/exploitation trade-off*, is difficult to optimize. More recent approaches to optimizing the exploration/exploitation trade-off in reinforcement learning estimate the variance of the value function to decide where they need to explore (Auer 2007).

The requirement for exploration leads to two different value functions that could be estimated. The agent could estimate the value function of the pattern of behavior currently being executed, which includes the exploration. Or, the agent could estimate the value function of the current best policy, excluding the exploration currently in use. These are referred to as *on-policy* and *off-policy* methods respectively.

Q-Learning is an off-policy update rule:

$$Q(s_t, a_t) \leftarrow Q(s_t, a_t) + \alpha(r_t + \gamma V(s_{t+1}) - Q(s_t, a_t))$$

Where $V(s_{t+1}) = \max_{a \in \mathcal{A}} Q(s_{t+1}, a)$

SARSA is an on-policy update rule:

$$Q(s_t, a_t) \leftarrow Q(s_t, a_t) + \alpha(r_t + \gamma Q(s_{t+1}, a_{t+1}) - Q(s_t, a_t))$$

Then for both:

$$\pi(s) = argmax_{a \in \mathcal{A}} Q(s, a)$$

and some exploration.

As can be seen above, the update rules for SARSA and Q-learning are very similar – they only differ in the value used for the resulting state. Q-learning uses the value of the best action, whereas SARSA uses the value of the action that will actually be chosen.

Q-Learning converges to the best policy to use once you have converged and can stop exploring. SARSA converges to the best policy to use if you want to keep exploring as you follow the policy (Lagoudakis 2003).

Approximation

A major problem with many state based algorithms, including TD learning, is the so-called ▶ curse of dimensionality. In a factored state representation, the number of states increases exponentially with the number of factors. This explosion of states produces two problems: it can be difficult to store a function over the state space, and even if the function can be stored, so much data is required to learn the function that learning is impractical.

The standard response to the curse of dimensionality is to apply function approximation to any function of state. This directly attacks the representation size, and also allows information from one state to affect another "similar" state allowing generalisation and learning.

While the addition of function approximation can significantly speed up learning, it also causes difficulty with convergence. Some types of function approximation will stop TD from converging at all. The resulting algorithms can either oscillate forever or approach infinite values. Other forms of approximation cause TD to converge to a estimate of long term reward which is only weakly related to the true long term reward (Gordon 1995; Boyan and Moore 1995; Baird 1995).

Most styles of function approximation used in conjunction with TD learning are parameterized, and the output is differentiable with respect to those parameters. Formally we have $V : \Theta \to \mathcal{S} \to \mathbb{R}$, where Θ is the space of possible parameter vectors, so that $V_\theta(s)$ is the value of V at state s with parameter vector θ, and $\nabla V_\theta(s)$ is the gradient of V with respect to θ at s. The TD update then becomes:

$$\begin{aligned} \delta_t &= \alpha(r_t + \gamma V_\theta(s_{t+1}) - V_\theta(s_t)) \\ \theta &\leftarrow \theta + \delta_t \nabla V_\theta(s_t) \end{aligned}$$

We describe three styles of approximation: state abstraction, linear approximation, and smooth general approximators (e.g., neural networks).

State abstraction refers to grouping states together and thereafter using the groups, or *abstract states*, instead of individual states. This can significantly reduce the amount of storage required for the value function as only values for abstract states need to be stored. It also preserves convergence results. A slightly more advanced form of state abstraction is the tile coding or CMAC (Albus 1981). In this type of function approximation, the state representation is assumed to be factored, i.e., each state is represented by a vector of values rather than a single scalar value. The CMAC represents the value function as the sum of separate value functions; one for each dimension of the state. Those individual dimensions can each have their own state abstraction. Again, TD has been shown to converge when used with a CMAC value function representation.

In general, any form of function approximation that forms a contraction mapping will converge when used with TD (see the entry on ▶ Markov Decision Processes). Linear interpolation is a contraction mapping, and hence converges. Linear extrapolation is not a contraction mapping and care needs to be taken when using general linear functions with TD. It has been shown that general linear function approximation used with TD will converge, but only when complete trajectories are followed through the state space (Tsitsiklis 1997).

It is not uncommon to use various types of back-propagation neural nets with TD, e.g., Tesauro's TD-gammon. More recently, TD algorithms have been proposed that converge for arbitrary differentiable function approximators (Papavassiliou 1999; Maei et al. 2009). These use more complex update techniques than those shown above.

Related Differencing Systems

TD learning was originally developed for use in environments where accurate models were unavailable. It has a close relationship with the theory of Markov Decision Processes where an accurate model is assumed. Using the notation $V(s_t) \rightsquigarrow V(s_{t+1})$ for a TD-style update that moves the value at $V(s_t)$ closer to the value at $V(s_{t+1})$ (including any discounting and intermediate rewards), we can now consider many possible updates.

As noted above, one way of applying TD to control is to use forward search. Forward search can be implemented using dynamic programming, and the result is closely related to TD. Let state $c(s)$ be the best child of state s in the forward search. We can then consider an update, $V(s) \rightsquigarrow V(c(s))$. If we let $l(s)$ be the best leaf in the forward search, we could then consider an update $V(s) \rightsquigarrow V(l(s))$. Neither of these updates consider the world after an actual state transition, only simulated state transitions, and so neither is technically a TD update.

Some work has combined both simulated time steps and real time steps. The TD-Leaf learning algorithm for alternative move games uses the $V(l(s_t)) \rightsquigarrow V(l(s_{t+1}))$ update rule (Baxter et al. 1998).

An important issue to consider when using forward search is whether the state distribution where learning takes place is different to the state distribution where the value function is used. In particular, if updates only occur for states the agent chooses to visit, but the search is using estimates for states that the agent is not visiting, then TD may give poor results. To combat this, the TreeStrap($\alpha - \beta$) algorithm for alternating move games updates all nodes in the forward search tree to be closer to the bound information provided by their children (Veness et al. 2009).

Biological Links

There are strong relationships between TD learning and the Rescorla–Wagner model of Pavlovian conditioning. The Rescorla–Wagner model is one way to formalize the idea that learning occurs when the co-occurence of two events is surprising rather than every time a co-occurence is experienced. The Δ_t value calculated in the TD update can be viewed as a measure of surprise. These findings appear to have a neural substrate in that dopamine cells react to reward when it is unexpected and to the predictor when the reward is expected (Schultz et al. 1997; Sutton 1990).

Abstract

Text Mining also referred to as Data Mining on Text, has emerged at the intersection of several research areas, some focused on data analytics and others focused more on handling text data. This entry provides a definition of Text Mining and links it to related research areas, most of them included in this book.

Synonyms

Analysis of text; Data mining on text; Text learning

Definition

The term *text mining* is used analogous to ▶ Data Mining when the data is text. As there are some data specificities when handling text compared to handling data from ▶ databases, text mining has a number of specific methods and approaches. Some of these are extensions of data mining and machine learning methods, while others are rather text specific. Text mining approaches combine methods from several related fields, including machine learning, data mining, ▶ Information Retrieval, natural language processing, ▶ Statistical Learning, and ▶ Semantic Web. Basic text mining approaches are also extended to enable handling of different natural languages (▶ Cross-Lingual Text Mining) and are combined with methods for handling different data types, such as links and graphs (▶ Link Mining and Link Discovery, Graph Mining), images and video (multimedia mining), and sensor data. Adopting ▶ Stream Mining methods for text data enables analysis of text streams, such as news feed or social media texts. Text stream mining can be also combined with other types of data streams, such as sensor readings, economic indicators, and video, where time stamp and location of the data can play a crucial role in analytics.

Text Mining for Advertising

Massimiliano Ciaramita
Yahoo! Research Barcelona, Barcelona, Spain

Synonyms

Content match; Contextual advertising; Sponsored search; Web advertising

Definition

Text mining for advertising is an area of investigation and application of text mining and machine learning methods to problems such as Web advertising; e.g., automatically selecting the most appropriate ads with respect to a Web page, or query submitted to a search engine. Formally, the task can be framed as a ranking or matching problem where the unit of retrieval, rather than a Web page, is an advertisement. Most of the time ads have simple and homogeneous predefined textual structures, however, formats can vary and include audio and visual information. Advertising is a challenging problem due to several factors such as the economic nature of the transactions involved, engineering issues concerning scalability, and the inherent complexity of modeling the linguistic and multimedia content of advertisements.

Motivation and Background

The role of advertising in supporting and shaping the development of the Web has substantially increased over the past years. According to the Interactive Advertising Bureau (IAB), Internet advertising revenues in the USA totaled almost $8 billion in the first 6 months of 2006, a 36.7 % increase over the same period in 2005, the last in a series of consecutive growths. Search, i.e., ads placed by Internet companies in Web pages or in response to specific queries, is the largest source of revenue, accounting for 40 % of total revenue (Internet Advertising Bureau 2006). The most important categories of Web advertising are *keyword match*, also known as *sponsored search* or *paid listing*, which places ads in the search results for specific queries (see Fain and Pedersen 2006 for a brief history of sponsored search), and *content match*, also called *content-targeted advertising* or *contextual advertising*, which places ads in Web pages based on the page content. Figure 1 shows an example of sponsored search and ads are listed on the right side of the page.

Currently, most of the focus in Web advertising involves sponsored search, because matching based on keywords is a well-understood problem. Content match has greater potential for content providers, publishers, and advertisers, because users spend most of their time on the Web on content pages as opposed to search engine result pages. However, content match is a harder problem than sponsored search. Matching ads with query terms is to a certain degree straightforward, because advertisers themselves choose the keywords that characterize their ads that are matched against keywords chosen by users while searching. In contextual advertising, matching is determined automatically by the page content, which complicates the task considerably.

Advertising touches challenging problems concerning how ads should be analyzed, and how the accurately and efficiently systems select the best ads. This area of research is developing rapidly in information retrieval. How best to model the structure and components of ads, and the interaction between the ads and the contexts in that they appear are open problems. Information retrieval systems are designed to capture relevance, which is a basic concept in advertising as well. Elements of an ad such as text and images tend to be mutually relevant, and often (in print media for example) ads are placed in contexts that match a certain product at

Text Mining for Advertising, Fig. 1 Ads ranked next to a search results page for the query "Spain holidays"

a topical level; e.g., an ad for sneakers placed on a sport news page. However, topical relevance is only one the basic parameters which determine a successful advertisement placement. For example, an ad for sneakers might be appropriate and effective on a page comparing MP3 players, because they may share a target audience (e.g., joggers) although they arguably refer to different topics, and it is possible they share no common vocabulary. Conversely, there may be ads that are topically similar to a Web page, but cannot be placed there because they are inappropriate. An example might be placing ads for a product in the page of a competitor.

The language of advertising is rich and sophisticated and can rely considerably on complex inferential processes. A picture of a sunset in an ad for life insurance carries a different implication than a picture of a sunset in an ad for beer. Layout and visual content are designed to elicit inferences, possibly hinging on cultural elements; e.g., the age, appearance, and gender of people in an ad affect its meaning. Adequate automatic modeling will likely involve, to a substantial degree, understanding the language of advertisement and the inferential processes involved (Vestergaard and Schroeder 1985). Today this seems beyond what traditional information retrieval systems are designed to cope with. In addition, the global context can be captured only partially by modeling the text alone. As the Web evolves into an immense infrastructure for social interaction and multimedia information sharing the need for modeling structured "content" becomes more and more crucial. This applies to information retrieval and specifically to advertising. For this reason, the problem of content match is of particular interest and opens new problems and opportunities for interdisciplinary research.

Today, contextual advertising, the most interesting sub-task from a mining perspective, consists mostly in selecting ads from a pool to match the textual content of a particular Web page. Ads provide a limited amount of text: typically a few keywords, a title, and brief description. The ad-placing system needs to identify relevant ads, from huge ad inventories, quickly and efficiently based on this very limited amount of information.

Current approaches have focused on augmenting the representation of the page to increase the chance of a match (Ribeiro-Neto et al. 2005), or by using machine learning to find complex ranking functions (Lacerda et al. 2006), or by reducing the problem of content match to that of sponsored search by extracting keywords from the Web page (Yih et al. 2006). All these approaches are based on methods that quantify the similarity between the ad and the target page on the basis of traditional information retrieval notions such as cosine similarity and *tf.idf* features. The relevance of an ad for a page depends on the number of overlapping words, weighted individually and independently as a function of their individual distributional properties in the collection of documents or ads.

Structure of Learning Problem

The typical elements of an advertisement are a set of *keywords*, a *title*, a *textual description* and a hyperlink pointing to page, the *landing page*, relative to a product or service, etc. In addition, an ad has an *advertiser id* and can be part of a *campaign*, i.e., a subset of all the ads with same advertiser id. This latter information can be used, for example, to impose constraints on the number of ads to display relative to the campaign or advertiser. While this is possibly the most common layout, it is important to realize that ads structure can vary significantly and include relevant audio and visual content.

In general, the learning problem for an ad-placing system can be formalized as a ranking task. Let $\mathcal{A}$ be a set of ads, $\mathcal{P}$ the set of possible pages, and $\mathcal{Q}$ the set of possible queries. In keyword match, the goal is to find a function $F : \mathcal{A} \times \mathcal{Q}$; e.g., a function that counts the number of individual common terms or n-grams of such terms. In content match, the objective is to find a function $F : \mathcal{A} \times \mathcal{P} \rightarrow \mathbb{R}$. The keyword match problem is to a certain extent straightforward and amounts to matching small set of terms defined manually by both the user and the advertiser. The content match task shares with the former task the peculiarities of the units of retrieval (the ads), but introduces new and interesting issues for text mining and learning because of the more complex conditioning environment, the Web page content, which needs to modeled automatically.

In general terms, an ad can be represented as a feature vector $\mathbf{x} = \Phi(a_i, p_j)$ such that $a_i \in \mathcal{A}$, $p_j \in \mathcal{P}$, and given a d-dimensional feature space $\mathcal{X} \subset \mathbb{R}^d$, $\Phi : \mathcal{A} \times \mathcal{P} \rightarrow \mathcal{X}$. In the traditional machine learning setting, one introduces a weight vector $\alpha \in \mathbb{R}^d$ which quantifies each feature's contribution individually. The vector's weights can be learned from manually edited rankings (Lacerda et al. 2006; Ribeiro-Neto et al. 2005) or from click-through data as in search results optimization (Joachims 2002). In the case of a linear classifier the score of an ad-target page pair x_i would be:

$$F(\mathbf{x}; \alpha) = \sum_{s=1}^{d} \alpha_s x_s. \tag{1}$$

Several methods can be used to learn similar or related models such as perceptron, SVM, boosting, etc. Constraints on the number of advertisers or campaigns could be easily implemented as post-ranking filters on the top of the ranked list of ads or included in a suitable objective function.

A basic model for ranking ads can be defined in the vector space model for information retrieval, using a ranking function based on cosine similarity, where ads and target pages are represented as vectors of terms weighted by fixed schemes such as *tf.idf*. If only one feature is used, the cosine based on *tf.idf* between the ad and the page, a standard vector space model baseline is obtained, which is at the base of the ad-placing ranking functions variants proposed by Ribeiro-Neto et al. (2005). Recent work has shown that machine learning-based models are considerably more accurate than such baselines. However, as in document retrieval, simple feature maps which include mostly coarse-grained statistical properties of the ad-page pairs, such as *tfidf-based* cosine, are the most desirable for efficiency and bias reasons. Properties of the different components of the ad can be used and weighted in different ways, and soft or hard constraints introduced to model the presence of the ads keyword in the Web page. The design space for ad-place systems is vast and still little explored. All systems presented so far in the literature make use of manually annotated data for training and/or evaluating a model.

Structure of Learning Systems

Web advertising presents peculiar engineering and modeling challenges and has motivated research in different areas. Systems need to be able to deal in real time with huge volumes of data and transactions involving billions of ads, pages, and queries. Hence several engineering constraints need to be taken into account; efficiency and computational costs are crucial factors in the choice of matching algorithms (The Yahoo! Research Team 2006). Ad-placing systems might require new global architecture design; e.g., Attardi et al. (2004) proposed an architecture for information retrieval systems that need to handle large-scale targeted advertising based on an information filtering model. The ads that appear on Web pages or search results pages will ultimately be determined taking into account the expected revenues and the price of the ads. Modeling the microeconomics factors of such processes is a complex area of investigation in itself (Feng et al. 2005).

Another crucial issue is the evaluation of the effectiveness of the ad-placing systems. Studies have emphasized the impact of the quality of the matching on the success of the ad in terms of click-through rates (Gallagher et al. 2001; Sherman and Deighton 2001). Although click-through rates (CTRs) provide a traditional measure of effectiveness, it has been found that ads can be effective even when they do not solicit any conscious response and that the effectiveness of the ad is mainly determined by the level of congruency between the ad and the context in which it appears (Yoo 2006).

Keyword Extraction Approaches

Since the query-based ranking problem is better understood than contextual advertising, one way of approaching the latter would be to represent the content page as a set of keywords and then ranking the ads based on the keywords extracted from the content page. Carrasco et al. (2003) proposed clustering of bi-partite advertiser-keyword graphs for keyword suggestion and identifying groups of advertisers. Yih et al. (2006) proposed a system for keyword extraction from content pages. The goal is to determine which keywords, or key phrases, are more relevant in a Web page. Yih et al. develop a supervised approach to this task from a corpus of pages where keywords have been manually identified. They show that a model learned with ▸ logistic regression outperforms traditional vector models based on fixed *tf.idf* weights. The most useful features to identify good keywords efficiently are, in this case, term frequency and document frequency of the candidate keywords, and particularly the frequency of the candidate keyword in a search engine query log. Other useful features include the similarity of the candidate with the page's URL and the length, in number of words, of the candidate keyword. In terms of feature representation thus, they propose a feature map $\Phi : \mathcal{A} \rightarrow \mathcal{Q}$, which represent a Web page as a set of keywords. The accuracy of the best learned system is 30.06 %, in terms of the top predicted keyword being in the set of manually generated keywords for a page, against 13.01 % of the simpler *tf.idf* based model. While this approach is simple to apply, it remains to be seen how accurate it is at identifying good ads for a page. It identifies potentially useful sources of information in automatically-generated keywords. An interesting related finding concerning keywords is that longer keywords, about four words long, lead to increased click-through rates (OneUpWeb 2005).

The Vocabulary Impedance Problem

Ribeiro-Neto et al. (2005) introduced an approach to content match which focuses on the vocabulary mismatch problem. They notice that there tends to be not enough overlap in the text of the ad and the target page to guarantee good accuracy; they call this the *vocabulary impedance problem*. To overcome this limitation they propose to generate an augmented representation of the target page by means of a Bayesian model previously applied to document retrieval (Ribeiro-Neto and Muntz 1996). The expanded vector representation of the target page includes a significant number of additional words which can potentially match some of the terms in the ad. They find that such a model improves over a standard vector space model baseline, evaluated by means of 11-point average precision on a test bed of 100 Web pages, from 0.168 to 0.253. One possible shortcoming of such an approach is that generating the augmented representation involves crawling a significant number of additional related pages. It has also been argued (Yih et al. 2006) that this model complicates pricing of the ads because the keywords chosen by the advertisers might not be present in the content of the matching page.

Learning with Genetic Programming

Lacerda et al. (2006) proposed to use machine learning to find good ranking functions for contextual advertising. They use the same data-set described in Ribeiro-Neto et al. (2005), but use part of the data for training a model and part for evaluation purposes. They use a genetic programming algorithm to select a ranking function which maximizes the average precision on the training data. The resulting ranking function is a nonlinear combination of simple components based on the frequency of ad terms in the target page, document frequencies, document length, and size of the collections. Thus, in terms of the feature representation defined earlier, they choose a feature map which extracts traditional features from the ad-page pair, but then apply then genetic programming methods to select complex nonlinear combinations of such features that maximize a fitness function based on average precision. Lacerda et al. (2006) find that the ranking functions selected in this way are considerably more accurate than the baseline proposed in Ribeiro-Neto et al. (2005); in particular, the best function selected by genetic programming achieves an average precision at position three of 0.508, against 0.314 of the baseline.

Semantic Approaches to Contextual Advertising

The most common approaches to contextual advertising are based on matching terms between the ad and the content page. Broder et al. (2007) notice that this approach (which they call the "syntactic—" model), can be improved by adopting a matching model which additionally takes into account topical proximity; i.e., a "semantic" model. In their model the target page and the ad are classified with respect to a taxonomy of topics. The similarity of ad and target page estimated by means of the taxonomy provides an additional factor in the ads ranking function. The taxonomy, which has been manually built, contains approximately 6,000 nodes, where each node represents a set of queries. The concatenation of all queries at each node is used as a meta-document, ads and target pages are associated with a node in the taxonomy using a nearest neighbor classifier and *tf. idf* weighting. The ultimate score of an ad a_i for a page p is a weighted sum of the taxonomy similarity score and the similarity of a_i and p based on standard syntactic measures (vector cosine). On evaluation, Broder et al. (2007) report a 25 % improvement for mid-range recalls of the syntactic-semantic model over the pure syntactic one.

Text Mining for News and Blogs Analysis

Bettina Berendt
KU Leuven, Leuven, Belgium

Abstract

News and blogs are temporally indexed online texts and play a key role in today's information distribution and consumption. News communicate selected information on current events, written by professional or citizen journalists; blogs are updated publications on the Web that span a much wider range of topics, styles, and authors. Particularly important in recent years have been microblogs such as Twitter. The entry gives an overview of how text mining (for tasks such as description, classification, prediction, search, recommendation, or summarization) is applied to analyze the textual parts of news and blogs, extracting topics, events, opinions, sentiments, and other aspects of content. Often, textual analysis is complemented by the analysis of further data such as the social network of authors and readers. The properties of news and blogs data structures and language use require methods for preprocessing and analyzing that are tailored to news and (micro)blogs, and the tasks often profit from an interactive approach in which the user plays an active role in sensemaking. The methods are deployed in a wide range of applications and services.

Definition

News is "the communication of selected information on current events," where the selection is guided by "newsworthiness" or "what interests the public." News are also stories, from which the reader usually expects answers to the five Ws: who, what, when, where, and why, to which a "how" is often added. News-style writing – as opposed to, for example, commentary writing – generally strives for objectivity and/or neutrality (the representation of different views on the event).

In this content-centric sense, news can be written/authored and published by professional journalists and news outlets (such as newspapers or radio or TV stations) but also by anyone else and in any other form, often called *citizen journalism*: "an alternative and activist form of newsgathering and reporting that functions outside mainstream media institutions, often as a response to shortcomings in the professional journalistic field, that uses similar journalistic practices but is driven by different objectives and ideals and relies on alternative sources of legitimacy than traditional or mainstream journalism." (Radsch 2013, p. 159). However, news, or mainstream (media) news, is also often thought of in a source-centric way: reports authored by professional journalists in mainstream media institutions, as opposed to reporting from citizen journalists (or anyone else) who generally publish on the Web, in the form of blogs with a certain form of periodicity.

A *blog* is a (more or less) frequently updated publication on the Web, sorted in reverse chronological order of the constituent blog posts. Blog content may reflect any interest including journalistic, personal, corporate, and many others. Early blog posts (late 1990s) tended to be published on content management platforms without length restrictions; with the success of Twitter and similar *microblogging* platforms, much blogging (and of blog mining) has shifted to short posts (e.g., 140 characters on Twitter.com and Weibo.cn, although the latter's Chinese characters allow for much more complex messages). Twitter in particular has attained a major worldwide role in the fast diffusion of news (or short summaries and statements, enriched by hyperlinks to more text and other media), with citizen journalists, mainstream media themselves, politicians, and others being the publishers (Kwak et al. 2010). Current research in blog mining and the remainder of the present entry reflect this dominance of (a) news or news-related content and (b) microblog format. In addition, blog mining overlaps with *social-media mining* (Zafarani et al. 2014). In particular, the *social graph* of a microblogger allows the mining analyst to track the blogger's sources and readers/"followers" along with the contents.

News and blogs consist of textual and (in some cases) pictorial content and, when Web-based, may contain additional content in any other format (e.g., video, audio) and hyperlinks. They are indexed by time and structured into smaller units: news media into articles and blogs into blog posts. In most news and blogs, textual content dominates. Therefore, text analysis is the most often applied form of knowledge discovery. This comprises tasks and methods from data/text mining, ▶ information retrieval, and related fields. In accordance with the increasing convergence of these fields, this entry refers to all of them as ▶ *text mining*. The present entry will illustrate the overlap with/use of these fields and highlight the specifics that derive from the domain, including data, tasks, users, and use cases.

Motivation and Background

News and blogs are today's most common sources for learning about current events and also, in the case of blogs, for uttering opinions about current events. In addition, they may deal with topics of more long-term interest. Both reflect and form societies', groups', and individuals' views of the world, fast or even instantaneous with the events triggering the reporting. However, there are differences between these two types of media regarding authoring, content, and form. News is generally authored by people with journalistic training who abide by journalistic standards regarding the style and language of reporting. Topics and ways of reporting are circumscribed by general societal consensus and the policies of the news provider.

In contrast, everybody with Internet access can start a blog, and there are no restrictions on content and style (beyond the applicable types of censorship). Thus, blogs offer end users a wider range of topics and views on them.

These application characteristics lead to various linguistic and computational challenges for text mining analyses of news and blogs:

- Indexing, taxonomic categorization, partial redundancy, and data streams: News is indexed by time and by source (news agency or provider). In a multisource corpus, many articles published at about the same time (in the same or in other languages) describe the same events. Over time, a story may develop in the articles. Such multiple reporting and temporal structures are also observed for popular topics in blogs.
- Language and meaning: News is written in clear, correct, "objective," and somewhat schematized language. Usually, the start of a news article summarizes the whole article (feeds are a partial analogue of this in blogs). Information from external sources such as press agencies is generally reused rather than referenced. In sum, news makes fewer assumptions about the reader's background and context knowledge than many other texts.
- Nonstandard language and subjectivity: The language in blogs ranges from high-quality, "news-like" language via poor-quality, restricted-code language with many spelling and grammatical errors to creative, sometimes literary, language. A blog may employ high-quality language but operate outside the news genre or across journalistic genres (e.g., combining current-events reporting with commentary and background information). Jargon is very common in blogs, and new linguistic developments are adopted far more quickly than could be reflected in external resources such as lexica. Many blog authors strive not for objectivity but for subjectivity and emotionality.
- Thematic diversity and new forms of categorization: News are generally categorized by topic area ("politics," "business," etc.). In contrast, a blog author may choose to write about differing, arbitrary topics. When blogs are labeled, it is usually not with reference to a stable, taxonomic system, but with an arbitrary number of tags: free-form, often informal labels chosen by the user.
- Context and its impact on content and meaning: The content of a blog (post) is often not contained in the text alone. Rather, blog software supports "Web" and "Social Web" behavior, and bloggers practice it: multiway communication rather than broadcasting and semantics-inducing referencing of both content and people. Specifically, hyperlinks to other resources provide not only context but also content, as do links to and from cited resp. citing people/sources. The latter evolved from "blogrolls" resp. "trackback links" in early blog software to "followees" and "retweet" links resp. "followers" in platforms such as Twitter.

Structure of the Learning System

Tasks

From a text mining point of view, tasks can be grouped by different criteria:

- Basic task and type of result: description, classification, and prediction (supervised or unsupervised, includes, for example, topic identification, tracking, and/or novelty detection, spam detection), search (ad hoc or filtering), recommendation (of blogs, blog posts, or (hash-)tags), and summarization
- Higher-order characterization to be extracted: especially topic or event, opinion, or sentiment
- Time dimension: nontemporal, temporal (stream mining), and multiple streams (e.g., in different languages; see cross-lingual ▶ text mining)
- User adaptation: none (no explicit mention of user issues and/or general audience), customizable, and personalized

Real-world applications increasingly employ selections or, more often, combinations of these tasks by their intended users and use cases, in particular:

- News aggregators allow laypeople and professional users (e.g., journalists) to see “what’s in the news” and to compare different sources’ texts on one story. Reflecting the presumption that news (especially mainstream news – sources for news aggregators are usually whitelisted) are mostly objective/neutral, these aggregators focus on topics and events. News aggregators are now provided by all major search engines.
- Social-media monitoring tools allow laypeople and professional users to track not only topical mentions of a keyword or named entity (e.g., person, brand) but also aggregate sentiment toward it. The focus on sentiment reflects the perceptions that even when news-related, social-media content tends to be subjective and that studying the blogosphere is therefore an inexpensive way of doing market research or public opinion research. The whitelist here is usually the platforms (e.g., Twitter, Tumblr, LiveJournal, Facebook) rather than the sources themselves, reflecting the huge size and dynamic structure of the blogosphere/the Social Web. The landscape of commercial and free social-media monitoring tools is wide and changes frequently; up-to-date overviews and comparisons can easily be found on the Web.
- Emerging application types include text mining not of but for journalistic texts, in particular natural language generation in domains with highly schematized event structures and reporting, such as sports and finance reporting (e.g., Allen et al. 2010, narrativescience.com) and social-media monitoring tools for helping journalists find sources (Diakopoulos et al. 2012).

Some tools have dashboard-style interfaces and complex data graphics, which may be most interesting for some professional users. However, the increasing move especially of casual users toward mobile devices with small screens has led to most applications showing original content and mining output that consists of (especially short) texts and a small number of (especially numeric) analytics.

Solution Approaches

Standardization: Tasks, Datasets, and APIs

The development of methods for mining news, blogs, and social media in general has profited from *standard datasets* and *standard tasks* and *competitions*. Prominent examples are the Reuters-21578 dataset, which is not only a collection of newswire articles but also the most classical dataset for text mining in general (https://archive.ics.uci.edu/ml/datasets/Reuters-21578+Text+Categorization+Collection); the larger and also multilingual RCV1, RCV2, and TRC2 datasets (http://trec.nist.gov/data/reuters/reuters.html); the blog datasets provided by the International Conference on Weblogs and Social Media (ICWSM, http://www.icwsm.org); and the SNAP datasets (https://snap.stanford.edu/data). The Topic Detection and Tracking (TDT) research program and workshops (http://www.itl.nist.gov/iad/mig/tests/tdt; Allan 2002) were essential in the formation of news mining as a research topic. Important tasks and competitions that are ongoing, and that also offer important datasets, include the Text Retrieval Conference (TREC, http://trec.nist.gov) and the Text Analysis Conference (TAC, http://www.nist.gov/tac), formerly Document Understanding Conference (DUC, http://duc.nist.gov). The history of tracks/tasks over time in these conferences also illustrates how fields have matured or become less relevant; for example, “blog tracks” have been replaced since 2010 by “microblog tracks,” and “topic detection” has given way to “event detection.”

Standard datasets are one answer to a central problem in news, blogs, and social-media mining in general. Since most platforms are commercial, they restrict access to their current or archived editions. Other platforms offer a free API but make it return a sample whose representativeness and/or even sampling criteria are not known;

this can affect mining results severely (Morstatter et al. 2013). In addition, the terms of use present a challenge for creating reusable datasets (for a solution approach, see McCreadie et al. 2012).

A further caveat concerns all social-media mining results: In general, APIs only give access to "public" posts and not to posts that users have set to "private" or otherwise limited to a restricted audience. In addition, having gained access to an individual's online communication does not mean one may use or process it. Thus, privacy and data protection considerations limit the uses of social media for research, and they require careful interpretations of the results: these may be representative of the public utterances of users, but not all of their online communication.

The Modeling Phase of Text Mining

Solution approaches are based on general data mining methods and adapted to the conceptual specifics of news and blogs and their mining tasks (see list of tasks above). Methods include (document) ▶ classification and ▶ clustering and latent-variable techniques such as (P)LSA or LDA (cf. ▶ feature construction; specifically for an overview of topic models, see Blei 2012), ▶ mixture models, ▶ time series, and ▶ stream mining methods.

Named-entity recognition (e.g., Atkinson and Van der Goot 2009; Ritter et al. 2011; Li et al. 2012) is an important part or companion of tasks such as topic detection or text enrichment (e.g., Štajner et al. 2010). Topic tracking and event threading are used to follow a news story unfolding over time (e.g., Shahaf and Guestrin 2010), and especially for the purposes of summarization over time, special attention is paid to *bursty* topics or events (term introduced by Kleinberg 2002; see Subašić and Berendt 2013 for further references and empirical comparison), i.e., those that are marked by "spikes" in the frequency or other weight of reporting at certain points in time.

Information extraction can help to extract the *event(s)* of a news story. Events involve named entities (e.g., people and locations), a time, and a characterization of what the event is about. Information extraction can leverage background ontologies (e.g., Kuzey et al. 2014). This covers the first four of the "five Ws" of a news story; the "why" and "how" at present remain to be extracted by human readers from the original text (which is therefore generally accessible from platforms; see remarks on semiautomatic sensemaking below). Clustering can be useful for the extraction of events from multilingual sources (Leban et al. 2014). Regularities in how reporting (or the world?) evolves have also been used for predicting events from news (Radinsky and Horvitz 2013). The brevity of microblogs combined with the speed and volume of their streams poses special challenges for event detection (McCreadie et al. 2013).

Sentiment analysis and *opinion mining* are key especially for analyzing blogs and other social media (see overviews in Feldman 2013; Pang and Lee 2007; Potts 2013), and they are evolving toward more sophisticated methods that take syntactic structure and background knowledge/semantics into account (e.g., Gangemi et al. 2014). Sentiment analysis and opinion mining are designed to detect and classify "subjective" content and as such describes (some) social-media content well. It can also be appropriate for "subjective" journalistic genres such as commentary. However, this does not mean that news is really – or can ever be truly – objective. The often subtle and often subconscious structures, backgrounds, and convictions that express themselves in how a news story is told are referred to as media bias or framing, and text mining has begun to address them (e.g., Recasens et al. 2013; Pollak et al. 2011; Odijk et al. 2013).

Further classification tasks that are specifically relevant for news and blogs are generally solved with features that are characteristic of the domain and/or can be easily extracted from its data. They include (a) geolocation (e.g., Hale et al. 2012), (b) recommendation (e.g., tracking multiple topics over time in news, personalized to a user whose interests may change over time was developed by Pon et al. 2007; an approach for microblogs was proposed by Ren et al. 2013), and (c) spam detection and blocking (Kolari et al. 2006; for a general overview, see Castillo and Davison 2011).

Text summarization (for an overview, see Fiori 2014; specifically for microblogs, see Mackie et al. 2014) is a key technique for helping users to get an overview of (a) a single document's key messages or (b) a multitude by different documents, often from different sources that in turn may have copied from one another. Today, most summarizations are extractive, either extracting key sentences or non-sentence structures such as graphs. In real-world applications, even simpler forms are still predominant, including the extraction of single terms based, for example, on frequency and their display in tag clouds and the use of the first sentences of news articles that, by journalistic writing conventions, are designed to summarize the text. Abstractive summarization involves the generation of natural language, which remains a hard problem. Today, it is used mostly for text genres that are highly schematized, such that templates can be used and filled with the entities/constants relevant to the story at hand (see "Emerging application types" above).

Texts, or text summaries, can be represented not only as bags of words, sets of topics or events but also as graphs in which words and/or named entities stand in multiple relations to one another (see Berendt et al. 2014, for examples and further references). (Shallow) semantic parsing is often used to extract triples (e.g., subject-predicate-object statements) (e.g., Štajner et al. 2010; Sudhahar et al. 2015).

Text-based modeling can be enhanced by (e.g., social) *network* structure (e.g., Mei et al. 2008) (cf. ▶ link mining and link discovery). The analysis of how the actors in a network influence one another is important for the domain of news and social media (Guille et al. 2013). Such analyses are applied not only to individual text producers but more often to whole domains. One general question is how blogs and news, viewed in the aggregate, refer to and contextualize each other (e.g., Gamon et al. 2008; Berendt and Trümper 2009; Leskovec et al. 2009).

Specifics of Data Understanding, Data Cleaning, and Data Preparation

Data cleaning is similar to that of other online documents; in particular, it requires the provision or learning of wrappers for removing mark-up elements. Analysis methods that focus on text mining usually ignore hypermedia elements such as photographs and videos or use only their metadata.

While news texts employ standard language and can be handled with general-purpose text-analysis software, the *language* of (micro-)blogs requires specific lexica (e.g., containing the frequently used emoticons), abbreviation expansion and grammatical rules, and similar techniques (see "Noah's ARK" at http://www.ark.cs.cmu.edu/TweetNLP/ for a suite of tools and references), and linguists have found that rather than being "wrong" and ungrammatical, microblogs are evolving toward new systems that resemble spoken language and indicate nuances such as geographical region (Eisenstein 2015). Like other social media, they often contain irony and other indirect uses of language for expressing appreciation or discontent (e.g., Veale and Hao 2010), and this remains a major stumbling block for the machine understanding of these texts.

The *semi-structured* nature of blogs and news can give valuable cues for understanding. For example, the format elements "timestamp" and "number of comments" can be treated as indicators of increased topical relevance and likelihood of being opinionated, respectively (Mishne 2007). A combination of text clustering and *tag* analysis can serve to identify topics as well as the blogs that are on topic and likely to retain this focus over time (Hayes et al. 2007). Twitter *hashtags* have been used, for example, as indicators of sentiment (Wang et al. 2011).

Like other online texts, news and blogs make frequent use of *hyperlinks*, and the content of linked materials may be necessary even for a human reader to understand a post. This is particularly true for microblogs that are often mere pointers to a URL, or a URL plus a short comment. Many mining methods therefore enrich the text by, for example, the contents of referenced URLs (e.g., Abel et al. 2011). *Semantic enrichment* can also utilize external (semi-)structured data; for example, Wikification can add context information to microblogs by drawing on Wikipedia or DBPedia (e.g., Cheng and Roth 2013). All these methods can help to enrich and to disambiguate meaning.

The Importance of Interactive Tools for Semi-automatic Sensemaking

Like most of text mining, machine analyses of news, blogs, and other social media are a first step in a process of human sensemaking, whether for news consumers or for news producers. It is therefore imperative to provide them with interfaces that support further steps. Thus, tools for news consumers (such as news aggregators) typically provide links to the original articles. Tools for news producers show statistics (such as aggregate opinions of "the crowd" or properties of one potential source) as an information for journalists, and topics or events detected in corpora are generally a starting point for a story, but not a story in and of themselves. Reading, understanding, and writing news and blogs can probably never be totally automated. One reason for this is that different people read a given text differently, which is well known in social science media research but still often neglected in computational research – maybe because it requires us to question key methodological concepts of text mining such as "the ground truth." Interactive tools for story detection and tracking have been proposed as an answer to this dilemma (Berendt et al. 2014), and drag-and-drop story editors are used to create one's own new story (storify.com).

In addition, text mining as a method for dealing with large data volumes is often in competition with or combined with human intelligence for doing the same. Thus, for example, the contributions from many (often unpaid) volunteers and interface elements such as voting constitute the "social news aggregator" reddit.com, and Twitter's "retweeting" is a major, and human-led, way in which tweets are fed into, and develop influence across, multiple sub-networks formed by the platform's users. In these human-machine collaborations, the algorithms employed by a platform however are not neutral companions, but shape how users perceive others' opinions, which in turn affects their further posting behavior. For example, Twitter's "trending topics" algorithm rewards bursty topics (cf. Wilson 2013). This implies that even a topic contained in many tweets can, if the interest over time remains stable, disappear from the trending topics and thereby from public visibility. The implications of such algorithmic decisions on user choices and perceptions as well as public decisions and policy are a new research topic that will be relevant not only for text mining.

Synonyms

Commercial Email Filtering; Junk email filtering; Spam detection; Unsolicited commercial email filtering

Definition

Spam filtering is the process of detecting unsolicited commercial email (UCE) messages on behalf of an individual recipient or a group of recipients. Machine learning applied to this problem is used to create discriminating models based on labeled and unlabeled examples of spam and nonspam. Such models can serve populations of users (e.g., departments, corporations, ISP customers) or they can be personalized to reflect the judgments of an individual. An important aspect of spam detection is the way in which textual information contained in email is extracted and used for the purpose of discrimination.

Motivation and Background

Spam has become the bane of existence for both Internet users and entities providing email services. Time is lost when sifting through unwanted messages and important emails may be lost through omission or accidental deletion. According to various statistics, spam constitutes the majority of emails sent today and a large portion of emails actually delivered. This translates to large costs related to bandwidth and storage use. Spam detection systems help to alleviate these issues, but they may introduce problems of their own, such as more complex user interfaces, delayed message delivery, and accidental filtering of legitimate messages. It is not clear if any one approach to fighting spam can lead to its complete eradication and a multitude of approaches have been proposed and implemented. Among existing techniques are those relying on the use of supervised and unsupervised machine learning techniques, which aim to derive a model differentiating spam from legitimate content using textual and nontextual attributes. These methods have become an important component of the antispam arsenal and draw from the body of related research such as text classification, fraud detection and cost-sensitive learning. The text mining component of these techniques is of particular prominence given that email messages are primarily composed of text. Application of machine learning and data mining to the spam domain is challenging, however, due, among others, to the adversarial nature of the problem (Dalvi et al. 2004; Fawcett 2003).

Structure of the Learning System

Overview

A machine-learning approach to spam filtering relies on the acquisition of a learning sample of email data, which is then used to induce a classification or scoring model, followed by tuning and setup to satisfy the desired operating conditions. Domain knowledge may be injected at various stages into the induction process. For example, it is common to a priori specific features that are known be highly correlated with the spam label, e.g., certain patterns contained in email headers or certain words or phrases. Depending on the application environment, messages classified as spam are prevented from being delivered (e.g., are blocked or “bounced”), or are delivered with a mechanism to alert users to their likely spam nature. Filter deployment is followed by continuous evaluation of its performance, often accompanied by the collection of error feedback from its users.

Data Acquisition

A spam filtering system relies on the presence of labeled training data, which are used to induce a model of what constitutes spam and what is legitimate email. Spam detection represents a two-class problem, although it may sometimes be desired to introduce special handling of messages for which a confident decision, either way, cannot be made. Depending on the application environment, the training data may represent emails received by one individual or a group of users. Ideally, the data should correspond to a uniform sample acquired over some period of time preceding filter deployment. Typical problems with data collection revolve around privacy issues, whereby users are unwilling to donate emails of personal or sensitive nature. Additionally, lab- eling mistakes are common where legitimate emails may be erroneously marked as spam or vice versa. Also, since for certain types of emails, the spam/legitimate distinction is personal, one may find that the same message content is labeled in a conflicting manner by different users (or even by the same user at different times). Therefore, data cleaning and conflict resolution techniques may need to be deployed, especially when building filters that serve a large and diverse user population.

Due to privacy concerns, few large publicly email corpora exist. The ones created for the TREC Spam Track (TREC data is available from: http://plg.uwaterloo.ca/ gvcormac/treccorpus/). stand out in terms of size and availability of published comparative results.

Content Encoding and Deobfuscation

Spam has been evolving in many ways over the course of time. Some changes reflect the shift in content advertised in such messages (e.g., from pornography and pharmaceuticals to stock schemes and *phish*). Others reflect the formatting of content. While early spam was sent in the form of plain text, it subsequently evolved into more complex HTML, with deliberate attempts to make extraction of meaningful textual features as difficult as possible. Typically, obfuscation (a list of obfuscation techniques is maintained at http://www.jgc.org/tsc.html) aims at

(a) Altering the text extracted from the message for words visible to the user (e.g., by breaking up the characters in message source by HTML tags, encoding the characters in various ways, using character look-alikes, wrapping the display of text using script code executed by the message viewer). This tactic is used to hide the message "payload."
(b) Adding content that is not visible to the user (e.g., using the background color or zero-width font to render certain characters/words). This tactic typically attempts to add "legitimate content."
(c) Purposeful misspelling of words known to be fairly incriminating (e.g., *Viagra* as *V1agr@*), in a way that allows the email recipient to still understand the spammer's message.

The line of detection countermeasures aiming at preventing effective content extraction continues in the form of image spam, where the payload message is encoded in the form of an image that is easily legible to a human but poses challenges to an automatic content extraction system. To the extent that rich and multimedia content gets sent out by legitimate users in increasing proportions, spammers are likely to use the complexity of these media to obfuscate their messages even further. The very fact that obfuscation is attempted, however, provides an opportunity for machine learning techniques to use obfuscation presence as a feature. Thus, even if payload content cannot be faithfully decoded, the very presence of elaborate encoding may help in identifying spam.

Feature Extraction and Selection

An email message represents a semistructured document, commonly following the rfc822 standard (www.faqs.org/rfcs/rfc822.html). Its header consists of fields indicative of formatting, authorship, and delivery information, while its body contains the actual content being sent. There can be little correctness enforcement of the header fields and spamming techniques often rely on spoofing and forging of the header data, although this may provide evidence of tempering. Many early approaches to detect spam depended predominantly on hand-crafted rules identifying inconsistencies and peculiarities of spam email headers. Manually or automatically generated header features continue to be relevant even when other features (e.g., message text) are considered.

Given that an email message tends to be primarily text, features traditionally useful in text categorization have also been found useful in spam detection. These include individual words, phrases, character n-grams, and other textual components (Siefkes et al. 2004). Natural language processing (NLP) techniques such as stemming, stop-word removal, and case folding are also sometimes applied to normalize the features further. Text extraction is often nontrivial due to the application of content obfuscation techniques. For example, standard lexical feature extractors may need to be strengthened to correctly identify word boundaries (e.g., in cases where groups of characters within a word are separated by zero-width HTML tags).

Extraction of features from nontextual attachments (e.g., images, audio, and video) is also possible but tends to be more computationally demanding. Other types of features capture the way a message if formatted, encoded in HTML, composed of multiple parts, etc.

Although nontextual features have different properties than text, it is common practice to combine them with textual features and present a single unified representation to the classifier. Indeed, some approaches make no distinction between text and formatting even during the process of feature extraction, and apply pattern discovery techniques to identifying complex features automatically (Rigoutsos and Huynh 2004). The advantage of such techniques is that they do not require rich domain knowledge and can discover new useful patterns. Due to the large space of possible patterns they can potentially be computationally expensive. However, even the seemingly simplistic treatment of an email message as a plain-text document with "words" delimited by white space often leads to very good results.

Even though typical text documents are already very sparse, the problem is even more pronounced for the email medium due to frequent misspelling and deliberate randomization performed by spammers. Insisting on using all such variations may lead to overfitting for some classifiers, and it leads to large filter memory footprints that are undesirable from an operational standpoint. However, due to the constantly changing distribution of content, it may be dangerous to rely on very few features. Traditional approaches to feature selection based on measures such as Information Gain have been reported as successful in the spam filtering domain, but even simple rudimentary attribute selection based on removing very rare and/or very frequent features tends to work well.

There are a number of entities that can be extracted from message text and that tend to be of relevance in spam detection. Among others, there are telephone numbers and URLs. In commercial email and in spam, these provide a means of ordering products and services and thus, offer important information for vendor and campaign tracking. Detection of signature and mailing address blocks can also be of interest, even if only to indicate their presence or absence.

Learning Algorithms

A variety of learning algorithms have been applied in the spam filtering domain. These range from linear classifiers such as Naive Bayes (Metsis et al. 2006), logistic regression (Goodman and Yih 2006), or linear support vector machines (Drucker et al. 1999; Kołcz and Alspector 2001; Sculley and Wachman 2007) to nonlinear ones such as boosted decision trees (Carreras and Màrquez 2001). Language modeling and statistical compression techniques have also been found quite effective (Bratko et al. 2006). In general, due to the high dimensionality of the feature space, the classifier chosen should be able to handle tens of thousand, or more, attributes without overfitting the training data.

It is usually required that the learned model provides a scoring function, such that for email message x score(x) $\in$ R, with higher score values corresponding to higher probability of the message being spam. The score function can also be calibrated to represent the posterior probability Pspam $|x \in 0, 1$, although accurate calibration is difficult due to constantly changing class and content distributions. The scoring function is used to establish a decision rule:

$$\text{score}(x) \geq th \rightarrow \text{spam}$$

where the choice of the decision threshold th is driven by the minimization of the expected cost. In the linear case, the scoring function takes the form

$$\text{score}(x) = w \cdot x + b$$

where w is the weight vectors, and x is a vector representation of the message. Sometimes scores are normalized with a monotonic function, e.g., to give an estimate of the probability of x being spam.

Linear classifiers tend to provide sufficiently high accuracy, which is also consistent with other application domains involving the text medium. In particular, many variants of the relatively simple Naive Bayes classifier have been found successful in detecting spam, and Naive Bayes often provides a baseline for systems employing more complex classification algorithms (Metsis et al. 2006).

One Model Versus Multiple Models

It often pays off to combine different types of classifiers (even different linear ones) in a sequential or parallel fashion to benefit from the fact that different classifiers may provide an advantage in different regions of the feature space. Stacking via ▶ linear regression has been reported to be effective for this purpose (Sakkis et al. 2001; Segal et al. 2004). One can generally distinguish between cases where all classifiers are induced over the same data and cases where several different datasets are used. In the former case, the combination process exploits the biases of different learning algorithms. In the latter case, one can consider building a multitude of detectors, each targeting a different subclass of spam (e.g., phish, pharmaceutical spam, “Nigerian” scams, etc.). Datasets can also be defined on a temporal basis, so that different classifiers have shorter or longer memory spans. Other criteria of providing different datasets are also possible (e.g., based on the language of the message).

Additional levels of complexity in the classifier combination process can be introduced by considering alternative feature representations for each dataset. For example, a single data collection and a single learning method can be used to create several different classifiers, based upon alternative representations of the same data (e.g., using just the header features or just the message text features).

The method of classifier combination will necessarily depend on their performance and intended area of applications. The combination regimes can range from simple logical-OR through linear combinations to complex nonlinear rules, either derived automatically to maximize the desired performance or specified manually with the guidance of expert domain knowledge.

Off-Line Adaptation Versus Online Adaptation

A spam filtering system can be configured to receive instant feedback from its users, informing it whenever certain messages get misdelivered (this necessarily does not include cases where misclassified legitimate messages are simply blocked). In the case of online filters, the feedback information may be immediately used to update the filtering profile. This allows a filter to adjust to the changing distribution of email content and to detection countermeasures employed by spammers. Not all classifiers are easily amenable to the online learning update, although online versions of well-known learners such as logistic regression (Goodman and Yih 2006) and linear SVMs (Sculley and Wachman 2007) have been proposed. The distinguishing factor is the amount of the original training data that needs to be retained in addition to the model itself to perform future updates. In this respect, Naive Bayes is particularly attractive since it does not require any of the original data for adaptation, with the model itself providing all the necessary information.

One issue with the user feedback signal, however, is its bias toward current errors of the classifier, which for learners depending on the training data being an unbiased sample drawn from the underlying distribution may lead to overcompensation rather than an improvement in filtering accuracy. As an alternative, unbiased feedback can be obtained by either selectively querying users about the nature of uniformly sampled messages or by deriving the labels implicitly.

In the case where off-line adaptation is in use, the feedback data is collected and saved for later use, whereby the filtering models are retrained periodically or only as needed using the data collected. The advantage of off-line adaptation is that it offers more flexibility in terms of the learning algorithm and its optimization. In particular, model retraining can take advantage of a larger quantity of data, and does not have to be constrained to be an extension of the current version of the model. As a result, it is, e.g., possible to redefine the features from one version of the spam filter to the next. One disadvantage is that model updates are likely to be performed less frequently and may be lagging behind the most recent spam trends.

User-Specific Versus User-Independent Spam Detection

What constitutes a spam message tends to be personal, at least for some types of spam. Various commercial messages, such as promotions and advertisements, e.g., may be distributed in a solicited or unsolicited manner, and sometimes only the end recipient may be able to judge which. In that sense, user-specific spam detection has the potential of being most accurate, since a user’s own judgments are used to drive the training process. Since the nonspam content received by any particular user is likely to be more narrowly distributed when compared a larger user population, this makes the discrimination problem much simpler. Additionally, in the adversarial context, a spammer should find it more difficult to measure the success of penetrating personalized filter defenses, which makes it more difficult to craft a campaign that reaches sufficiently many mail inboxes to be profitable.

One potential disadvantage of such solutions is the need for acquiring labeled data on a user by user basis, which may be challenging. For some users historical data may not yet exist (or has already been destroyed), for others even if such data exist, labeling may seem too much of a burden for the users. Aside from the data collection issues, personal spam filtering faces maintainability issues, as the filter is inherently controlled by its user. This may result in less-than-perfect performance, e.g., if the user misdirects filter training.

From the perspective of institutions and email service providers, it is often more attractive to maintain just one set of spam filters that service a larger user population. This makes them simpler to operate and maintain, but their accuracy may depend on the context of any particular user. The advantage of centralized filtering when serving large user populations is that global trends can be more readily spotted and any particular user may be automatically protected against spam, affecting other users. Also, the domain knowledge of the spam-filtering analysts can be readily injected into the filtering pipeline.

To the extent that a service provider maintains personal filters for its population of users, there are potential large system costs to account for, so that a complete cost-benefit analysis needs to be performed to assess the suitability of such as solution as opposed to a user-independent filtering complex. More details on the nature of such trade-offs can be found in Kołcz et al. (2006).

Clustering and Volumetric Techniques

Content clustering can serve as an important data understanding technique in spam filtering. For example, large clusters can justify the use of specialized classifiers and/or the use of cost-sensitive approaches in classifier learning and evaluation (e.g., where different costs are assigned to different groups of content within each class (Kołcz and Alspector 2001).

Both spam and legitimate commercial emails are often sent in large campaigns, where the same or highly similar content is sent to a large number of recipients, sometimes over prolonged periods of time. Detection of email campaigns can therefore play an important role in spam filtering. Since individual messages of a campaign are highly similar to one another, this can be considered a variant of near-replica document detection (Kołcz 2005). It can also be seen as relying on identification of highly localized spikes in the content density distribution. As found in Yoshida et al. (2004), density distribution approaches can be highly effective, which is especially attractive given that they do not require the explicitly labeled training data. Tracking of spam campaigns may be made difficult due to content randomization, and some research has been directed at making the detection methods robust in the presence such countermeasures (Kołcz 2005; Kołcz and Chowdhury 2007).

Misclassification Costs and Filter Evaluation

An important aspect of spam filtering is that the costs of misclassifying spam as legitimate email are not the same as the costs of making the opposite mistake. It is thus commonly assumed that the costs of a false positive mistake (i.e., a legitimate email being misclassified as spam) are much higher than the cost of mistaking spam for legitimate email. Given the prevalence of spam π and the false-spam (FS) and false-legitimate (FL) rates of the classifier, the misclassification cost c can be expressed as

$$c = C_{\mathrm{FS}} \cdot (1 - \pi) \cdot \mathrm{FS} + C_{\mathrm{FL}} \cdot \pi \cdot \mathrm{FL}$$

where C_{FS} and C_{FL} are the costs of making a false-spam and false-legitimate mistake, respectively (there is no penalty for making the correct decision). Since actual values of C_{FS} and C_{FL} are difficult to quantify, one typically sees them combined in the form of a ratio, $\lambda = C_{\mathrm{FS}}/C_{\mathrm{FL}}$, and the overall cost can be expressed as relative to the cost of a false-legitimate misclassification e.g.,

$$c_{\mathrm{rel}} = \lambda \cdot (1 - \pi) \cdot \mathrm{FS} + \pi \cdot FL$$

Practical choices of λ tend to range from 1 to 1,000. Nonuniform misclassification costs can be used during the process of model induction or in postprocessing when setting up the operating parameters of a spam filter, e.g., using the receiver operating characteristic (ROC) analysis.

Since the costs and cost ratios are sometimes hard to define, some approaches to evaluation favor direct values of the false-spam and false-legitimate error rates. This captures the intuitive requirement that an effective spam filter should provide high detection rate at a close-to-zero false-spam rate. Alternatively, threshold independent metrics such as the area under the ROC (AUC) can be used (Bratko et al. 2006; Cormack and Lynam 2006), although other measures have also been proposed (Sakkis et al. 2001).

Adaptation to Countermeasures

Spam filtering is an inherently adversarial task, where any solution deployed on a large scale is likely to be met with a response on the part of the spammers. To that extent that the success of a spam filter can be pinpointed to any particular component (e.g., the type of features used), that prominent component is likely to be attacked directly and may become a victim of its own success. For example, the use of word features in spam filtering encourages countermeasures in the form of deliberate misspellings, word fragmentation, and "invisible ink" in HTML documents. Also, since some words are considered by a model inherently more legitimate than others, "word stuffing" has been used to inject large blocks of potentially legitimate vocabulary into an otherwise spammy message in the hope that this information outweighs the evidence provided by the spam content (Lowd and Meek 2005).

Some authors have attempted to put the adversarial nature of spam filtering in the formal context of game theory (Dalvi et al. 2004). One difficulty of drawing broad conclusion based on such analyses is the breadth of the potential attack/defense front, of which only small sections have been successfully captured in the game-theory formalism. The research on countering the countermeasures points at using multiple diverse filtering components, normalization of features to keep them invariant to irrelevant alterations. A key point is that frequent filter retraining is likely to help in keeping up with the shifts in content distribution, both natural and due to countermeasures.

Future Directions

Reputation Systems and Social Networks

There has been a growing interest in developing reputation systems capturing the trustworthiness of a sender with respect to a particular user or group of users. To this end however, the identity of the sender needs to be reliably verified, which poses challenges and presents a target for potential abuses of such systems. Nevertheless, reputation systems are likely to grow in importance, since they are intuitive from the user perspective in capturing the communication relationships between users. Sender reputation can be hard or soft. In the hard variant, the recipient always accepts or declines messages from a given sender. In the soft variant, the reputation reflects the level of trustworthiness of the sender in the context of the given recipient. When sender identities resolve to individual email addresses, the reputation system can be learned via analysis of a large social network that documents who exchanges email with whom. The sender identities can also be broader however, e.g., assigning reputation to a particular mail server or all mail servers responsible for handling the outbound traffic for a particular domain. On the recipient side, reputation can also be understood globally to represent the trustworthiness of the sender with respect to all recipients hosted by the system. Many open questions remain with regard to computing and maintaining reputations as well as using them effectively to improve spam detection. In the context of text mining, one such question is the extent to which email content analysis can be used to aid the process of reputation assessment.

Definition

▶ Text Mining methods allow for the incorporation of textual data within applications of semantic technologies on the Web. Application of these techniques is appropriate when some of the data needed for a Semantic Web use scenario are in textual form. The techniques range from simple processing of text to reducing vocabulary size, through applying shallow ▶ natural language processing to constructing new semantic features or applying information retrieval to selecting relevant texts for analysis, through complex methods involving integrated visualization of semantic information, semantic search, semiautomatic ontology construction, and large-scale reasoning.

Motivation and Background

Semantic Web applications usually involve deep structured knowledge integrated by means of some kind of ontology. Text mining methods, on the other hand, support the discovery of structure in data and effectively support semantic technologies on data-driven tasks such as (semi)automatic ▶ ontology acquisition, extension, and mapping. Fully automatic text mining approaches are not always the most appropriate for combination with Semantic Web content, because often it is too difficult or too costly to fully integrate the available background domain knowledge into a suitable representation. For such cases, semiautomatic methods, such as ▶ Active Learning and ▶ Semi-supervised Text Processing (see ▶ Semi-supervised Learning), can be applied to make use of small pieces of human knowledge to provide guidance toward the desired ontology or other models. Application of these semiautomated techniques can reduce the amount of human effort required to produce training data by an order of magnitude while preserving the quality of results.

To date, Semantic Web applications have typically been associated with data, such as text documents, and corresponding metadata that have been designed to be relatively easily manageable by humans. Humans are, for example, very good at reading and understanding text and tables. General semantic technologies, on the other hand, aim more broadly at handling data modalities including multimedia, signals from emplaced or remote sensors, and the structure and content of communication and transportation graphs and networks. In handling such multimodal data, much of which is not readily comprehensible by unaugmented humans, there must be significant emphasis on fully or semiautomatic methods offered by knowledge discovery technologies whose application is not limited to a specific data representation (Grobelnik and Mladenic 2005).

Data and the corresponding semantic structures change over time, and semantic technologies also aim at adapting the ontologies that model the data accordingly. For most such scenarios, extensive human involvement in building models and adapting them according to the data is too costly, too inaccurate, and too slow. ▶ Stream mining (Gaber et al. 2005) techniques (Data Streams: Clustering) allow text mining of dynamic data (e.g., notably in handling a stream of news or of public commentary).

Ontology is a fundamental method for organizing knowledge in a structured way and is applied, along with formalized reasoning, in areas from philosophy to scientific discovery to knowledge management and the Semantic Web. In computer science, an ontology generally refers to a graph or network structure consisting of a set of concepts (vertices in a graph), a set of relationships connecting those concepts (directed edges in a graph), and, possibly, a set of distinguished instance concepts assigned to particular class concepts (data records assigned to vertices in a graph). Although much useful knowledge can be represented by the ground binary relations most conveniently encoded as graphs, more complex relationships involving more than two entities are needed, and the graph metaphor is more remote. In many cases, knowledge is structured in one of these ways to allow for automated inference based on a logical formalism such as the ▶ predicate calculus (Barwise and Etchemendy 2002); for these applications, an ontology often further comprises a set of rules or produces new knowledge within the representation from existing knowledge. An ontology containing both instance data and rules for its application is often referred to as a knowledge base (KB) (e.g., Lenat 1995).

Machine learning practitioners refer to the task of automatically constructing these ontologies as ▶ ontology learning. From this point of view, an ontology is seen as a class of models – somewhat more complex than most used in machine learning – which need to be expressed in some ▶ Hypothesis Language. This definition of ontology learning (from Grobelnik and Mladenic 2005) enables a decomposition into several machine learning tasks, including ▶ learning concepts, identifying relationships between existing concepts, populating an existing ontology/structure with instances, identifying change in dynamic ontologies, and inducing rules over concepts, background knowledge, and instances.

Following this scheme, text mining methods have been applied to extending existing ontologies based on Web documents, learning semantic relations from text based on collocations, semiautomatic data-driven ontology construction based on ▶ document clustering and classification, extracting semantic graphs from text, transforming text into ▶ RDF triples (a commonly used Semantic Web data representation), and mapping triplets to semantic classes using several kinds of lexical and ontological background knowledge. Text mining is also intensively used in the effort to produce a Semantic Web for annotation of text with concepts from ontology. For instance, a text document is split into sentences, each sentence is represented as a word vector, sentences are clustered, and each cluster is labeled by the most characteristic words from its sentences and mapped upon the concepts of a general ontology. Several approaches that integrate ontology management, knowledge discovery, and human language technologies are described in Davies et al. (2009).

Extending the text mining paradigm, efforts are aimed at giving machines an approximation of the full human ability to acquire knowledge from text. Some of the systems (Curtis et al. 2009; Mitchell 2005; Rusu 2014) actively use background knowledge in the extraction process for disambiguation or knowledge structuring. Machine reading aims at full text understanding by integrating knowledge-based construction and use into syntactically sophisticated natural ▶ language analysis, leading to systems that autonomously improve their ability to extract further knowledge from text (e.g., Curtis et al. 2009; Etzioni et al. 2007; Mitchell 2005; Starc and Fortuna 2012; Starc and Mladenic 2013).

Biomedical Text Mining

Because of the development and widespread use of high-quality biomedical knowledge bases, such as the Gene Ontology (Ashburner et al. 2000), Cell Ontology (Bard et al. 2005), and Linked Neuron Data (Zeng et al. 2015), and the overwhelming volume of the relevant literature (24 million biomedicine citations in PubMed), biomedical knowledge extraction is subject to a great deal of research. Relevant shared evaluation tasks include BioCreative (Hirschman et al. 2005) and BioNLP (Cohen et al. 2014). Although much of the work on biological fact extraction still relies on supervised training with closely annotated training data, with the risk of over-constraining the mapping of semantics to particular text substrings, volume of high-quality Semantic Web fact bases has enabled more natural training methods, such as distant supervision (Augenstein et al. 2014).

Definition

The term *text visualization* describes a class of knowledge discovery techniques that use interactive graphical representations of textual data to enable knowledge discovery via recruitment of human visual pattern recognition and spatial reasoning capabilities. It is a subclass of *information visualization*, which more generally encompasses visualization of nonphysically based (or "abstract") data of all types. Text visualization is distinguished by its focus on the unstructured (or *free text*) component of information. While the term "text visualization" has been used to describe a variety of graphical methods for deriving knowledge from text, it is most closely associated with techniques for depicting the semantic characteristics of large document collections. Text visualization systems commonly employ unsupervised machine learning techniques as part of broader strategies for organizing and graphically representing such collections.

Motivation and Background

The Internet enables universal access to vast quantities of information, most of which (despite admirable efforts Berners-Lee et al. 2001) exists in the form of unstructured and unorganized text. Advancements in search technology make it possible to retrieve large quantities of this information with reasonable precision; however, only a tiny fraction of the information available on any given topic can be effectively exploited.

Text visualization technologies, as forms of computer-supported knowledge discovery, aim to improve our ability to understand and utilize the wealth of text-based information available to us. While the term "text visualization" has been used to describe a variety of techniques for graphically depicting the characteristics of free-text data (Havre et al. 2002; Small 1996), it is most closely associated with the so-called *semantic clustering* or *semantic mapping* techniques (Chalmers and Chitson 1992; Kohonen et al. 2000; Lin et al. 1991; Wise et al. 1995). These methods attempt to generate summary representations of document collections that convey information about their general topical content and similarity structure, facilitating general domain understanding and analytical reasoning processes.

Text visualization methods are generally based on vector space models of text collections (Salton 1989), which are commonly used in information retrieval, clustering, and categorization. Such models represent the text content of individual documents in the form of vectors of frequencies of the terms (*text features*) they contain. A document collection is therefore represented as a collection of vectors. Because the number of unique terms present in a document collection generally is in the range of tens of thousands, a dimensionality reduction method such as singular value decomposition (SVD) (Deerwester et al. 1990) or other matrix decomposition method (Kao et al. 2008; Booker et al. 1999) is typically used to eliminate noise terms and reduce the length of the document vectors to a tractable size (e.g., 50–250 dimensions). Some systems attempt to first identify discriminating features in the text and then use mutual probabilities to specify the vector space (York et al. 1995).

To enable visualization, the dimensions must be further reduced to two or three. The goal is a graphical representation that employs a "spatial proximity means conceptual similarity" metaphor where topically similar text documents are represented as nearby points in the display. Various regions of the semantic map are subsequently labeled with descriptive terms that convey the primary concepts described by nearby documents. The text visualization can thus serve as a kind of graphical "table of contents" depicting the conceptual similarity structure of the collection.

Text visualization systems therefore typically implement four key functional components, namely,

1. A *tokenization* component that characterizes the lexical content of text units via extraction, normalization, and selection of key terms
2. A *vector space modeling* component that generates a computationally tractable vector space representation of a collection of text units
3. A *spatialization* component that uses the vector space model to generate a 2D or 3D spatial configuration that places the points representing conceptually similar text units in near spatial proximity
4. A *labeling* component that assigns characteristic text labels to various regions of the semantic map

Although machine learning techniques can be used in several of these steps, their primary usage is in the spatialization stage. An unsupervised learning algorithm is typically used to find meaningful low-dimensional structures hidden in high-dimensional document feature spaces.

Structure of Learning System

Spatialization is a term generically used in ▸information visualization to describe the process of generating a spatial representation of inherently nonspatial information. In the context of text visualization, this term generally refers to the application of a nonlinear dimensionality reduction algorithm to a collection of text vectors in order to generate a visually interpretable two- or three-dimensional representation of the similarity structure of the collection. The goal is the creation of a *semantic similarity map* that positions graphical features representing text units (e.g., documents) conceptually similar to one another near one another in the visualization display. These maps may be further abstracted to produce more general summary representations of text collections that do not explicitly depict the individual text units themselves (Wise et al. 1995).

A key assumption in text visualization is that text units which express similar concepts will employ similar word patterns and that the existence of these word correlations creates coherent structures in high-dimensional text feature spaces. A further assumption is that text feature spaces are nonlinear but that their structural characteristics can be approximated by a smoothly varying low-dimensional manifold. The text spatialization problem thus becomes one of finding an embedding of the feature vectors in a two- or three-dimensional manifold that best approximates this structure. Because the intrinsic dimensionality of the data is invariably much larger than two (or three), significant distortion is unavoidable. However, because the goal of text visualization is not necessarily the development of an accurate representation of interdocument similarities, but rather the depiction of broad (and ambiguously defined) semantic relationships, this distortion is generally considered acceptable.

Text vector spatialization therefore involves the fitting of a model into a collection of observations. Most text visualization systems developed to date have employed some type of unsupervised learning algorithm for this purpose. In general, the desired characteristics of an algorithm used for text spatialization include that it (1) preserves global properties of the input space, (2) preserves the pairwise input distances to the greatest extent possible, (3) supports out-of-sample extension (i.e., the incremental addition of new documents), and (4) has low computational and memory complexity. Computational and memory costs are key considerations, as a primary goal of text visualization is the management and interpretation of extremely large quantities of textual information.

A leading approach is to iteratively adapt the nodes of a fixed topology mesh to the high-dimensional feature space via adaptive refinement. This is the basis of the well-known Kohonen feature mapping algorithm, more commonly referred to as the ▶ self-organizing map (SOM) (Kohonen 1997). In a competitive learning process, text vectors are presented one at a time to a (typically triangular) grid, the nodes of which have been randomly initialized to points in the term space. The Euclidean distance to each node is computed, and the node closest to the sample is identified. The position of the winning node, along with those of its topologically nearest neighbors, is incrementally adjusted toward the sample vector. The magnitude of the adjustments is gradually decreased over time. The process is generally repeated using every vector in the set for many hundreds or thousands of cycles until the mesh converges on a solution. At the conclusion, the samples are assigned to their nearest nodes, and the results are presented as a uniform grid. In the final step, the nodes of the grid are labeled with summary terms which describe the key concepts associated with the text units that have been assigned to them.

Although self-organizing maps can be considered primarily a clustering technique, the grid itself theoretically preserves the topological properties of the input feature space. As a consequence, samples that are nearest neighbors in the feature space generally end up in topologically adjacent nodes. However, while SOMs are topology-preserving, they are not distance-preserving. Vectors that are spatially distant in the input space may be presented as proximal in the output, which may be semantically undesirable. SOMs have a number of attractive characteristics, including straightforward out-of-sample extension and low computational and memory complexity. Examples of the use of SOMs in text visualization applications can be found in Lin et al. (1991), Kaski et al. (1998), and Kohonen et al. (2000).

Often, it is considered desirable to attempt to preserve the distances among the samples in the input space to the greatest extent possible in the output. The rationale is that the spatial proximities of the text vectors capture important and meaningful characteristics of the associated text units: spatial "nearness" corresponds to conceptual "nearness." As a consequence, many text visualization systems employ distance-preserving dimensionality reduction algorithms. By far, the most commonly used among these is the class of algorithms known as *multidimensional scaling* (MDS) algorithms.

Multidimensional scaling is "a term used to describe any procedure which starts with the 'distances' between a set of points (or individuals or objects) and finds a configuration of the points, preferably in a smaller number of dimensions, usually 2 or 3" (Chatfield and Collins 1980, quoted in Chalmers and Chitson 1992). There are two main subclasses of MDS algorithms. Metric (quantitative, also known as classical) MDS algorithms attempt to preserve the pairwise input distances to the greatest extent possible in the output configuration, while nonmetric (qualitative) techniques attempt only to preserve the rank order of the distances. Metric techniques are most commonly employed in text visualization.

Metric MDS maps the points in the input space to the output space while maintaining the pairwise distances among the points to the greatest extent possible. The quality of the mapping is expressed in a stress function which is minimized using any of a variety of optimization methods, e.g., via eigen decomposition of a pairwise dissimilarity matrix, or using iterative techniques such as generalized Newton–Raphson, simulated annealing, or genetic algorithms. A simple example of a stress function is the raw stress function (Kruskal 1964) defined by

$$\phi(Y) = \sum_{ij} (||x_i - x_j|| - ||y_i - y_j||)^2$$

in which $||x_i - x_j||$ is the Euclidean distance between points x_i and x_j in the high-dimensional space and $||y_i - y_j||$ is the distance between the corresponding points in the output space. A variety of alternative stress functions have been proposed (Cox and Cox 2001). In addition to its distance-preserving characteristics, MDS has the added advantage of preserving the global properties of the input space. A major disadvantage of MDS, however, is its high computational complexity, which is approximately $O(kN^2)$, where N is the number of data points and k is the dimensionality of the embedding. Although computationally expensive, MDS can be used practically on data sets of up to several hundred documents in size. Another disadvantage is that out-of-core extension requires reprocessing of the full data set if an optimization method which computes the output coordinates all at once is used.

The popularity of MDS methods has led to the development of a range of strategies for improving on its computational efficiency to enable scaling of the technique to text collections of larger size. One approach is to use either cluster centroids or a randomly sampled subset of input vectors as surrogates for the full set. The surrogates are down-projected independently using MDS, and then the remainder of the data is projected relative to this "framework" using a less expensive algorithm, e.g., distance-based triangulation. This is the basis for the *anchored least stress* algorithm used in the SPIRE text visualization system (York et al. 1995), as well as the more recently developed Landmark MDS (de Silva and Tenenbaum 2003) algorithm.

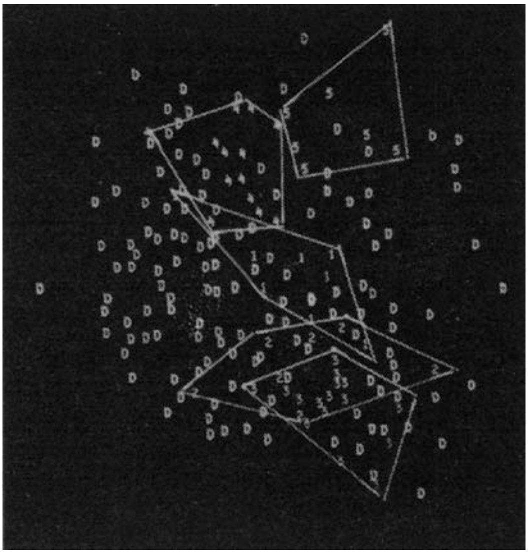
While self-organizing maps and multidimensional scaling techniques have received the most attention to date, a number of other machine learning techniques have also been used for text spatialization. The Starlight system (Risch et al. 1999) uses *stochastic proximity embedding* (Agrafiotis 2003), a high-speed nonlinear manifold learning algorithm. Other approaches have employed methods based on graph layout techniques (Fabrikant 2001). Generally speaking, any of a number of techniques for performing dimensionality reduction in a correlated system of measurements (classified under the rubric of factor analysis in statistics) may be employed for this purpose.

Machine learning algorithms can also be used in text visualization for tasks other than text vector spatialization. For example, generation of descriptive labels for semantic maps requires partitioning of the text units into related sets. Typically, a partitioning-type ▶ clustering algorithm such as K-means is used for this purpose (see ▶ Partitional Clustering), either as an element of the spatialization strategy (see York et al. 1995) or as a postspatialization step. The labeling process itself may also employ machine learning algorithms. For instance, the TRUST system (Booker et al. 1999; Kao et al. 2008) employed by Starlight generates meaningful labels for document clusters using a kind of ▶ unsupervised learning. By projecting a cluster centroid defined in the reduced dimensional representation (e.g., 50–250 dimensions) back into the full-term space, terms related to the content of the documents in the cluster are identified and used as summary terms. Machine learning techniques can also be applied indirectly during the tokenization phase of text visualization. For example, information extraction systems commonly employ rule sets that have been generated by a supervised learning algorithm (Mooney and Bunescu 2006). Such systems may be used to identify tokens that are most characteristic of the overall topic of a text unit or are otherwise of interest (e.g., the names of people or places). In this way, the dimensionality of the input space can be drastically reduced, accelerating downstream processing while simultaneously improving the quality of the resulting visualizations.

Applications

Sammon

The first text visualization system based on a text vector space model was likely a prototype developed in the 1960s by John Sammon's "nonlinear mapping," or *NLM*, algorithm (today referred to as organizing text data). The configuration depicted here is the result of applying Sammon's algorithm to a collection of 188 documents represented as 17-dimensional vectors determined according to document relevance to 1,125 keywords and phrases. Among other interesting and prescient ideas, Sammon describes techniques for interacting with text visualizations depicted on a "CRT display" using a light pen (Fig. 1).



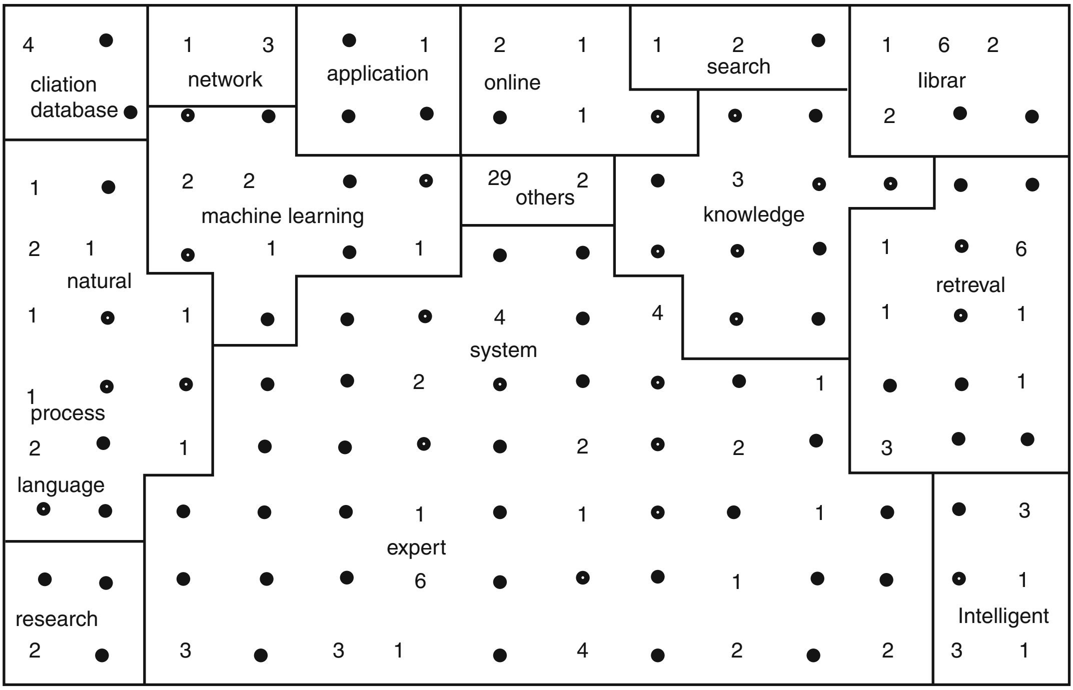
Text Visualization, Fig. 1 Text Visualisation on a CRT display using a light pen

Lin

Lin's 1991 prototype (Lin et al. 1991) was one of the first to demonstrate the use of self-organizing maps for organizing text documents. Lin formed a 25-dimensional vector space model of a 140-document collection using 25 key index terms extracted from the text. The document vectors were used to train a 140-node feature map, generating the result shown here (the fact that the number of nodes matches the number of documents is coincidental). Lin was also among the first to assign text labels to various regions of the resulting map to improve the interpretability and utility of the resulting product (Fig. 2).

BEAD

The BEAD system (Chalmers and Chitson 1992) was a text visualization prototype



Text Visualization, Fig. 2 Labelled self-organising maps

developed during the early 1990s at Rank Xerox EuroPARC. BEAD employed a vector space model constructed using document keywords and a hybrid MDS algorithm based on an optimized form of simulated annealing. Although it did not include a region labeling component, BEAD did support highlighting of visualization features in response to query operations, a now standard text visualization system feature. The BEAD project also pioneered a number of now common interaction techniques and was among the first to explore 3D representations of document collections (Fig. 3).

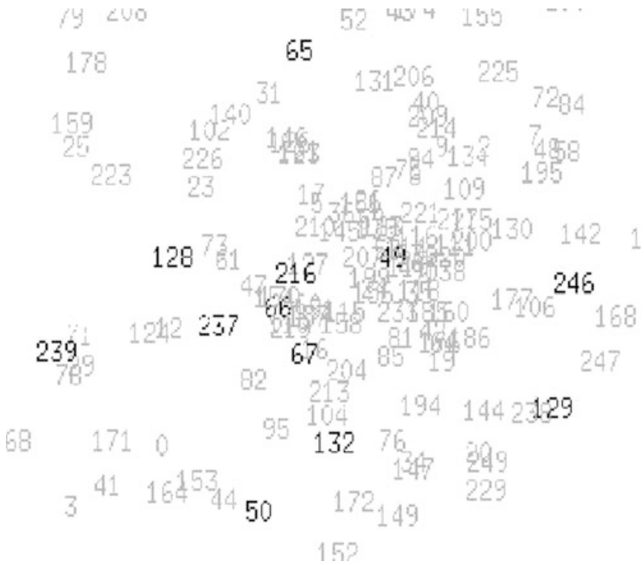
IN-SPIRE

IN-SPIRE (formerly SPIRE, Spatial Paradigm for Information Retrieval and Exploration) (Wise et al. 1995) was originally developed in 1995 at Pacific Northwest National Laboratory (PNNL). Over the years, IN-SPIRE has evolved from using MDS to anchored least stress to a hybrid clustering/PCA projection scheme. The SPIRE/IN-SPIRE system introduced several new concepts, including the use of a 3D "landscape" abstraction (called a *ThemeView*) for depicting the general characteristics of large text collections. A recently developed parallelized version of the software is capable of generating visualizations of document collections containing millions of items (Fig. 4).

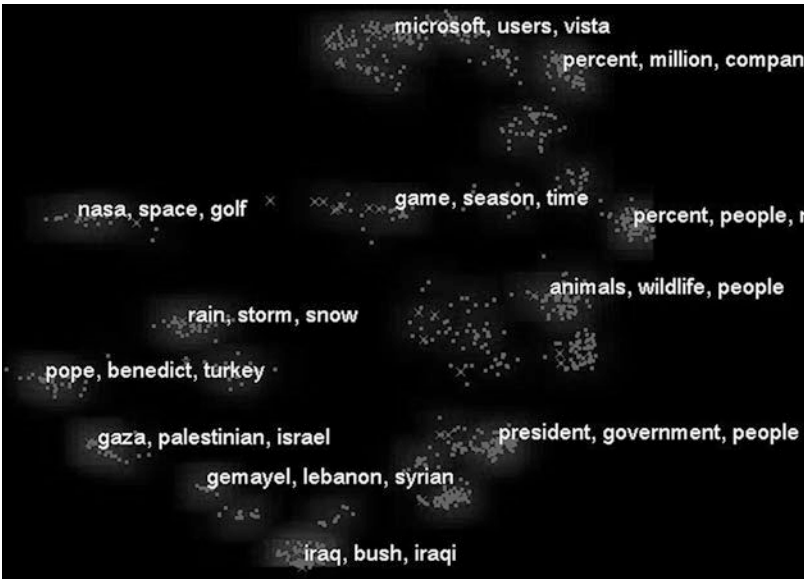
WEBSOM

WEBSOM (Kaski et al. 1998) was another early application of Kohonen self-organizing maps to text data. Early versions of WEBSOM used an independent SOM to generate reduced dimensionality text vectors which were then mapped with a second SOM for visualization purposes. More recent SOM-based text visualization experiments have employed vectors constructed via random projections of weighted word histograms (Kohonen et al. 2000). SOMs have been used to generate semantic maps containing millions of documents (Fig. 5).

Text Visualization, Fig. 3 3D representation of document collections



Text Visualization, Fig. 4 Large scale 3D representation of document collections



Starlight

Starlight (Risch et al. 1999) is a general-purpose information visualization system developed at PNNL that includes a text visualization component. Starlight's text visualization system uses the Boeing *Text Representation Using Subspace Transformation* (TRUST) text engine for vector space modeling and text summarization. Text vectors generated by TRUST are clustered, and the cluster centroids are down-projected to 2D and 3D using a nonlinear manifold learning algorithm. Individual document vectors associated with each cluster are likewise projected within a local coordinate system established at the projected coordinates of their associated cluster centroid, and TRUST is used to generate topical labels for each cluster. Starlight is unique in that it couples text visualization with a range of other information visualization techniques (such as link displays) to depict multiple aspects of information simultaneously (Fig. 6).

TF–IDF

TF–IDF (*term frequency–inverse document frequency*) is a term weighting scheme commonly used to represent textual documents as vectors (for purposes of classification, clustering, visualization, retrieval, etc.). Let $T = \{t_1, \ldots, t_n\}$ be the set of all terms occurring in the document corpus under consideration. Then a document d_i is represented by a n-dimensional real-valued vector $\mathbf{x}_i = (x_{i_1}, \ldots, x_{in})$ with one component for each possible term from T.

The weight x_{ij} corresponding to term t_j in document d_i is usually a product of three parts: one which depends on the presence or frequency of t_j in d_i, one which depends on t_j's presence in the corpus as a whole, and a normalization part which depends on d_j. The most common TF–IDF weighting is defined by $x_{ij} = \mathrm{TF}_i \cdot \mathrm{IDF}_j \cdot (\sum_j (\mathrm{TF}_{ij} \mathrm{IDF}_j)^2)^{-1/2}$, where TF_{ij} is the *term frequency* (i.e., number of occurrences) of t_j in d_i, and IDFj is the IDF of t_j, defined as $\log(N/\mathrm{DF}_j)$, where N is the number of documents in the corpus and DF_j is the document frequency of t_j (i.e., the number of documents in which t_j occurs). The normalization part ensures that the vector has a Euclidean length of 1.

Several variations on this weighting scheme are also known. Possible alternatives for TF_{ij} include $\min\{1, \mathrm{TF}_{ij}\}$ (to obtain binary vectors) and $(1 + \mathrm{TF}_{ij} / \max_j \mathrm{TF}_{ij})/2$ (to normalize TF within the document). Possible alternatives for IDF_j include 1 (to obtain plain TF vectors instead of TF–IDF vectors) and $\log\,(\sum_i \sum_k \mathrm{TF}_{ik} / \sum_i \mathrm{TF}_{ij})$. The normalization part can be omitted altogether or modified to use some other norm than the Euclidean one.

Time Sequence

▶ Time Series

Time Series

Eamonn Keogh
University of California-Riverside, Riverside, CA, USA

Synonyms

Temporal data; Time sequence; Trajectory data

Definition

A *Time Series* is a sequence $T = (t_1, t_2, \ldots, t_n)$ which is an ordered set of n real-valued numbers. The ordering is typically temporal; however, other kinds of data such as color distributions (Hafner et al. 1995), shapes (Ueno et al. 2006), and spectrographs also have a well-defined ordering and can be fruitfully considered "time series" for the purposes of machine learning algorithms.

Motivation and Background

The special structure of time series produces unique challenges for machine learning researchers.

It is often the case that each individual time series object has a very high dimensionality. Whereas classic algorithms often assume a relatively low dimensionality (for example, a few dozen measurements such as "height, weight, blood sugar," etc.), time series learning algorithms must be able to deal with dimensionalities in hundreds or thousands. The problems created by high-dimensional data are more than mere computation time considerations; the very meaning of normally intuitive terms, such as "similar to" and "cluster forming," become unclear in high-dimensional space. The reason for this is that as dimensionality increases, all objects become essentially equidistant to each other and thus classification and clustering lose their meaning. This surprising result is known as the ▶ *curse of dimensionality* and has been the subject of extensive research. The key insight that allows meaningful time series machine learning is that although the actual dimensionality may be high, the *intrinsic* dimensionality is typically much lower. For this reason, virtually all time series data mining algorithms avoid operating on the original "raw" data; instead, they consider some higher level representation or abstraction of the data. Such algorithms are known as ▶ *dimensionality reduction* algorithms. There are many general dimensionality reduction algorithms, such as singular value decomposition and random projections, in addition to many reduction algorithms specifically designed for time series, including piecewise liner approximations, Fourier transforms, wavelets, and symbol approximations (Ding et al. 2008).

In addition to the high dimensionality of individual time series objects, many time series datasets have very high numerosity, resulting in a large volume of data. One implication of high numerosity combined with the high dimensionality of this is that the entire dataset may not fit in main memory. This requires an efficient disk-aware learning algorithm or a careful *sampling* approach.

A final consideration due to the special nature of time series is the fact that individual datapoints are typically highly correlated with their neighbors (a phenomenon known as *autocorrelation*). Indeed, it is this correlation that makes most time series excellent candidates for dimensionality reduction. However, for learning algorithms that assume the independence of features (i.e., ▶ Naive Bayes), this lack of independence must be countered or mitigated in some way.

While virtually every machine learning method has been used to classify time series, the current state-of-the-art method is the nearest neighbor algorithm (Ueno et al. 2006) with a suitable distance measure (Ding et al. 2008). This simple method outperforms neutral networks and Bayesian classifiers.

The major database (SIGMOD, VLDB, PODS) and data mining (SIGKDD, ICDM, SDM) conferences typically feature several time series machine learning/data mining papers each year. In addition, because of the ubiquity of time series, several other communities have active subgroups that conduct research on time series; for example, the SIGGRAPH conference typically has papers on learning or indexing or motion capture time series, and most medical conferences have tracks devoted to medical time series, such as electrocardiograms and electroencephalograms.

The UCR Time Series Archive has several dozen time series datasets which are widely used to test classification and clustering algorithms, and the UCI Data Mining archive has several additional datasets.

Topic Models for NLP Applications

Zhiyuan Chen and Bing Liu
University of Illinois at Chicago, Chicago, IL, USA

Abstract

Topic modeling is a machine learning technique for discovering semantic topics from a document collection. It typically assumes that a document is a multinomial distribution over latent topics, and a topic is a multinomial distribution over words. By capturing the co-occurrence statistics of words in the documents, it uncovers these distributions which indicate important semantic relationships. Topic modeling has been widely studied in machine learning, text mining, and natural language processing (NLP). This chapter gives an introduction to topic modeling. It covers both the fundamental techniques and some of its important applications in NLP.

Synonyms

Topic modeling

Definition

Given a collection of documents, how to discover semantic topics from the documents is an important yet challenging task. It is infeasible to ask human beings to manually read and identify the topics in every available document. This calls for an automated approach to extracting topics. Topic models are statistical machine learning methods that aim to discover a set of latent semantic topics from a document collection or corpus. A topic model is usually represented in a directed graphical model where topics and words are modeled as random variables. In a classic topic model, a document is modeled as an admixture of latent topics, while a topic is regarded as a probability distribution over words. The words are assumed to be generated conditioned on the topics, while topics are assumed to be sampled from a predefined distribution. Topic models are based on “higher-order co-occurrence,” i.e., how often words co-occur in different contexts. They usually perform well with a large number of documents which provide reliable co-occurrence statistics.

Motivation and Background

Discovering semantic topics from text corpora is beneficial to many applications in natural language processing. Due to the wide variety, high volume, and dynamic nature of topics, manual topic identification is clearly not scalable. To address it, topic models, such as latent Dirichlet allocation (LDA) (Blei et al. 2003) and probabilistic latent semantic analysis (pLSA) (Hofmann 1999), have been proposed to automatically discover latent topics from text corpora. In general, topic models assume that each document is a multinomial distribution over topics, while each semantic topic is a multinomial distribution over words. The two types of resulting distributions in topic models are document-topic distributions and topic-word distributions, respectively. The intuition is that certain words are more or less likely to be present given the topics of a document. For example, “sport” and “player” will appear more often in documents about sports, and “rain” and “cloud” will appear more frequently in documents about weather.

Structure of the Learning System

Topic modeling represents a class of statistical methods that can automatically extract thematic information from unstructured text documents. Topic models usually assume a generative process to describe how words are generated in documents. We use the most popular topic model, LDA (latent Dirichlet allocation) (Blei et al. 2003), as an example to explain. We denote the number of documents by M and the number of topics by T. Each document $m \in \{1, \ldots, M\}$

contains N_m words. The vocabulary in the corpus is denoted by $\{1, \ldots, V\}$. The generative process of LDA is given as follows:

1. For each topic $t \in \{1, \ldots, T\}$
   (i) Draw a per topic distribution over words, $\varphi_t \sim Dir(\beta)$
2. For each document $m \in \{1, \ldots, M\}$
   (i) Draw a topic distribution, $\theta_m \sim Dir(\alpha)$
   (ii) For each word position n in document m, where $n \in \{1, \ldots, N_m\}$
      (a) Draw a topic $z_{m,n} \sim Mult(\theta_m)$
      (b) Emit word $w_{m,n} \sim Mult(\varphi_{z_{m,n}})$

Here, α and β are called Dirichlet priors representing hyperparameters. $Dir()$ denotes the Dirichlet distribution and $Mult()$ indicates the multinomial distribution. Note that Dirichlet distribution is the conjugate prior of the multinomial distribution which simplifies the model inference derivation. θ is the document-topic distribution and φ is the topic-word distribution.

Inference and Parameter Estimation

The posterior inference of the LDA model is intractable and cannot be solved by exact inference. Common approximate inference techniques include collapsed Gibbs sampling (Griffiths and Steyvers 2004), variational methods (Blei et al. 2003), and expectation propagation (Minka and Lafferty 2002). Collapsed Gibbs sampling is the most popular inference approach due to its simplicity.

Gibbs sampling is a special case of Metropolis-Hastings algorithm which is a MCMC (Markov chain Monte Carlo) technique. It is usually used to generate samples from a joint probability of many random variables to approximate the marginal distribution. Gibbs sampling is especially useful when it is hard to sample from the joint distribution directly due to its complexity, but sampling from the conditional distribution of the random variables is easy. It is an iterative process that starts with a random initialization of the Markov chain's state. In each iteration, the value of each random variable is updated by drawing a sample from its conditional distribution based on the current state of all other random variables and the data.

The conditional distribution of assigning topic t to a word w_i in the collapsed Gibbs sampler for LDA is stated as below:

$$P(z_i = t | z^{-i}, \boldsymbol{w}, \alpha, \beta) \propto \frac{n_{m,t}^{-i} + \alpha}{\sum_{t'=1}^{T} (n_{m,t'}^{-i} + \alpha)} \times \frac{n_{t,w_i}^{-i} + \beta}{\sum_{v'=1}^{V} (n_{t,v'}^{-i} + \beta)} \tag{1}$$

where z^{-i} are the topic assignments excluding the current topic assignment of w_i. $\boldsymbol{w}$ denotes all the words in the documents. n^{-i} is the count that excludes the current word. $n_{m,t}$ is the number of times that topic t appears in document m, and $n_{t,w}$ is the number of occurrences of word w under topic t. Equation 1 is quite intuitive: the first ratio expresses the probability of topic t in document m, and the second ratio implies the probability of word w under topic t. Since this information is sufficient to compute the conditional distribution, Gibbs sampling can be implemented efficiently by caching and updating these counts only.

The estimation of document-topic distribution θ and topic-word distribution φ is straightforward given the samples of Gibbs sampling as below:

$$\theta_{m,t} = \frac{n_{m,t} + \alpha}{\sum_{t'=1}^{T} (n_{m,t'} + \alpha)} \tag{2}$$

$$\varphi_{t,w} = \frac{n_{t,w} + \beta}{\sum_{v'=1}^{V} (n_{t,v'} + \beta)} \tag{3}$$

Nonparametric Topic Models

Classic topic models such as LDA and pLSA generally require the number of topics to be specified by the user before running the actual models. In practice, this number is usually set empirically by conducting some initial experiments, which may not guarantee the optimal parameters for the model. Nonparametric topic

T

models automatically learn the appropriate number of topics from the data itself without manual setting for the number of topics. The hierarchical Dirichlet process mixture model (Teh et al. 2006) is the first nonparametric topic model. It introduces the Dirichlet process into topic models to automatically estimate the number of topics. The intuition is that there is a set of infinite groups in the data where each observation is generated independently given a group. This is the same as LDA as there is a set of topics where each word is sampled given a topic except that LDA fixes the number of topics, while the hierarchical Dirichlet process mixture model assumes that there are infinite topics. For the inference of the hierarchical Dirichlet process mixture model, Gibbs sampling is also used. More details can be found in Teh et al. (2006).

Knowledge-Based Topic Models

Most of the traditional topic models are fully unsupervised. However, researchers have shown that fully unsupervised topic models often produce incoherent topics because the objective functions of topic models do not always correlate well with human judgments (Chang et al. 2009). To address this issue, several knowledge-based topic models (KBTM), also called semi-supervised topic models, have been proposed and used in NLP applications.

DF-LDA (Andrzejewski et al. 2009) is the first KBTM which incorporates prior knowledge in the forms of must-links and cannot-links where a must-link states that two words should belong to the same topic and a cannot-link states that two words should not be in the same topic. In a similar but more generic vein, must-sets and cannot-sets are used in MC-LDA (Chen et al. 2013). Mukherjee and Liu (2012) proposed a model that allows the human user to provide some seed words in some topics. Interactive topic models were also proposed to allow the user to interact with the model during its inference process (Hu et al. 2011). In Blei and McAuliffe (2010), document class labels were considered in a supervised setting. However, these works in KBTM require the user to be involved to provide the knowledge or guidance for a superior model performance. As we know, expert knowledge can be hard to obtain. To address it, lifelong topic modeling (LTM) (Chen and Liu 2014) was proposed to automatically mine the prior knowledge from past domains and leverage the knowledge to help discover topics of higher quality in a new domain.

Applications in NLP

Since topic models are primarily designed for analysis of text documents, there are numerous applications in almost every subarea of NLP. It is difficult to describe them all. Here we discuss only a few subareas to give a flavor of the types of NLP applications.

Part-of-speech (POS) tagging is one of core NLP tasks. The task is to specify a particular part of speech to a given word based on the definition and context of that word. For example, in a sentence “Bob enjoys reading books,” the word *enjoys* is marked up with POS tag *VBZ*, indicating that this word is a verb with third-person singular present. The challenge is that some words may have multiple POS tags, e.g., the word *move* can be a verb or a noun. In such cases, the context of the given word is usually required to decide the correct POS tag.

Topic models have been widely applied in the task of POS tagging. Griffiths et al. (2004) proposed a topic model that can model both the semantic and syntactic information for part-of-speech tagging. Their motivation is that a word in a sentence can have one of the two roles: serving a syntactic function or providing a semantic meaning (Griffiths et al. 2004). Syntactic words usually have short-range dependencies, i.e., spanning several words without going beyond the scope of a sentence. In contrast, semantic words tend to have long-range dependencies: some sentences within a document are likely to share similar words and express similar contexts. Based on it, a hidden Markov model (HMM) was used inside the generative model to decide whether a word belongs to the syntactic class or the semantic class. Obtaining such information is helpful in determining POS tags. For example, knowing that a word "control" in a text corpus belongs to the syntactic class makes it more likely to be a verb than a noun. Toutanova and Johnson (2008) further added a sparse prior to topic models on the distribution over tags for each word. They also explicitly modeled ambiguity classes, i.e., the set of part-of-speech tags that a word can be associated with. In their model, each word type is assigned with a set of possible parts of speech, and each token of this word type is associated with a part-of-speech tag.

Word sense disambiguation (WSD) is another important NLP area where topic models have been popularly applied. Its objective is to identify the sense or meaning of an ambiguous word in its context. For example, the word *light* in "the light of the sun" refers to the meaning "something that makes things visible," while *light* in "The box is light to carry" indicates the sense "of little weight." A dictionary, e.g., WordNet (https://wordnet.princeton.edu/), is usually used to help provide word senses. Boyd-Graber et al. (2007) proposed a model called LDAWN (LDA with WordNet) model to distinguish word senses. In WordNet, a word sense is represented by a synset (short for synonym sets). For example, in the above examples, the synset {light, luminance} is associated with the sense of "something that makes things visible." LDAWN models the synset path, i.e., a path from one synset to another synset, as a hidden variable. It assumes that words under the same topic are likely to share the same meaning as well as their synset path. The posterior inference of LDAWN was conducted using Gibbs sampling to infer the synset path, i.e., the sense, of a word. The key advantage of LDAWN is that it does not need labeled data to disambiguate a corpus. It simultaneously decomposes a corpus into topics with words grouping into their word senses.

Sentiment analysis (or opinion mining) is perhaps one of the biggest application areas of topic models in NLP. The goal of sentiment analysis is to extract subjective information such as opinions, evaluations, appraisals, and emotions from text. Liu (2012) gave a comprehensive survey of the sentiment analysis and opinion mining research. Topic models have been widely applied in aspect-based sentiment analysis, which is a fine-grained analysis of opinions, to infer aspects and opinion words. Aspects in the sentiment analysis context are entity features on which opinions have been expressed. For example, in a review sentence, "The picture looks great," about a camera, the aspect is "picture" and the opinion word is "great." Mei et al. (2007) proposed the topic-sentiment mixture (TSM) model to reveal the latent topics and their associated sentiments in a Weblog collection. They also designed a special HMM structure in the topic model to detect topic life cycles and sentiment dynamics. A semi-supervised topic model was proposed in Lu and Zhai (2008) to integrate opinions expressed in well-written expert reviews and opinions expressed by the general public in sources such as weblogs to generate an aligned and integrated opinion summary. Titov and McDonald (2008) proposed a topic model to distinguish global aspects and local aspects. In their model, global aspects correspond to global properties of objects, e.g., the brand of a product type, while local aspects are the aspects of an object or entity that tend to be rated or evaluated by users.

More recently, Lin and He (2009) proposed the joint sentiment/topic (JST) model that jointly models topics (aspects) and sentiments. Rather than having only one set of latent topic variables as in LDA, JST adds another set of hidden sentiment variables. The advantage of JST is that it is able to model both aspects and sentiments in a fully unsupervised fashion without the need of supervised information such as labels. Based on JST, Jo and Oh (2011) made an assumption that one sentence represents only one aspect, i.e., all the words in a sentence are generated from one aspect. However, these models do not actually separate aspects and opinion words in their results. The maximum entropy model was integrated into a topic model by Zhao et al. (2010) to explicitly separate opinions from aspects. Chen et al. (2014) proposed the AKL (automated knowledge LDA) model that learns prior knowledge from reviews of other products/domains and applies such knowledge to mine more coherent aspects. The knowledge base is represented by a set of clusters, where each cluster consists of words that are semantically correlated.

Some other NLP applications of topic models include machine translation (Eidelman et al. 2012), summarization (Haghighi and Vanderwende 2009), tagging (Krestel et al. 2009), multi-language topic synchronization (Petterson et al. 2010), topical keyphrase extraction (Zhao et al. 2011), relation extraction between named entities (Yao et al. 2011), entity linking (Han and Sun 2012), and document retrieval (Wei and Croft 2006).

University of Texas at Austin, Austin, TX, USA

Synonyms

Architecture; Connectivity; Structure; Topology

Definition

Topology of a neural network refers to the way the neurons are connected, and it is an important factor in how the network functions and learns. A common topology in unsupervised learning is a direct mapping of inputs to a collection of units that represents categories (e.g., ▶ Self-Organizing Maps). The most common topology in supervised learning is the fully connected, three-layer, feedforward network (see ▶ Backpropagation and ▶ Radial Basis Function Networks): All input values to the network are connected to all neurons in the hidden layer (hidden because they are not visible in the input or output), the outputs of the hidden neurons are connected to all neurons in the output layer, and the activations of the output neurons constitute the output of the whole network. Such networks are popular partly because they are known theoretically to be universal function approximators (with, e.g., a sigmoid or Gaussian nonlinearity in the hidden layer neurons), although networks with more layers may be easier to train in practice (e.g., ▶ Cascade-Correlation). In particular, deep learning architectures (see ▶ Deep Learning) utilize multiple hidden layers to form a hierarchy of gradually more structured representations that support a supervised task on top. Layered networks can be extended to processing sequential input and/or output by saving a copy of the hidden layer activations and using it as additional input to the hidden layer in the next time step (see ▶ Simple Recurrent Network). Fully recurrent topologies, where each neuron is connected to all other neurons (and possibly to itself), can also be used to model time-varying behavior, although such networks may be unstable and difficult to train (e.g., with backpropagation; but see also ▶ Boltzmann Machines). Modular topologies, where different parts of the networks perform distinctly different tasks, can improve stability and can also be used to model high-level behavior (e.g., ▶ Echo-State Machines and ▶ Adaptive Resonance Theory). Whatever the topology, in most cases, learning involves modifying the ▶ Weight on the network connections. However, arbitrary network topologies are possible as well and can be constructed as part of the learning (e.g., with backpropagation or ▶ Neuroevolution) to enhance feature selection, recurrent memory, abstraction, or generalization.

Trace-Based Programming

Abstract

Trace-based programming is introduced as a specific approach to inductive programming where a, typically recursive, program is inferred from a small set of example computational traces.

Most of the work by this author was done while on leave of absence in 2006/2007 as a Visiting Faculty Member and Erasmus Exchange Teacher at Sabancı University, Turkey.

Synonyms

Programming from traces

Definition

Trace-based programming addresses the inference of a program from a small set of example computation traces. The induced program is typically a recursive program. A computation *trace* is a non-recursive expression that describes the transformation of some specific input into the desired output with help of a predefined set of primitive functions. While the construction of traces is highly dependent on background knowledge or even on knowledge about the program searched for, the inductive **generalization** is based on syntactical methods of detecting regularities and dependencies between traces, as proposed in classical approaches to ▶ inductive programming or ▶ explanation-based learning. As an alternative to providing traces by hand simulation, AI planning techniques or **programming by demonstration** can be used.

Definition

Tree augmented ▶ naive Bayes is a ▶ semi-naive Bayesian Learning method. It relaxes the naive Bayes attribute independence assumption by employing a tree structure, in which each attribute only depends on the class and one other attribute. A maximum weighted spanning tree that maximizes the likelihood of the training data is used to perform classification.

Classification with TAN

Interdependencies between attributes can be addressed directly by allowing an attribute to depend on other non-class attributes. However, techniques for learning unrestricted Bayesian networks often fail to deliver lower zero-one loss than naive Bayes (Friedman et al. 1997). One possible reason for this is that full ▶ Bayesian networks are oriented toward optimizing the likelihood of the training data rather than the conditional likelihood of the class attribute given a full set of other attributes. Another possible reason is that full Bayesian networks have high variance due to the large number of parameters estimated. An intermediate alternative technique is to use a less restrict structure than naive Bayes. Tree augmented naive Bayes (TAN) (Friedman et al. 1997) employs a tree structure, allowing each attribute to depend on the class and at most one other attribute. Figure 1 shows Bayesian network representations of the types of model that NB and TAN respectively create.

Chow (1968) proposed a method that efficiently constructs a maximum weighted spanning tree which maximizes the likelihood that the training data was generated from the tree. The weight of an edge in the tree is the mutual information of the two attributes connected by the edge. TAN extends this method by using conditional mutual information as weights. Since the selection of root does not affect the log-likelihood of the tree, TAN randomly selects a root attribute and directs all edges away from it. The parent of each attribute X_i is indicated as $\pi(X_i)$ and the parent of the class is $\varnothing$. It assumes that attributes are independent given the class and their parents and classifies the test instance $\mathbf{x} = \langle x_1, \ldots, x_n \rangle$ by selecting

$$\underset{y}{\operatorname{argmax}}\ \hat{P}(Y) \prod_{1 \le i \le n} \hat{P}(x_i | y, \pi(x_i)), \qquad (1)$$

where $\pi(x_i)$ is a value of $\pi(X_i)$ and y is a class label.

Due to the relaxed attribute independence assumption, TAN considerably reduces the ▶ bias of naive Bayes at the cost of an increase in variance. Empirical results (Friedman et al. 1997) show that it substantially reduces zero-one loss of naive Bayes on many data sets and that of all data sets examined it achieves lower zero-one loss than naive Bayes more often than not.

Definition

Tree mining is an instance of constraint-based pattern mining and studiesthe discovery of tree patterns in data that is represented as a tree structure or as a set of trees structures. Minimum frequency is the most studied constraint.

Motivation and Background

Tree mining is motivated by the availability of many types of data that can be represented as tree structures. There is a large variety in tree types, for instance, ordered trees, unordered trees, rooted trees, unrooted (free) trees, labeled trees, unlabeled trees, and binary trees; each of these has its own application areas. An example are trees in tree banks, which store sentences annotated with parse trees. In such data, it is not only of interest to find commonly occurring sets of words (for which frequent itemset miners could be used), but also to find commonly occurring parses of these words. Tree miners aim at finding patterns in this structured information. The patterns can be interesting in their own right, or can be used as features in classification algorithms.

Structure of Problem

All tree miners share a similar problem setting. Their input consists of a set of trees and a set of constraints, usually a minimum frequency constraint, and their output consists of all subtrees that fulfill the constraints.

Tree miners differ in the constraints that they are able to deal with, and the types of trees that they operate on. The following types of trees can be distinguished:

Free trees, which are graphs without cycles, and no order on the nodes or edges;

Unordered trees, which are free trees in which one node is chosen to be the root of the tree;

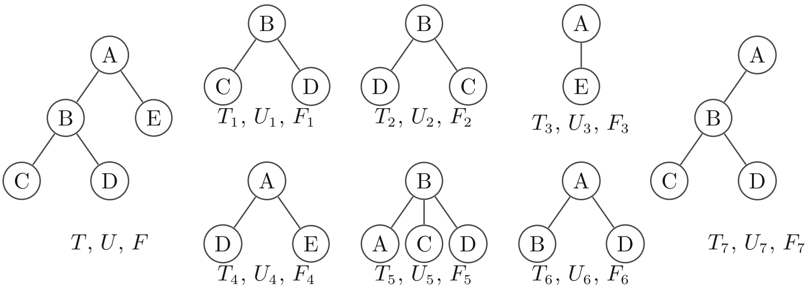
Ordered trees, which are rooted trees in which the nodes are totally ordered.

For each of these types of tree, we can choose to have labels on the nodes, or on the edges, or on both.

The differences between these types of trees are illustrated in Fig. 1. Every graph in this figure can be interpreted as a free tree F_i, an unordered tree U_i, or an ordered tree T_i. When interpreted as ordered trees, none of the trees are equivalent. When we interpret them as unordered trees, U_1 and U_2 are equivalent representations of the same unordered tree that has B as its root and C and D as its children. Finally, as free trees, not only F_1 and F_2 are equivalent, but also F_5 and F_7.

Intuitively, a free tree requires less specification than an ordered tree. The number of possible free trees is smaller than the number of possible ordered trees. On the other hand, to test if two trees are equivalent we need a more elaborate computation for free trees than for ordered trees.

Assume that we have data represented as (a set of) trees, then the data mining problem is to find patterns, represented as trees, that fulfill constraints based on this data. To express these constraints, we need a coverage relation that expresses when one tree can be considered to occur in another tree. Different coverage relations can be expressed for free trees, ordered trees, and unordered trees. We will introduce these relations through operations that can be used to transform



Tree Mining, Fig. 1 The leftmost tree is part of the data, the other trees could be patterns in this tree, depending on the subtree relation that is used

trees. As an example, consider the operation that removes a leaf from a tree. We can repeatedly apply this operation to turn a large tree into a smaller one. Given two trees A and B, we say that A occurs in B as

Induced subtree, if A can be obtained from B by repeatedly removing leaves from B. When dealing with rooted trees, the root is here also considered to be a leaf if it has one child;

Root-induced subtree, if A can be obtained from B by repeatedly removing leaves from B. When dealing with rooted trees, the root is not allowed to be removed;

Embedded subtree, if A can be obtained from B by repeatedly either (1) removing a leaf or (2) removing an internal node, reconnecting the children of the removed node with the parent of the removed node;

Bottom-up subtree, if there is a node v in B such that if we remove all nodes from B that are not a descendant of v, we obtain A;

Prefix, if A can be obtained from B by repeatedly removing the last node from the ordered tree B;

Leaf set, if A can be obtained from B by selecting a set of leaves from B, and all their ancestors in B.

For free trees, only the induced subtree relation is well-defined. A prefix is only well-defined for ordered trees, the other relations apply both to ordered and unordered trees. In the case of unordered trees, we assume that each operation maintains the order of the original tree B. The relations are also illustrated in Fig. 2.

Intuitively, we can speak of *occurrences* (also called *embeddings* by some authors) of a small tree in a larger tree. Each such occurrence (or embedding) can be thought of as a function φ that maps every node in the small tree to a node in the large tree.

Using an occurrence relation, we can define frequency measures. Assume given a forest $\mathcal{F}$ of trees, all ordered, unordered, or free. Then the frequency of a tree A can be defined

Transaction-based, where we count the number of trees $B \in \mathcal{F}$ such that A is a subtree of B;

Node-based, where we count the number of nodes v in $\mathcal{F}$ such that A is a subtree of the bottom-up subtree below v.

Node-based frequency is only applicable in rooted trees, in combination with the root-induced, bottom-up, prefix, or leaf set subtree relations.

Given a definition of frequency, constraints on trees of interest can be expressed:

Minimum frequency, to specify that only trees with a certain minimum number of occurrences are of interest;

Closedness, to specify that a tree is only of interest if its frequency is different from all its supertrees;

Maximality, to specify that a tree is only of interest if none of its supertrees is frequent.

Observe that in all of these constraints, the subtree relation is again important. The subtree relation is not only used to compare patterns with data, but also patterns among themselves.

The tree mining problem can now be stated as follows. Given a forest of trees $\mathcal{F}$ (ordered, unordered, or free) and a set of constraints, based on a subtree relation, the task is to find all trees that satisfy the given constraints.

Theory/Solution

The tree mining problem is an instance of the more general problem of constraint-based pattern mining under constraints. For more information about the general setting, see the sections on constraint-based mining, itemset mining, and graph mining.

All algorithms iterate a process of generating candidate patterns, and testing if these candidates satisfy the constraints. Essential is to avoid that every possible tree is considered as a candidate. To this purpose, the algorithms exploit that many frequency measures are anti-monotonic. This property states that for two given trees A and B, where A is a subtree of B, if A is infrequent, then also B is infrequent, and therefore, we do not need to consider it as a candidate.

This observation can make it possible to find all trees that satisfy the constraints, if these requirements are fulfilled:

- We have an algorithm to enumerate candidate subtrees, which satisfies these properties:
  - It should be able to enumerate all trees in the search space;
  - It should avoid that no two equivalent subtrees are listed;
  - It should only list a tree after at least one of its subtrees has been listed, to exploit the anti-monotonicity of the frequency constraint;
- We have an algorithm to efficiently compute in how many database trees a pattern tree occurs.

The algorithmic solutions to these problems depend on the type of tree and the subtree relation.

Encoding and Enumerating Trees

We will first consider how tree miners internally represent trees. Two types of encodings have been proposed, both of which are string-based. We will illustrate these encodings for node-labeled trees, and start with *ordered* trees.

The first encoding is based on a *preorder* listing of nodes: (1) for a rooted ordered tree T with a single vertex r, the *preorder string* of T is $S_{T,r} = l_r - 1$, where l_r is the label for the single vertex r, and (2) for a rooted ordered tree T with more than one vertex, assuming the root of T is r (with label l_r) and the children of r are $r_1, \ldots, r_K$ from left to right, then the preorder string for T is

$S_{T,r} = l_r S_{T,r_K} - 1$, where $S_T, r_1, \dots, S_T, r_k$ are the preorder strings for the bottom-up subtrees below nodes $r_1, \dots, r_K$ in T.

The second encoding is based on listing the *depths* of the nodes together with their labels in prefix-order. The depth of a node v is the length of the path from the root to the node v. The code for a tree is $S_{T,r} = d_r, l_r, S_{T,r_1} \dots S_{T,r_k}$, where d_r is the depth of the node r in tree T.

Both encodings are illustrated in Fig. 3.

A search space of trees can be visualized as in Fig. 4. In this figure, every node corresponds to the depth encoding of a tree, while the edges visualize the partial order defined by the subtree relation. It can be seen that the number of induced subtree relations between trees is smaller than the number of embedded subtree relations.

Tree	Depth-sequence	Preorder string
T_6	$1A2B2D$	AB-1D-1
T_7	$1A2B3C3D$	ABC-1D-1-1-1
T	$1A2B3C3D2E$	ABC-1D-1-1E-1
T_4	$1A2D2E$	AD-1E-1-1
T_3	$1A2E$	AE-1-1
T_5	$1B2A2C2D$	BA-1C-1D-1-1
T_1	$1B2C2D$	BC-1D-1-1
T_2	$1B2D2C$	BD-1C-1-1

Tree Mining, Fig. 3 Depth sequences for all the trees of Fig. 1, sorted in lexicographical order. Tree T_2 is the canonical form of unordered tree U_2, as its depth sequence is the highest among equivalent representations

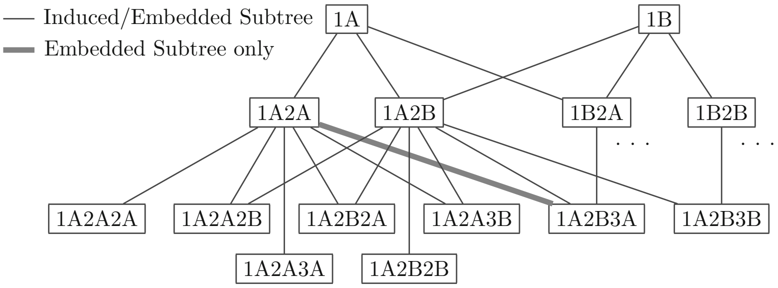
The task of the enumeration algorithm is to traverse this search space starting from trees that contain only one node. Most algorithms perform the search by building an enumeration tree over the search space. In this enumeration tree every pattern should have a single parent. The children of a pattern in the enumeration tree are called its *extensions* or its *refinements*. An example of an enumeration tree for the induced subtree relation is given in Fig. 5.

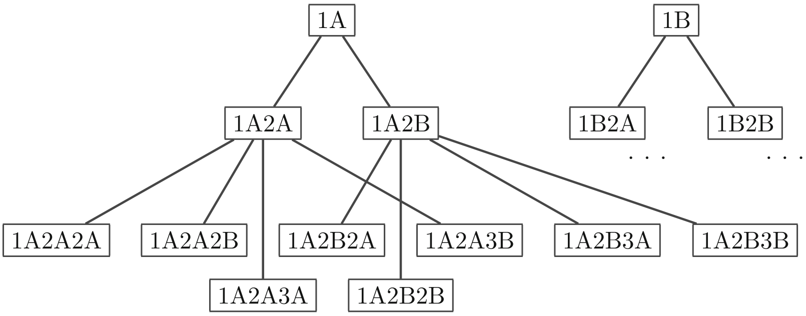
In the enumeration tree that is given here, the parent of a tree is its prefix in the depth encoding. An alternative definition is that the parent of a tree can be obtained by removing the last node in a prefix order traversal of the ordered tree. Every refinement in the enumeration has one additional node that is connected to the *rightmost path* of the parent.

The enumeration problem is more complicated for *unordered trees*. In this case, the trees represented by the strings $1A2A2B$ and $1A2B2A$ are equivalent, and we only wish to enumerate one of these strings. This can be achieved by defining a total order on all strings that represent trees, and to define that only the highest (or lowest) string of a set of equivalent strings should be considered.

For depth encodings, the ordering is usually lexicographical, and the highest string is chosen to be the *canonical* encoding. In our example, $1A2B2A$ would be canonical. This code has the desirable property that every prefix of a canonical code is also a canonical code. Furthermore it can be determined in polynomial time which

Tree Mining, Fig. 4 A search space of ordered trees, where edges denote subtree relationships





Tree Mining, Fig. 5 Part of an enumeration tree for the search space of Fig. 4

extensions of a canonical code lead to a canonical code, such that it is not necessary to consider any code that is not canonical.

Alternative codes have also been proposed, which are not based on a preorder, depth-first traversal of a tree, but on a level-wise listing of the nodes in a tree.

Finally, for *free trees* we have the additional problem that we de not have a root for the tree. Fortunately, it is known that every free tree either has a uniquely determined *center* or a uniquely determined *bicenter*. This (bi)center can be found by determining the longest path between two nodes in a free tree: the node(s) in the middle of this path are the center of the tree. It can be shown that if multiple paths have the same maximal length, they will have the same (bi)center. By appointing one center to be the root, we obtain a rooted tree, for which we can compute a code.

To avoid that two codes are listed that represent equivalent free trees, several solutions have been proposed. One is based on the idea of first enumerating paths (thus fixing the center of a tree), and for each of these paths enumerating all trees that can be grown around them. Another solution is based on enumerating all rooted, unordered trees under the constraint that at least two different children of the root have a bottom-up subtree of equal, maximal depth. In the first approach, a preorder depth encoding was used; in the second approach a level-wise encoding was used.

Counting Trees

To evaluate the frequency of a tree the subtree relation between a candidate pattern tree and all trees in the database has to be computed. For each of our subtree relations, polynomial algorithms are known to decide the relation, which are summarized in Table 1.

Tree Mining, Table 1 Worst case complexities of the best known algorithms that determine whether a tree relation holds between two trees; m is the number of nodes in the pattern tree, l is the number of leafs in the pattern tree, n the number of nodes in the database tree

Ordered	
Embedding	$O(nl)$
Induced	$O(nm)$
Root-induced	$O(n)$
Leaf-set	$O(n)$
Bottom-up	$O(n)$
Prefix	$O(m)$
Unordered	
Embedding	NP-complete
Induced	$O(nm^{1\frac{1}{2}}/\log m)$
Root-induced	$O(nm^{1\frac{1}{2}}/\log m)$
Leaf-set	$O(nm^{1\frac{1}{2}}/\log m)$
Bottom-up	$O(n)$

Even though a subtree testing algorithm and an algorithm for enumerating trees are sufficient to compute all frequent subtrees correctly, in practice fine-tuning is needed to obtain an efficient method. There are two reasons for this:

- In some databases, the number of candidates can by far exceed the number of trees that are actually frequent. One way to reduce the number of candidates is to only generate a particular candidate after we have encountered at least one occurrence of it in the data (this is called *pattern growth*); another way is to require that a candidate is only generated if at least two of its subtrees satisfy the constraints (this is called *pattern joining*).

- The trees in the search space are very similar to each other: a parent only differs from its children by the absence of a single node. If memory allows, it is desirable to *reuse* the subtree matching information, instead of starting the matching from scratch.

A large number of data structures have been proposed to exploit these observations. We will illustrate these ideas using the FreqT algorithm, which mines induced, ordered subtrees, and uses a depth encoding for the trees.

In FreqT, for a given pattern tree A, a list of (database tree, database node) pointers is stored. Every element (B, v) in this list corresponds to an occurrence of tree A in tree B in which the last node (in terms of the preorder) of A is mapped to node v in database tree B. For a database and three example trees this is illustrated in Fig. 6.

Every tree in the database is stored as follows. Every node is given an index, and for every node, we store the index of its parent, its righthand sibling, and its first child.

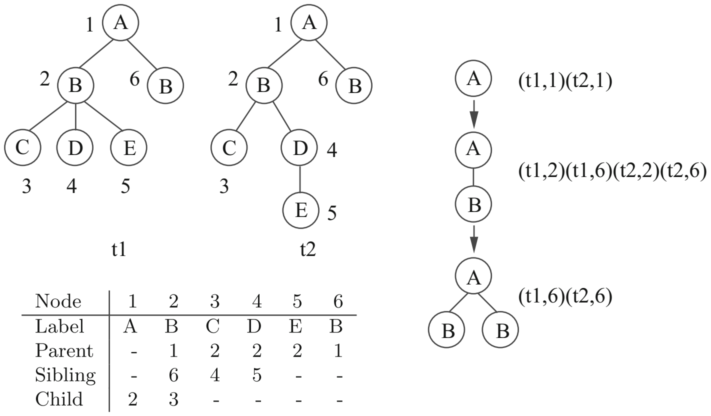
Let us consider how we can compute the occurrences of the subtree $1A2B2B$ from the occurrences of the tree $1A2B$. The first occurrence of $1A2B$ is $(t1, 2)$, which means that the B labeled node can be mapped to node 2 in $t1$. Using the arrays that store the database tree, we can then conclude that node 6, which is the right-hand sibling of node 2, corresponds to an occurence of the subtree $1A2B2B$. Therefore, we add $(t1, 6)$ to the occurrence list of $1A2B2B$. Similarly, by scanning the data we find out that the first child of node 2 corresponds to an occurrence of the subree $1A2B3C$, and we add $(t1, 3)$ to the occurrence list of $1A2B3C$.

Overall, using the parent, sibling and child pointers we can scan every node in the data that could correspond to a valid expansion of the subtree $1A2B$, and update the corresponding lists. After we have done this for every occurrence of the subtree, we know the occurrence lists of all possible extensions.

From an occurrence list we can determine the frequency of a tree. For instance, the transaction-based frequency can be computed by counting the number of different database trees occurring in the list.

As we claimed, this example illustrates two features that are commonly seen in tree miners: first, the occurrence list of one tree is used to compute the occurrence list of another tree, thus reusing information; second, the candidates are collected from the data by scanning the nodes that connect to the occurrence of a tree in the data. Furthermore, this example illustrates that a careful design of the datastructure that stores the data can ease the frequency evaluation considerably.

FreqT does not perform pattern joining. The most well-known example of an algorithm that



Node	1	2	3	4	5	6
Label	A	B	C	D	E	B
Parent	-	1	2	2	2	1
Sibling	-	6	4	5	-	-
Child	2	3	-	-	-	-

Tree Mining, Fig. 6 A tree database (*left*) and three ordered trees with their occurrence lists according to the FreqT algorithm (*right*). The datastructure that stores $t1$ in FreqT is given in the table (*right*) performs tree joining is the embedded TreeMiner (Zaki 2002). Both the FreqT and the TreeMiner perform the search depth-first, but also tree miners that use the traditional level-wise approach of the Apriori algorithm have been proposed. The FreqT and the TreeMiner have been extended to unordered trees.

Other Constraints

As the number of frequent subtrees can be very large, approaches have been studied to reduce the number of trees returned by the algorithm, of which closed and maximal trees are the most popular. To find closed or maximal trees, two issues need to be addressed:

- How do we make sure that we only output a tree if it is closed or maximal, that is, how do we determine that none of its supertrees has the same support, or is frequent?
- Can we conclude that some parts of the search space will never contain a closed or maximal tree, thus making the search more efficient?

Two approaches can be used to address the first issue:

- All closed patterns can be stored, and every new pattern can be compared with the stored set of patterns;
- When we evaluate the frequency of a pattern in the data, we also (re)evaluate the frequency of all its possible extensions, and only output the pattern if its support is different.

The second approach requires less memory, but in some cases requires more computations.

To prune the search space, a common approach is to check all occurrences of a tree in the data. If every occurrence of a tree can be extended into an occurrence of another tree, the small tree should not be considered, and the search should continue with the tree that contains all common edges and nodes. Contrary to graph mining, it can be shown that this kind of pruning can safely be done in most cases.

Applications

Examples of databases to which tree mining algorithms have been applied are

Parse tree analysis: Since the early 1990s large *Treebank* datasets have been collected consisting of sentences and their grammatical structure. An example is the Penn TreeBank (Marcus et al. 1993). These databases contain rooted, ordered trees. To discover differences in domain languages it is useful to compare commonly occurring grammatical constructions in two different sets of parsed texts, for which tree miners can be used (Sekine 1998).

Computer network analysis: IP *multicast* is a protocol for sending data to multiple receivers. In an IP multicast session a webserver sends a packet once; routers copy a packet if two different routes are required to reach multiple receivers. During a multicast session rooted trees are obtained in which the root is the sender and the leaves are the receivers. Commonly occurring patterns in the routing data can be discovered by analyzing these unordered rooted trees (Chalmers and Almeroth 2003).

Webserver access log analysis: When users browse a website, this behavior is reflected in the access log files of the webserver. Servers collect information such as the webpage that was visited, the time of the visit, and the webpage that was clicked to reach the webpage. The access logs can be transformed into a set of ordered trees, each of which corresponds to a visitor. Nodes in these trees correspond to webpages; edges are inserted if a user browses from one webpage to another. Nodes are ordered in viewing order. A tool was developed to perform this transformation in a sensible way (Punin et al. 2002).

Phylogenetic trees: One of the largest tree databases currently under construction is the TreeBASE database, which is comprised of a large number of phylogenetic trees (Morell 1996). The trees in the TreeBASE database are submitted by researchers and are collected from publications. Originating from multiple sources, they can disagree on parts of the phylogenetic tree. To find common agreements between the trees, tree miners have been used (Zhang and Wang 2005). The phylogenetic trees are typically unordered; labels among siblings are unique.

Hypergraph mining: Hypergraphs are graphs in which one edge can have more than two endpoints. Those hypergraphs in which no two nodes share the same label can be transformed into unordered trees, as follows. First, an artificial root is inserted. Second, for each edge of the hypergraph a child node is added to the root, labeled with the label of the hyperedge. Finally, the labels of nodes within hyperedges are added as leaves to the tree. An example of hypergraph data is bibliographic data: if each example corresponds to a paper, nodes in the hypergraph correspond to authors cited by the paper, and hyperedges connect coauthors of cited papers.

Multi-relational data mining: Many multi-relational databases are tree shaped, or a tree-shaped view can be created. For instance, a transaction database in which every transaction is associated with customers and their information, can be represented as a tree (Berka 1999).

XML data mining: Several authors have stressed that tree mining algorithms are most suitable for mining XML data. XML is a tree–shaped data format, and tree miners can be helpful when trying to (re)construct Document Type Definitions (DTDs) for such documents.

Underlying Objective

The term *objective* used in Evolutionary Multi-Objective Optimization refers to an indicator of quality returning an element from an ordered set of scalar values, such as a real number. For any test-based coevolutionary problem, a set of underlying objectives exists such that knowledge of the objective values of an individual is sufficient to determine the outcomes of all possible tests. The existence of a set of underlying objectives is guaranteed, as the set of possible tests itself satisfies this property.

Abstract

This encyclopedic article gives a mini-introduction into the theory of universal learning, founded by Ray Solomonoff in the 1960s and significantly developed and extended in the last decade. It explains the spirit of universal learning, but necessarily glosses over technical subtleties.

Definition, Motivation, and Background

Universal (machine) learning is concerned with the development and study of algorithms that are able to learn from data in a very large range of environments with as few assumptions as possible. The class of environments typically considered includes all computable stochastic processes. The investigated learning tasks range from ▸ inductive inference, sequence prediction, sequential decisions, to (re)active problems such as ▸ reinforcement learning (Hutter 2005), but also include ▸ clustering, ▸ regression, and others (Li and Vitányi 2008). Despite various ▸ no free lunch theorems, universal learning is *possible* by assuming that the data possess *some* effective structure, but without specifying any further *which* structure (Lattimore and Hutter 2011). Learning algorithms that are universal (at least to some degree) are also *necessary* for developing autonomous general intelligent systems, required, e.g., for exploring other planets, as opposed to decision *support* systems which keep a human in the loop. There is also an *intrinsic* interest in striving for generality: Finding new learning algorithms for every particular (new) problem is possible but cumbersome and prone

C. Sammut, G.I. Webb (eds.), *Encyclopedia of Machine Learning and Data Mining*,
DOI 10.1007/978-1-4899-7687-1

to disagreement or contradiction. A sound formal general and ideally complete theory of learning can unify existing approaches, guide the development of practical learning algorithms, and last but not least lead to novel and deep insights.

Deterministic Environments

Let $t, n \in \mathbb{N}$ be natural numbers, $\mathcal{X}^*$ be the set of finite strings, and $\mathcal{X}^\infty$ be the set of infinite sequences over some alphabet $\mathcal{X}$ of size $|\mathcal{X}|$. For a string $x \in \mathcal{X}^*$ of length $\ell(x) = n$, we write $x_1x_2\ldots x_n$ with $x_t \in \mathcal{X}$ and further abbreviate $x_{t:n} := x_t x_{t+1}\ldots x_{n-1}x_n$ and $x_{<n} := x_1\ldots x_{n-1}$, and $\epsilon = x_{<1}$ for the empty string. Consider a countable class of deterministic hypotheses $\mathcal{M} = \{H_1, H_2, \ldots\}$. Each hypothesis $H \in \mathcal{M}$ (also called model) shall describe an infinite sequence $x^H_{1:\infty}$, e.g., like in IQ test questions "2,4,6,8,…." In online learning, for $t = 1, 2, 3, \ldots$, we predict x_t based on past observations $\dot{x}_{<t}$, then nature reveals $\dot{x}_t$, and so on, where the dot above x indicates the true observation. We assume that the true hypothesis is in $\mathcal{M}$, i.e., $\dot{x}_{1:\infty} = x^{H_m}_{1:\infty}$ for some $m \in \mathbb{N}$. The goal is to ("quickly") identify the unknown H_m from the observations.

Learning by enumeration works as follows: Let $\mathcal{M}_t = \{H \in \mathcal{M} : x^H_{<t} = \dot{x}_{<t}\}$ be the set of hypotheses consistent with our observations $\dot{x}_{<t}$ so far. The hypothesis in $\mathcal{M}_t$ with smallest index, say m'_t, is selected and used for predicting x_t. Then $\dot{x}_t$ is observed and all $H \in \mathcal{M}_t$ inconsistent with x_t are eliminated, i.e., they are not included in $\mathcal{M}_{t+1}$. Every prediction error results in the elimination of at least $H_{m'_t}$, so after at most $m-1$ errors, the true hypothesis H_m gets selected forever, since it never makes an error ($H_m \in \mathcal{M}_t \forall t$). This identification may take arbitrarily long (in t), but the number of errors on the way is bounded by $m-1$, and the latter is often more important. As an example for which the bound is attained, consider H_i with $x^{H_i}_{1:\infty} := 1^{f(i)}0^\infty$ $\forall i$ for any strictly increasing function f, e.g., $f(i) = i$. But we now show that we can do much better than this, at least for finite $\mathcal{X}$.

Majority learning. Consider (temporarily in this paragraph only) a binary alphabet $\mathcal{X} = \{0, 1\}$ and a *finite* deterministic hypothesis class $\mathcal{M} = \{H_1, H_2, \ldots, H_N\}$. H_m and $\mathcal{M}_t$ are as before, but now we take a majority vote among the hypotheses in $\mathcal{M}_t$ as our prediction of x_t. If the prediction turns out to be wrong, then at least half (the majority) of the hypotheses get eliminated from $\mathcal{M}_t$. Hence after at most $\log N$ errors, there is only a single hypothesis, namely, H_m, left over. So this majority predictor makes at most $\log N$ errors. As an example where this bound is essentially attained, consider $m = N = 2^n - 1$ and let $x^{H_i}_{1:\infty}$ be the digits after the comma of the binary expansion of $(i-1)/2^n$ for $i = 1, \ldots, N$.

Weighted majority for countable classes. Majority learning can be adapted to denumerable classes $\mathcal{M}$ and general finite alphabet $\mathcal{X}$ as follows: Each hypothesis H_i is assigned a weight $w_i > 0$ with $\sum_i w_i \leq 1$. Let $W := \sum_{i:H_i \in \mathcal{M}_t} w_i$ be the total weight of the hypotheses in $\mathcal{M}_t$. Let $\mathcal{M}^a_t := \{H_i \in \mathcal{M}_t : x^{H_i}_t = a\}$ be the consistent hypotheses predicting $x_t = a$, and W_a their weight, and take the weighted majority prediction $x_t = \arg\max_a W_a$. Similarly as above, a prediction error decreases W by a factor of $1 - 1/|\mathcal{X}|$, since $\max_a W_a \geq W/|\mathcal{X}|$. Since $w_m \leq W \leq 1$, this algorithm can at most make $\log_{1-1/|\mathcal{X}|} w_m = O(\log w_m^{-1})$ prediction errors. If we choose, for instance, $w_i = (i+1)^{-2}$, the number of errors is $O(\log m)$, which is an exponential improvement over the Gold-style learning by enumeration above.

Algorithmic Probability

Algorithmic probability has been founded by Ray Solomonoff (1964). The so-called universal probability or a priori probability is the key quantity for universal learning. Its philosophical and technical roots are ▶ Ockham's razor (choose the simplest model consistent with the data), Epicurus' principle of multiple explanations (keep all explanations consistent with the data), (Universal) Turing machines (to compute, quantify, and assign codes to all quantities of interest), and Kolmogorov complexity (to define what simplicity/complexity means) (Rathmanner and Hutter 2011). This section considers deterministic computable sequences and the next section the general setup of computable probability distributions.

(Universal) monotone Turing machines. Since we consider infinite computable sequences, we need devices that convert input data streams to output data streams. For this we define the following variants of a classical deterministic Turing machine: A monotone Turing machine T is defined as a Turing machine with one unidirectional input tape, one unidirectional output tape, and some bidirectional work tapes (Li and Vitányi 2008). The input tape is binary (no blank) and read only, the output tape is over finite alphabet $\mathcal{X}$ (no blank) and write only, unidirectional tapes are those where the head can only move from left to right, work tapes are initially filled with zeros, and the output tape with some fixed element from $\mathcal{X}$. We *say* that *monotone Turing machine* T outputs/computes a string starting with $x \in \mathcal{X}^*$ on input $p \in \{0,1\}^*$ and write $T(p) = x*$ if p is to the left of the input head when the last symbol of x is output (T reads all of p but no more). T may continue operation and need not halt. For a given x, the set of such p forms a prefix code. Such codes are called *minimal* programs. Similarly we write $T(p) = \omega$ if p outputs the infinite sequence ω. A *prefix code* $\mathcal{P}$ is a set of binary strings such that no element is proper prefix of another. It satisfies *Kraft's inequality* $\sum_{p\in\mathcal{P}} 2^{-\ell(p)} \leq 1$.

The table of rules of a Turing machine T can be prefix encoded in a canonical way as a binary string, denoted by $\langle T \rangle$. Hence, the set of Turing machines $\{T_1, T_2, \ldots\}$ can be effectively enumerated. There are so-called universal Turing machines that can "simulate" all other Turing machines. We define a particular one which simulates monotone Turing machine $T(q)$ if fed with input $\langle T \rangle q$, i.e., $U(\langle T \rangle q) = T(q)\ \forall T, q$. Note that for p not of the form $\langle T \rangle q$, $U(p)$ does not output anything. We call this particular U the *reference universal Turing machine*.

Universal weighted majority learning. $T_1(\epsilon), T_2(\epsilon), \ldots$ constitutes an effective enumeration of all finite and infinite computable sequences, hence so does monotone $U(p)$ for $p \in \{0,1\}^*$. As argued below, the class of computable infinite sequences is conceptually very interesting. The halting problem implies that there is no recursive enumeration of all partial recursive functions with infinite domain; hence we cannot remove the finite sequences algorithmically. It is very fortunate that we don't have to. Hypothesis H_p is identified with the sequence $U(p)$, which may be finite, infinite, or possibly even empty. The class of considered hypotheses is $\mathcal{M} := \{H_p : p \in \{0,1\}^*\}$.

The weighted majority algorithm also needs weights w_p for each H_p. Ockham's razor combined with Epicurus' principle demand to assign a high (low) prior weight to a simple (complex) hypothesis. If complexity is identified with program length, then w_p should be a decreasing function of $\ell(p)$. It turns out that $w_p = 2^{-\ell(p)}$ is the "right" choice, since minimal p form a prefix code and therefore $\sum_p w_p \leq 1$ as required.

Using H_p for prediction can now fail in two ways. H_p may make a wrong prediction or no prediction at all for x_t. The true hypothesis H_m is still assumed to produce an infinite sequence. The weighted majority algorithm in this setting makes at most $O(\log w_p^{-1}) = O(\ell(p))$ errors. It is also plausible that learning $\ell(p)$ bits requires $O(\ell(p))$ "trials."

Universal mixture prediction. Solomonoff (1978) defined the following universal a priori probability:

$$M(x) := \sum_{p:U(p)=x*} 2^{-\ell(p)} \tag{1}$$

That is, $M(x) = W$ is the total weight of the computable deterministic hypotheses consistent with x for the universal weight choice $w_p = 2^{-\ell(p)}$. The universal weighted majority algorithm predicted $\arg\max_a M(\dot{x}_{<t}a)$. Instead, one could also make a probability prediction $M(a|\dot{x}_{<t}) := M(\dot{x}_{<t}a)/M(\dot{x}_{<t})$, which is the relative weight of hypotheses in $\mathcal{M}_t$ predicting a. The higher the probability $M(\dot{x}_t|\dot{x}_{<t})$ that is assigned to the true next observation $\dot{x}_t$, the better. Consider the absolute prediction error $|1 - M(\dot{x}_t|\dot{x}_{<t})|$ and the logarithmic error$-\log M(\dot{x}_t|\dot{x}_{<t})$. The cumulative logarithmic error is bounded by $\sum_{t=1}^{n} -\log M(\dot{x}_t|\dot{x}_{<t}) = -\log M(\dot{x}_{1:n}) \leq \ell(p)$ for any program p that prints $\dot{x}_{1:n}*$. For instance, p could be chosen as the shortest one printing $\dot{x}_{1:\infty}$, which has length $Km(\dot{x}_{1:\infty}) := \min\{\ell(p) : U(p) = \dot{x}_{1:\infty}\}$. Using $1-z \leq -\log z$ and letting $n \to \infty$, we get

$$\sum_{t=1}^{\infty}|1 - M(\dot{x}_t|\dot{x}_{<t})| \leq \sum_{t=1}^{\infty} -\log M(\dot{x}_t|\dot{x}_{<t}) \leq Km(\dot{x}_{1:\infty}) \qquad (2)$$

Hence again, the cumulative absolute and logarithmic errors are bounded by the number of bits required to describe the true environment.

Universal Bayes

The exposition so far has dealt with deterministic environments only. Data sequences produced by real-world processes are rarely as clean as IQ test sequences. They are often noisy. This section deals with stochastic sequences sampled from computable probability distributions. The developed theory can be regarded as an instantiation of Bayesian learning. Bayes' theorem allows to update beliefs in face of new information but is mute about how to choose the prior and the model class to begin with. Subjective choices based on prior knowledge are informal, and traditional "objective" choices such as Jeffreys prior are not universal (Rathmanner and Hutter 2011). Machine learning, the computer science branch of statistics, develops (fully) automatic inference and decision algorithms for very large problems. Naturally, machine learning has (re)discovered and exploited different principles (Ockham's and Epicurus') for choosing priors, appropriate for this situation. This leads to an alternative representation of universal probability as a mixture over all lower semi-computable semimeasures with Kolmogorov complexity based prior as described below.

Bayes. Sequences $\omega = \omega_{1:\infty} \in \mathcal{X}^\infty$ are now assumed to be sampled from the "true" probability measure μ, i.e., $\mu(x_{1:n}) := \mathrm{P}[\omega_{1:n} = x_{1:n}|\mu]$ is the μ-probability that ω starts with $x_{1:n}$. Expectations w.r.t. μ are denoted by $\mathbf{E}$. In particular for a function $f : \mathcal{X}^n \to \mathbb{R}$, we have $\mathbf{E}[f] = \mathbf{E}[f(\omega_{1:n})] = \sum_{x_{1:n}} \mu(x_{1:n})f(x_{1:n})$. Note that in Bayesian learning, measures, environments, and models are the same objects; let $\mathcal{M} = \{\nu_1, \nu_2, \ldots\} \equiv \{H_{\nu_1}, H_{\nu_2}, \ldots\}$ denote a countable class of these measures≡hypotheses. Assume that μ is unknown but known to be a member of $\mathcal{M}$, and $w_\nu := \mathrm{P}[H_\nu]$ is the given prior belief in H_ν. Then the Bayes mixture

$$\xi(x_{1:n}) := \mathrm{P}[\omega_{1:n} = x_{1:n}] = \sum_{\nu\in\mathcal{M}} \mathrm{P}[\omega_{1:n} = x_{1:n}|H_\nu]\mathrm{P}[H_\nu] \equiv \sum_{\nu\in\mathcal{M}} \nu(x_{1:n})w_\nu \qquad (3)$$

must be our a priori belief in $x_{1:n}$, and $\mathrm{P}[H_\nu|\omega_{1:n} = x_{1:n}] = w_\nu\nu(x_{1:n})/\xi(x_{1:n})$ be our posterior belief in ν by Bayes' rule.

Universal choice of $\mathcal{M}$. Next we need to find a universal class of environments $\mathcal{M}_U$. Roughly speaking, Bayes works if $\mathcal{M}$ contains the true environment μ. The larger the $\mathcal{M}$, the less restrictive is this assumption. The class of all computable distributions, although only countable, is pretty large from a practical point of view, since it includes for instance all of today's valid physics theories. (Finding a non-computable physical system would indeed overturn the generally accepted Church-Turing thesis.) It is the largest class, relevant from a computational point of view. Solomonoff (1964, Eq. (13)) defined and studied the mixture over this class.

One problem is that this class is not (effectively = recursively) enumerable, since the class of computable functions is not enumerable due to the halting problem, nor is it decidable whether a function is a measure. Hence ξ is completely incomputable. Leonid Levin (Li and Vitányi 2008) had the idea to "slightly" extend the class and include also lower semi-computable semimeasures.

A function $\nu : \mathcal{X}^* \to [0,1]$ is called a semimeasure iff $\nu(x) \geq \sum_{a\in\mathcal{X}} \nu(xa) \forall x \in \mathcal{X}^*$. It is a proper probability measure iff equality holds and $\nu(\epsilon) = 1$. $\nu(x)$ still denotes the ν-probability that a sequence starts with string x. A function is called lower semi-computable if it can be approximated from below. Similarly to that fact that the class of partial recursive functions is recursively enumerable, one can show that the class $\mathcal{M}_U = \{\nu_1, \nu_2, \ldots\}$ of lower semi-computable semimeasures is recursively enumerable. In some sense $\mathcal{M}_U$ is the largest class of environments for which ξ is in some sense computable, but even larger classes are possible (Schmidhuber 2002).

Kolmogorov complexity. Before we can turn to the prior w_ν, we need to quantify complexity/simplicity. Intuitively, a string is simple if it can be described in a few words, such as "the string of one million ones," and is complex if there is no such short description, like for a random object whose shortest description is specifying it bit by bit. We are interested in effective descriptions and hence restrict decoders to be Turing machines. One can define the *prefix Kolmogorov complexity* of string x as the length ℓ of the shortest *halting* program p for which U outputs x:

$$K(x) := \min_p\{\ell(p) : U(p) = x \text{ halts}\}$$

Simple strings such as 000…0 can be generated by short programs and, hence, have low Kolmogorov complexity, but irregular (e.g., random) strings are their own shortest description and hence have high Kolmogorov complexity. For non-string objects o (such as numbers and functions), one defines $K(o) := K(\langle o\rangle)$, where $\langle o\rangle \in \mathcal{X}^*$ is some standard code for o. In particular, $K(\nu_i) = K(i)$.

To be brief, K is an excellent universal complexity measure, suitable for quantifying Ockham's razor.

The universal prior. We can now quantify a prior biased toward simple models. First, we quantify the complexity of an environment ν or hypothesis H_ν by its Kolmogorov complexity $K(\nu)$. The universal prior should be a decreasing function in the model's complexity and of course sum to (less than) one. Since $\sum_x 2^{-K(x)} \leq 1$ by the prefix property and Kraft's inequality, this suggests the choice

$$w_\nu = w_\nu^U := 2^{-K(\nu)} \qquad (4)$$

Since $\log i \leq K(\nu_i) \leq \log i + 2\log\log i$ for "most" i, most ν_i have prior approximately reciprocal to their index i as also advocated by Jeffreys and Rissanen.

Representations. Combining the universal class $\mathcal{M}_U$ with the universal prior (4), we arrive at the universal mixture

$$\xi_U(x) := \sum_{\nu\in\mathcal{M}_U} 2^{-K(\nu)}\nu(x) \qquad (5)$$

which has remarkable properties. First, it is itself a lower semi-computable semimeasure, that is, $\xi_U \in \mathcal{M}_U$, which is very convenient. Note that for most classes, $\xi \notin \mathcal{M}$.

Second, ξ_U coincides with M (Wood et al. 2011) and $M \in \mathcal{M}_U$. This means that the mixture over deterministic computable sequences is as rich as the mixture over the much larger class of semi-computable semimeasures. The intuitive reason is that the probabilistic semimeasures are in the convex hull of the deterministic ones and therefore need not be taken extra into account in the mixture.

There is another, possibly the simplest, representation: One can show that $M(x)$ is equal to the probability that U outputs a string starting with x when provided with uniform random noise on the program tape. Note that a uniform distribution is also used in many no free lunch theorems to prove the impossibility of universal learners, but in our case, the uniform distribution is piped through a universal Turing machine, which defeats these negative implications as we will see in the next section (Lattimore and Hutter 2011).

Applications

In the stochastic case, identification of the true hypothesis is problematic. The posterior P$[H|x]$ may not concentrate around the true hypothesis H_μ if there are other hypotheses H_ν that are not asymptotically distinguishable from H_μ. But even if model identification (*induction* in the narrow sense) fails, *predictions*, *decisions*, and *actions* can be good, and indeed, for universal learning, this is generally the case.

Universal sequence prediction. Given a sequence $x_1x_2\ldots x_{t-1}$, we want to predict its likely continuation x_t. We assume that the strings which have to be continued are drawn from a computable "true" probability distribution μ. The maximal prior information a prediction algorithm can possess is the exact knowledge of μ, but often the true distribution is unknown. Instead, prediction is based on a guess ρ of μ. Let $\rho(a|x) := \rho(xa)/\rho(x)$ be the *predictive* ρ-probability that the next symbol is $a \in \mathcal{X}$, given sequence $x \in \mathcal{X}^*$. Since $\mu \in \mathcal{M}_U$ it is natural to use ξ_U or M for prediction.

Solomonoff's (1978, 2005) celebrated result indeed shows that M converges to μ. For general alphabet it reads

$$\sum_{t=1}^{\infty}\mathbf{E}\Big[\sum_{a\in\mathcal{X}}\big(M(a|\omega_{<t})-\mu(a|\omega_{<t})\big)^2\Big] \leq K(\mu)\,\text{In}\,2+O(1) \qquad (6)$$

Analogous bounds hold for ξ_U and for other than the Euclidian distance, e.g., the Hellinger and the absolute distance and the relative entropy.

For a sequence $a_1, a_2, \ldots$ of random variables, $\sum_{t=1}^{\infty}\mathbf{E}[a_t^2] \leq c < \infty$ implies $a_t \to 0$ for $t \to \infty$ with μ-probability 1 (w.p.1). Convergence is rapid in the sense that the probability that a_t^2 exceeds $\varepsilon > 0$ at more than $c/\varepsilon\delta$ times is bounded by δ. This might loosely be called the number of errors. Hence Solomonoff's bound implies

$$M(x_t|\omega_{<t}) - \mu(x_t|\omega_{<t}) \longrightarrow 0 \quad \text{for any } x_t \text{ rapid w.p.1 for } t\to\infty \qquad (7)$$

The number of times M deviates from μ by more than $\varepsilon > 0$ is bounded by $O(K(\mu))$, i.e., is proportional to the complexity of the environment, which is again reasonable. A counting argument shows that $O(K(\mu))$ errors for most μ are unavoidable. No other choice for w_ν would lead to significantly better bounds. Again, in general it is not possible to determine *when* these "errors" occur. Multistep lookahead convergence $M(x_{t:n_t}|\omega_{<t}) - \mu(x_{t:n_t}|\omega_{<t}) \to 0$ even for unbounded lookahead $n_t - t \geq 0$, relevant for delayed sequence prediction and in reactive environments, can also be shown.

In summary, M is an excellent sequence predictor under the only assumption that the observed sequence is drawn from some (unknown) computable probability distribution. No ergodicity, stationarity, or identifiability or other assumption is required.

Universal sequential decisions. Predictions usually form the basis for decisions and actions, which result in some profit or loss. Let $\ell_{x_t y_t} \in [0,1]$ be the received loss for decision $y_t \in \mathcal{Y}$ when $x_t \in \mathcal{X}$ turns out to be the true tth symbol of the sequence. The ρ-optimal strategy

$$y_t^{\Lambda_\rho}(\omega_{<t}) := \arg\min_{y_t}\sum_{x_t}\rho(x_t|\omega_{<t})\ell_{x_t y_t} \qquad (8)$$

minimizes the ρ-expected loss. For instance, if we can decide among $\mathcal{Y} = \{\textit{sunglasses}, \textit{umbrella}\}$

and it turns out to be $\mathcal{X} = \{sun, rain\}$, and our personal loss matrix is $\ell = \left(\begin{smallmatrix} 0.0 & 0.1 \\ 1.0 & 0.3 \end{smallmatrix}\right)$, then Λ_ρ takes $y_t^{\Lambda_\rho}$ =*sunglasses* if $\rho(rain|\omega_{<t}) < {}^1\!/_8$ and an *umbrella* otherwise. For $\mathcal{X} = \mathcal{Y}$ and 0–1 loss $\ell_{xy} = 0$ for $x = y$ and 1 else, Λ_ρ predicts the most likely symbol $y_t^{\Lambda_\rho} = \arg\max_a \rho(a|\omega_{<t})$ as in section "Deterministic Environments".

The cumulative μ(= true)-expected loss of Λ_ρ for the first n symbols is

$$\text{Loss}_n^{\Lambda_\rho} := \sum_{t=1}^{n} \mathbf{E}[\ell_{\omega_t y_t^{\Lambda_\rho}(\omega_{<t})}]$$

$$\equiv \sum_{t=1}^{n} \sum_{x_{1:t}} \mu(x_{1:t}) \ell_{x_t y_t^{\Lambda_\rho}(x_{<t})} \qquad (9)$$

If μ is known, Λ_μ obviously results in the best decisions in the sense of achieving minimal expected loss among all strategies. For the predictor Λ_M based on M (and similarly ξ_U), one can show (Hutter 2007)

$$\sqrt{\text{Loss}_n^{\Lambda_M}} - \sqrt{\text{Loss}_n^{\Lambda_\mu}} \le \sqrt{2K(\mu)\ \text{In}\ 2 + O(1)} \qquad (10)$$

This implies that $\text{Loss}_n^{\Lambda_M}/\text{Loss}_n^{\Lambda_\mu} \to 1$ for $\text{Loss}_n^{\Lambda_\mu} \to \infty$, or if $\text{Loss}_\infty^{\Lambda_\mu}$ is finite, then also $\text{Loss}_\infty^{\Lambda_M} < \infty$. This shows that M (via Λ_M) performs also excellent from a decision-theoretic perspective, i.e., suffers loss only slightly larger than the optimal Λ_μ strategy.

One can also show that Λ_M is Pareto optimal (admissible) in the sense that every other predictor with smaller loss than Λ_M in some environment $\nu \in \mathcal{M}_U$ must be worse in another environment.

Universal classification and regression. The goal of classification and regression is to infer the functional relationship $f : \mathcal{Y} \to \mathcal{X}$ from data $\{(y_1, x_1), \ldots, (y_n, x_n)\}$. In a predictive online setting, one wants to "directly" infer x_t from y_t given $(y_{<t}, x_{<t})$ for $t = 1, 2, 3, \ldots$. The universal induction framework has to be extended by regarding $y_{1:\infty}$ as independent side information presented in the form of an oracle or extra tape information or extra parameter. The construction has to ensure that $x_{1:n}$ only depends on $y_{1:n}$ but is (functionally or statistically) independent of $y_{n+1:\infty}$.

First, we augment a monotone Turing machine with an extra input tape containing $y_{1:\infty}$. The Turing machine is called chronological if it does not read beyond $y_{1:n}$ before $x_{1:n}$ has been written. Second, semimeasures $\rho = \mu, \nu, M, \xi_U$ are extended to $\rho(x_{1:n}|y_{1:\infty})$, i.e., one semimeasure $\rho(\cdot|y_{1:\infty})$ for each $y_{1:\infty}$ (no distribution over y is assumed, despite the suggestive |). Any such semimeasure must be chronological in the sense that $\rho(x_{1:n}|y_{1:\infty})$ is independent of y_t for $t>n$; hence we can write $\rho(x_{1:n}|y_{1:n})$. In classification and regression, ρ is typically (conditionally) i.i.d., i.e., $\rho(x_{1:n}|y_{1:n}) = \prod_{t=1}^{n} \rho(x_t|y_t)$, which is chronological, but note that the Bayes mixture ξ is *not* i.i.d. One can show that the class of lower semi-computable chronological semimeasures $\mathcal{M}_U^{|} = \{\nu_1(\cdot|\cdot), \nu_2(\cdot|\cdot), \ldots\}$ is effectively enumerable.

The generalized universal a priori semimeasure also has two equivalent definitions:

$$M(x_{1:n}|y_{1:n}) := \sum_{p:U(p,y_{1:n})=x_{1:n}} 2^{-\ell(p)}$$

$$= \sum_{\nu \in \mathcal{M}} 2^{-K(\nu)} \nu(x_{1:n}|y_{1:n}) \qquad (11)$$

which is again in $\mathcal{M}_U^{|}$. In case of $|\mathcal{Y}| = 1$, this reduces to (1) and (5). The bounds (6) and (10) and others continue to hold, now for all individual y's, i.e., M predicts asymptotically x_t from y_t and $(y_{<t}, x_{<t})$ for *any* y, provided x is sampled from a computable probability measure $\mu(\cdot|y_{1:\infty})$. Convergence is rapid if μ is not too complex.

Universal reinforcement learning. The generalized universal a priori semimeasure (11) can be used to construct a universal reinforcement learning agent, called AIXI. In reinforcement learning, an *agent* interacts with an *environment* in cycles $t = 1, 2, \ldots, n$. In cycle t, the agent chooses an *action* y_t (e.g., a limb movement) based on past *perceptions* $x_{<t}$ and past actions $y_{<t}$. Thereafter, the agent perceives $x_t \equiv o_t r_t$, which consists of a (regular) *observation* o_t (e.g., a camera image) and a real-valued *reward* r_t. The reward may be scarce (e.g., just +1 (-1) for winning (losing) a chess game and 0 at all other times), internal (e.g., a robot's battery level), external (provided by a teacher), or universal (Orseau et al. 2013). Then the next cycle $t + 1$ starts. The goal of the agent is to maximize its expected reward over its lifetime n. Probabilistic planning deals with the situation in which the environmental probability distribution $\mu(x_{1:n}|y_{1:n})$ is known. Reinforcement learning deals with the case of unknown μ. In universal reinforcement learning, the unknown μ is replaced by M similarly to the prediction, decision, and classification cases above. The universally optimal action in cycle t is Hutter (2005, 2012)

$$y_t := \arg\max_{y_t} \sum_{x_t} \ldots \max_{y_n} \sum_{x_n} [r_t + \ldots + r_n] M(x_{1:n}|y_{1:n}) \qquad (12)$$

The expectations (Σ) and maximizations (max) over future x and y are interleaved in chronological order to form an expectimax tree similarly to minimax decision trees in extensive zero-sum games such as chess. Optimality and universality results similar to the prediction case exist.

Approximations and practical applications. Since K and M are only semi-computable, they have to be approximated in practice. For instance, $-\log M(x) = K(x) + O(\log \ell(x))$, and $K(x)$ can and has been approximated by off-the-shelf compressors such as Lempel-Ziv and successfully applied to a plethora of clustering problems (Cilibrasi and Vitányi 2005). The approximations upper-bound $K(x)$ and, e.g., for Lempel-Ziv converge to $K(x)$ if x is sampled from a context tree source. The ▶ minimum message length principle also attempts to approximate $K(x)$ for stochastic x. The context tree weighting algorithm considers a relatively large subclass of $\mathcal{M}_U$ that can be summed over efficiently. This can and has been combined with Monte Carlo sampling to efficiently approximate AIXI (12) (Veness et al. 2011). The time-bounded versions of K and M, namely, Levin complexity Kt and the speed prior S, have also been applied to various learning tasks (Gaglio 2007).

Other applications. Continuously parameterized model classes are very common in statistics. Bayesians usually assume a prior *density* over some parameter $\theta \in \mathbb{R}^d$, which works fine for many problems, but has its problems. Even for continuous classes $\mathcal{M}$, one can assign a (proper) universal prior (not density) $w_\theta^U := 2^{-K(\theta)} > 0$ for computable θ (and ν_θ) and 0 for uncomputable ones. This effectively reduces $\mathcal{M}$ to a discrete class $\{\nu_\theta \in \mathcal{M} : w_\theta^U > 0\} \subseteq \mathcal{M}_U$ which is typically dense in $\mathcal{M}$. There are various fundamental philosophical and statistical problems and paradoxes around (Bayesian) induction, which nicely disappear in the universal framework. For instance, universal induction has no zero and no improper p(oste)rior problem, i.e., can confirm universally quantified hypotheses, is reparametrization and representation invariant, and avoids the old evidence and updating problem, in contrast to most classical continuous prior densities. It even performs well in incomputable environments, actually better than latter (Rathmanner and Hutter 2011).

Discussion and Future Directions

Universal learning is designed to work for a wide range of problems without any a priori knowledge. In practice we often have extra information about the problem at hand, which could and should be used to guide the forecasting. One can incorporate it by explicating all our prior knowledge z and place it on an extra input tape of our universal Turing machine U or prefix our observation sequence x by z and use $M(zx)$ for prediction.

Another concern is the dependence of K and M on U. The good news is that a change of U

changes $K(x)$ only within an additive and $M(x)$ within a multiplicative constant independent of x. This makes the theory practically immune to any “reasonable” choice of U for large data sets x, but predictions for short sequences (shorter than typical compiler lengths) can be arbitrary. One solution is to take into account our (whole) scientific prior knowledge z (Hutter 2006), and predicting the now long string zx leads to good (less sensitive to “reasonable” U) predictions. This is a kind of grand transfer learning scheme. It is unclear whether a more elegant theoretical solution is possible.

Finally, the incomputability of K and M prevents a *direct* implementation of Solomonoff induction. Most fundamental theories have to be approximated for practical use, sometimes systematically such as polynomial time approximation algorithms or numerical integration, and sometimes heuristically like in many AI search problems or in non-convex optimization problems. Universal machine learning is similar, except that its core quantities are only semi-computable. This makes them often hard, but as described in the previous section, not impossible, to approximate.

In any case, universal induction can serve as a “gold standard” which practitioners can aim at. Solomonoff’s theory considers the class of all computable (stochastic) models, and a universal prior inspired by Ockham and Epicurus, quantified by Kolmogorov complexity. This led to a universal theory of induction, prediction, and decisions and, by including Bellman, to universal actions in reactive environments. Future progress on the issues above (incorporating prior knowledge, getting rid of the compiler constants, and finding better approximations) will lead to new insights and will continually increase the number of applications.

Unknown Attribute Values

▶ Missing Attribute Values

Unknown Values

▶ Missing Attribute Values

Unlabeled Data

Unlabeled data are data for which there are no target values. Unlabeled data are used in ▶ unsupervised learning. They stand in contrast to *labeled data* that have target values and are used in ▶ supervised learning.

Unsolicited Commercial Email Filtering

▶ Text Mining for Spam Filtering

Unstable Learner

An *unstable learner* produces large differences in generalization patterns when small changes are made to its initial conditions. The obvious initial condition is the set of training data used – for an unstable learner, sampling a slightly different training set produces a large difference in testing behavior. Some models can be unstable in additional ways, for example ▶ neural networks are unstable with respect to the initial weights. In general this is an undesirable property – high sensitivity to training conditions is also known as high variance, which results in higher overall mean squared error. The flexibility enabled by being sensitive to data can thus be a blessing or a curse. Unstable learners can however be used to an advantage in ▶ ensemble learning methods, where large variance is "averaged out" across multiple learners.

Examples of unstable learners are: neural networks (assuming gradient descent learning), and ▶ decision trees. Examples of stable learners are ▶ support vector machines, K-nearest neighbor classifiers, and ▶ decision stumps. It should of course be recognized that there is a continuum between "stable" and "unstable," and the opinion of whether something is "sensitive" to initial conditions is somewhat of a subjective one. See also ▶ bias-variance decomposition for a more formal interpretation of this concept.

Unsupervised Learning

Unsupervised learning refers to any machine learning process that seeks to learn structure in the absence of either an identified output (cf. ▶ supervised learning) or feedback (cf. ▶ reinforcement learning). Three typical examples of unsupervised learning are ▶ clustering, ▶ association rules, and ▶ self-organizing maps.

Uplift Modeling

Szymon Jaroszewicz
Institute of Computer Science, Polish Academy of Sciences, Warsaw, Poland

Abstract

Uplift modeling is a machine learning technique which aims at predicting, on the level of

individuals, the gain from performing a given action with respect to refraining from taking it. Examples include medical treatments and direct marketing campaigns where the rate of spontaneous recovery and the background purchase rate need to be taken into account to assess the true gains from taking an action. Uplift modeling addresses this problem by using two training sets: the treatment dataset containing data on objects on which the action has been taken and the control dataset containing data on objects left untreated. A model is then built which predicts the difference between outcomes after treatment and without it conditional on available predictor variables.

An obvious approach to uplift modeling is to build two separate models on both training sets and subtract their predictions. In many cases, better results can be obtained with models which predict the difference in outcomes directly. A popular class of uplift models are decision trees with splitting criteria favoring tests which promote differences between treatment and control groups. Ensemble methods have proven to be particularly useful in uplift modeling, often leading to significant increases in performance over the base learners. Linear models, such as logistic regression and support vector machines, have also been adapted to this setting.

Dedicated methods, such as uplift or qini curves, are necessary for evaluating uplift models. Application of the methodology to survival data and scenarios with more than one possible action have also been considered.

Synonyms

Differential prediction; Net lift modeling; True lift modeling

Definition

Uplift modeling is a machine learning technique which aims at predicting, on the level of individuals, the gain from performing a given action such as a medical treatment or a direct marketing campaign. The learning task is to predict the difference between the outcome after applying the action to an individual and the outcome had the individual not been subjected to the action. The difficulty lies in the fact that the effects of the action cannot be reversed, so only one of those outcomes can be observed. Solving this task requires the use two training sets: the *experimental* or *treatment* group containing data on objects on which the action has been taken and the *control* group containing data on objects on which the action has not been taken. When the assignment to control and treatment groups is random, an uplift model assumes a *causal* interpretation and allows for selecting individuals to whom the action should be applied to achieve real benefits, for example, customers who will buy a product after a campaign but would not have bought it otherwise or patients who will recover after the treatment but will not be harmed by its side effects and would not have recovered spontaneously.

Introduction

Consider an application of a machine learning model to select customers for a direct marketing campaign. Typically, a small pilot campaign is conducted, and its results are used as training data to build the model. This approach, although frequently used in practice, is not correct. There are in fact four groups of customers:

1. Customers who bought *because* of the campaign, that is, bought after receiving the offer but would not have bought otherwise
2. Customers who bought the product but would have bought it even without the campaign
3. Customers who did not buy the product and the campaign had no effect
4. Customers who were originally going to buy the product but were put off by the campaign

Only customers in the first group should become targets of the marketing action. Targeting the two following groups only generates unnecessary costs and targeting the fourth group is outright harmful. The existence of the fourth group may seem counterintuitive, but is a well-known phenomenon in marketing. Similar groups can be identified in case of medical therapies: we only want to treat patients who recover after receiving the treatment and would not have recovered spontaneously. The fourth group in the above list corresponds to patients who would have recovered without the treatment but were, instead, harmed by its side effects.

The proper way to address the problem of selecting targets is to take into consideration the outcomes both after taking the action and after refraining from it. A typical approach is to use an additional—*control*—training set containing outcomes for individuals who where put aside and not subjected to the action. The other dataset, with outcomes for individuals subjected to the action is called the *experimental* or *treatment* training set.

The goal of *uplift modeling* is to build a model which predicts the difference between outcomes after taking the action and after refraining from taking it, based on the two training sets. For example, in case of a binary target variable Y, with the outcome $Y = 1$ interpreted as success, the quantity predicted by an uplift model typically is the difference between success probabilities in the two groups:

$$P(Y=1|x, \text{action applied}) - P(Y=1|x, \text{control}), \quad (1)$$

where x is a feature vector describing the object for which prediction is being made. This quantity is referred to as *net gain*, *true gain*, or *uplift*. Analogues for regression problems and modifications involving costs also exist (Holland 1986; Hansotia and Rukstales 2002).

The main algorithmic difficulty lies in the fact that for each individual only one of those outcomes is known, never both. This problem is called *fundamental problem of causal inference* (Holland 1986). As a result the predicted target value is not known at the level of individual data records, which has implications for the design of learning algorithms as well as for model quality assessment.

Structure of the Learning System

Uplift modeling works on two training sets: *treatment* and *control*, so uplift learning algorithms need to take into account the additional control dataset. Below we describe several types of uplift learners, most of which originate from corresponding classification algorithms.

The Two-Model Approach

An obvious approach to uplift modeling is the *two-model approach*. Separate probabilistic classifiers are built on the treatment and control datasets, and their predictions are subtracted to obtain an estimate of the net gain given in Eq. 1.

A clear advantage of the two-model approach is its intuitive clarity and simplicity. However, in many cases, its performance can be poor because both models try to predict the value of the target variable in the two training sets instead of focusing on the (usually quite small) differences in behavior between the two groups. An intuitive example is given in Radcliffe and Surry (2011) where an artificial dataset is constructed with one variable strongly influencing the outcome in both groups and a second variable weakly influencing the outcome in the treatment group only. A model based on two separate decision trees was then built on the data. Both trees split only based on the first variable, leading to a useless uplift model. A single decision tree built to directly predict the net gain would select tests based on the second variable, at least in the upper levels of the tree, leading to a much better performance.

Most research on uplift modeling has therefore concentrated on building models predicting the net gain *directly*.

Uplift Decision Trees

Decision trees were, historically, the first learning algorithms adapted the problem of uplift modeling. The term "uplift" first appeared in a machine learning context in Radcliffe and Surry (1999), where differential response trees were described, albeit with little technical detail given. A detailed description was later provided in Radcliffe and Surry (2011). The algorithm uses a special splitting criterion designed to pick tests which promote differences between success rates in the treatment and control groups. The criterion works by first constructing a linear model with an interaction term between the split outcome and the group to which data records belong (treatment or control). The coefficient estimate for this interaction term corresponds to the estimated difference between treatment and control group behavior on both sides of the split, and the quality of the split is measured by the p-value of a statistical test for this coefficient.

Uplift decision trees based on information theoretical criteria have been proposed in Rzepakowski and Jaroszewicz (2010, 2012). The difference in class distributions in the treatment and control groups is measured using a statistical divergence measure such as the Kullback-Leibler divergence. Splits are then selected which result in the highest increase of the divergence. The authors show that the proposed criteria possess several desirable properties such as not selecting tests independent from the outcome variable or reducing to standard decision tree criteria when the control group is absent. A dedicated pruning method is also provided. An advantage of this approach is that it is able to handle target variables with more than two outcomes.

Ensemble Methods

In classical machine learning, one way to improve performance of decision trees is to combine them into ensembles. This often results in significant increases in accuracy over the base learners. Ensemble methods have also been successfully applied in uplift modeling.

The first mention of the use of uplift bagging ensembles can be found in Radcliffe and Surry (2011) but little detail is given. Guelman et al. (2012) devised an uplift random forest by using additional randomization in the decision tree test selection based on the criterion given in Rzepakowski and Jaroszewicz (2012).

In Sołtys et al. (2015) a thorough experimental analysis of bagging and random forests in uplift modeling was conducted showing that those methods often dramatically improve the performance of base learners; moreover, the effect is more significant than for classification. Some theoretical justification has been offered: frequently, the class variable in both groups is strongly influenced by predictor variables, but the differences between the treatment and control groups are quite small. Modeling this small differences is difficult and leads to uplift trees with highly randomized structure and, as a consequence, to highly diverse ensembles.

Regression Methods

Linear regression techniques are a very important tool of predictive analytics, so there have been several attempts to apply them to uplift modeling. Many approaches are in fact variations on the two-model solution. For example, in medical applications, a model with interactions between predictors and the action indicator is often used:

$$y = \alpha' x + \beta' x A,$$

where A is an indicator variable taking the value of 1 if the action has been applied to a given individual and the value of 0 otherwise, x is the vector of input predictors (including a constant intercept term), α and β are regression coefficient vectors, and the prime denotes matrix transpose. The expression $\beta' x$ is the predicted net gain. A similar approach has been presented in Lo (2002); however, two additional steps of variable selection are used.

A method based on a class variable transformation which allows for building a single uplift regression model has been presented in Jaśkowski and Jaroszewicz (2012). The idea is to use a new target variable Z defined as follows:

$$Z = \begin{cases} Y & \text{if } A = 1, \\ 1 - Y & \text{if } A = 0. \end{cases}$$

In other words, the class variable in the control group is reversed, and both training sets are concatenated into a single dataset. It can be shown that modeling the probability of the event $Z = 1$ is equivalent to modeling the net gain given in Eq. 1. The transformation can thus be used to turn any probabilistic classifier into an uplift model. The idea has been presented earlier in Lai et al. (2006), but without a formal justification. In Jaśkowski and Jaroszewicz (2012) the approach has been used with a logistic regression model, but the benefits with respect to an approach based on subtracting predictions of two separate logistic models are less clear than in the case of decision trees.

Another technique, called *g-estimation*, which has been presented in medical statistics literature (Robins 1994), can be interpreted as an earlier approach to uplift regression. The technique is based on selecting a vector of uplift model coefficients which make the expectations of the target variable in the treatment and control groups equal. Asymptotic optimality results are provided but require correct specification of outcomes in the control group. Due to lack of publicly available implementations, the method has not yet gained significant popularity.

Other Algorithms and Extensions

Several other uplift modeling algorithms have been proposed. Two variants of uplift support vector machines have been developed in Zaniewicz and Jaroszewicz (2013) and Kuusisto et al. (2014). The first approach uses two parallel separating hyperplanes which split points into three groups with predicted positive, neutral, and negative impact of the action. The second approach uses a modified SVM to directly maximize the area under the uplift curve (see below). Other methods, such as k-nearest neighbors and naive Bayesian classifier, have been adapted to the uplift setting by Kim Larsen in a series of conference talks (Larsen 2011).

In many applications, uplift modeling needs to be applied to survival data which involves censoring. For example, if a patient entered a medical study a year ago and is still alive, we do not know her survival time; all we know is that it is at least one year. The true value has been *censored*. Typically, censored data requires special methods, but in Jaroszewicz and Rzepakowski (2014) it has been shown that in case of uplift modeling such data can, under certain assumptions, be converted into a problem with a binary class. Cases for which the observed (possibly censored) survival time exceeds some threshold are considered successes. The resulting uplift model cannot predict the true gain in survival rate but can make a correct decision whether the action should or should not be applied to a given individual.

In real-world applications, more than one action is often possible. For example, we may contact a customer using a text message, regular mail, or a phone call. The task now is not only to decide whether a given individual should be subjected to an action but also to select the most profitable action to take. The two-model approach can easily be extended to multiple actions. In Rzepakowski and Jaroszewicz (2012) direct extension of uplift decision trees to the multiple actions scenario is provided.

Evaluation of Uplift Models

Due to the fundamental problem of causal inference, we can never determine whether the action was truly beneficial for a given individual; such assessment can only be made on the level of groups of individuals. Moreover, two test sets are now necessary: treatment (test data on objects subjected to the action) and control (test data on objects left untreated).

A typical approach scores both test sets using the uplift model being evaluated and groups the test cases by deciles of the score. The success rate in the first decile of the control test set is subtracted from the success rate in the first decile of the treatment test set. This way, an estimate of model performance for individuals whose score was in the top 10 % is obtained. Analogous estimates are computed for the remaining deciles and tabulated (Hansotia and Rukstales 2002).

A more convenient approach is to visualize uplift model's performance using curves. A starting point is *cumulative gains curves* (also known as *lift curves*) drawn on the treatment and control training sets. The x-axis of a cumulative gains curve denotes the percentage of the population assigned highest scores by a model and the y-axis the success rate after targeting the given percentage of the population. Cumulative gains curves drawn on the treatment and control test sets are subtracted to obtain a single curve describing the performance of an uplift model. Such curves have been called *uplift curves* in Rzepakowski and Jaroszewicz (2012) and *incremental gains curves* or *qini curves* in Radcliffe and Surry (2011). The curves are a very convenient tool in campaign planning: the x-axis corresponds to the size of the campaign, and the y-axis provides an estimate of the resulting total net gain.

Applications

Uplift modeling is gaining importance primarily in predictive analytics and direct marketing. Several successful applications in the banking and telecommunication sectors are reported in literature (Radcliffe and Surry 2011; Siegel and Davenport 2013). Uplift modeling played a crucial role in Barak Obama's 2012 presidential campaign (Siegel and Davenport 2013). A potentially large application area is personalized medicine where appropriate treatment is selected based on patient's individual characteristics.

Value Function Approximation

Michail G. Lagoudakis
Technical University of Crete, Chania,
Greece

Abstract

The goal in sequential decision making under uncertainty is to find good or optimal policies for selecting actions in stochastic environments in order to achieve a long-term goal; such problems are typically modeled as Markov decision processes (MDPs). A key concept in MDPs is the *value function*, a real-valued function that summarizes the long-term goodness of a decision into a single number and allows the formulation of optimal decision making as an optimization problem. An exact representation of value functions in large real-world problems is infeasible; therefore, a large body of research has been devoted to *value-function approximation* methods, which sacrifice some representation accuracy for the sake of scalability. These approaches have delivered effective approaches to deriving good policies in hard decision problems and laid the foundation for efficient reinforcement learning algorithms, which learn good policies in unknown stochastic environments through interaction.

Synonyms

Approximate dynamic programming; Cost-to-go function approximation; Neuro-dynamic programming

Definition

Value Function Approximation is a collection of function approximation representations, techniques, and methods aiming at providing a scalable and effective approximation to an exact value function (a real-valued function indicating the long-term goodness of making decisions at any state within a sequential decision problem).

Motivation and Background

Markov Decision Processes

A *Markov decision process* (MDP) is a 6-tuple $(\mathcal{S}, \mathcal{A}, \mathcal{P}, \mathcal{R}, \gamma, \mathcal{D})$, where $\mathcal{S}$ is the state space of the process, $\mathcal{A}$ is a finite set of actions, $\mathcal{P}$ is a Markovian transition model ($\mathcal{P}(s'|s,a)$ denotes the probability of a transition to state s' when taking action a in state s), $\mathcal{R}$ is a reward function ($\mathcal{R}(s,a)$ is the reward for taking action a in state s), $\gamma \in (0,1]$ is the discount factor for future rewards (a reward received after t steps is weighted by γ^t), and $\mathcal{D}$ is the initial state distribution (Puterman 1994). MDPs are discrete-time processes. The process begins at time $t = 0$

C. Sammut, G.I. Webb (eds.), *Encyclopedia of Machine Learning and Data Mining*,
DOI 10.1007/978-1-4899-7687-1

in some state $s_0 \in \mathcal{S}$ drawn from $\mathcal{D}$. At each time step t, the decision maker observes the current state of the process $s_t \in \mathcal{S}$ and chooses an action $a_t \in \mathcal{A}$. The next state of the process s_{t+1} is drawn stochastically according to the transition model $\mathcal{P}(s_{t+1}|s_t, a_t)$, and the reward r_t at that time step is determined by the reward function $\mathcal{R}(s_t, a_t)$. The horizon h is the temporal extent of each run of the process and is typically infinite. A complete run of the process over its horizon is called an *episode* and consists of a long sequence of states, actions, and rewards:

$$s_0 \xrightarrow[r_0]{a_0} s_1 \xrightarrow[r_1]{a_1} s_2 \xrightarrow[r_2]{a_2} s_3 \xrightarrow[r_3]{a_3} s_4 \quad \ldots \quad s_{h-1} \xrightarrow[r_{h-1}]{a_{h-1}} s_h .$$

The quantity of interest is the *expected total discounted reward* from any state s:

$$E\Big(r_0 + \gamma r_1 + \gamma^2 r_2 + \gamma^3 r_3 + \cdots + \gamma^h r_h \;\Big|\; s_0 = s\Big) = E\left(\sum_{t=0}^{h} \gamma^t r_t \;\middle|\; s_0 = s\right),$$

where the expectation is taken with respect to all possible trajectories of the process in the state space under the decisions made and the transition model, assuming that the process is initialized in state s. The goal of the decision maker is to make decisions so that the expected total discounted reward, when s is drawn from $\mathcal{D}$, is optimized. (The optimization objective could be maximization or minimization depending on the problem. Here, we adopt a reward maximization viewpoint, but there are analogous definitions for cost minimization. There are also other popular optimality measures, such as maximization/minimization of the average reward/cost per step.)

Policies

A *policy* dictates how the decision maker chooses actions in each state. A *stationary, deterministic policy* π is a mapping $\pi : \mathcal{S} \mapsto \mathcal{A}$ from states to actions; $\pi(s)$ denotes the action the agent takes in state s. In this case, there is a single action choice for each state, and this choice does not change over time. In contrast, a *stationary, stochastic policy* π is a mapping $\pi : \mathcal{S} \mapsto \Omega(\mathcal{A})$, where $\Omega(\mathcal{A})$ is the set of all probability distributions over $\mathcal{A}$. Stochastic policies are also called *soft*, for they do not commit to a single action per state; $\pi(a|s)$ stands for the probability of choosing action a in state s under policy π. Each policy π (deterministic or stochastic) is characterized by the expected total discounted reward it accumulates during an episode. An *optimal policy* π^* for an MDP is a policy that maximizes the expected total discounted reward from any state $s \in \mathcal{S}$. It is well known that for every MDP, there exists at least one, not necessarily unique, optimal policy, which is stationary and deterministic.

Value Functions

The quality of any policy π can be quantified formally through a value function, which measures the expected return of the policy under different process initializations. For any MDP and any policy π, the *state value function* V assigns a numeric value to each state. The value $V^\pi(s)$ of a state s under a policy π is the expected return, when the process starts in state s and the decision maker follows policy π (all decisions at all steps are made according to π):

$$V^\pi(s) = E_{a_t \sim \pi\,;\, s_t \sim \mathcal{P}\,;\, r_t \sim \mathcal{R}} \left(\sum_{t=0}^{\infty} \gamma^t r_t \;\middle|\; s_0 = s\right).$$

Similarly, the *state-action value function* Q assigns a numeric value to each pair (s, a) of states and actions. The value $Q^\pi(s, a)$ of taking action a in state s under a policy π is the expected return when the process starts in state s, and the decision maker takes action a for the first step and follows policy π thereafter:

$$Q^{\pi}(s,a)$$

$$= E_{a_t \sim \pi\,;\, s_t \sim \mathcal{P}\,;\, r_t \sim \mathcal{R}} \left(\sum_{t=0}^{\infty} \gamma^t r_t \,\middle|\, s_0 = s,\, a_0 = a \right).$$

The state and the state-action value functions for a deterministic policy π are related as follows:

$$V^{\pi}(s) = Q^{\pi}\big(s, \pi(s)\big).$$

For a stochastic policy π this relationship needs to take into account the probability distribution over actions:

$$V^{\pi}(s) = \sum_{a \in \mathcal{A}} \pi(a|s) Q^{\pi}(s,a).$$

The state-action value function of a policy π (either deterministic or stochastic) can also be expressed in terms of the state value function:

$$Q^{\pi}(s,a) = \mathcal{R}(s,a) + \gamma \sum_{s' \in \mathcal{S}} \mathcal{P}(s'|s,a) V^{\pi}(s').$$

The *optimal value functions* $V^* = V^{\pi^*}$ and $Q^* = Q^{\pi^*}$ are the state and the state-action value functions of any optimal policy π^*. Even if there are several distinct optimal policies, they all share the same unique optimal value functions.

Bellman Equations

Given the full MDP model, the state or the state-action value function of any given policy can be computed by solving a linear system formed using the linear Bellman equations. In general, the linear *Bellman equation* relates the value of the function at any point to the values of the function at several – in fact, all – other points. This is achieved by separating the first step of an episode from the rest and using the definition of the value function recursively in the next step. In particular, for any deterministic policy π, the linear Bellman equation for the state value function is

$$V^{\pi}(s) = \mathcal{R}(s, \pi(s)) + \gamma \sum_{s' \in \mathcal{S}} \mathcal{P}(s'|s, \pi(s)) V^{\pi}(s'),$$

whereas for a stochastic policy π, it becomes

$$V^{\pi}(s) = \sum_{a \in \mathcal{A}} \pi(a|s) \Big(\mathcal{R}(s,a) + \gamma \sum_{s' \in \mathcal{S}} \mathcal{P}(s'|s,a) V^{\pi}(s') \Big).$$

The exact V^{π} values for all states can be found by solving the $(|\mathcal{S}| \times |\mathcal{S}|)$ linear system that results from writing down the linear Bellman equation for all states.

Similarly, the linear Bellman equation for the state-action value function given any deterministic policy π is

$$Q^{\pi}(s,a) = \mathcal{R}(s,a) + \gamma \sum_{s' \in \mathcal{S}} \mathcal{P}(s'|s,a) Q^{\pi}\big(s', \pi(s')\big),$$

whereas for a stochastic policy π, it becomes

$$Q^{\pi}(s,a) = \mathcal{R}(s,a) + \gamma \sum_{s' \in \mathcal{S}} \mathcal{P}(s'|s,a) \times \sum_{a' \in \mathcal{A}} \pi(a'|s') Q^{\pi}(s',a').$$

The exact Q^{π} values for all state-action pairs can be found by solving the $(|\mathcal{S}||\mathcal{A}| \times |\mathcal{S}||\mathcal{A}|)$ linear system that results from writing down the linear Bellman equation for all state-action pairs.

The unique optimal state or state-action value function can be computed even for an unknown optimal policy π^* using the nonlinear *Bellman optimality equation*, which relates values of the function at different points while exploiting the fact that there exists a deterministic optimal policy that achieves the maximum value at each point. In particular, the nonlinear Bellman optimality equation for the state value function is

$$V^*(s) = \max_{a \in \mathcal{A}} \Big\{ \mathcal{R}(s,a) + \gamma \sum_{s' \in \mathcal{S}} \mathcal{P}(s'|s,a) V^*(s') \Big\},$$

whereas for the state-action value function is

$$Q^*(s,a) = \mathcal{R}(s,a) + \gamma \sum_{s' \in \mathcal{S}} \mathcal{P}(s'|s,a) \max_{a' \in \mathcal{A}} \left\{ Q^*(s',a') \right\}.$$

The functions V^* and Q^* can be approximated arbitrarily closely by the iterative application of the operator formed by the right-hand side of the equations above (Bellman optimality operator). This iteration is a contraction with rate γ, so starting with any arbitrary initialization, it eventually converges to V^* or Q^*.

Significance of Value Functions

Value functions play a critical role in sequential decision making because they address two core problems: policy evaluation and policy improvement. Policy evaluation refers to the problem of quantifying the quality of any given policy π in a given MDP. Apparently, computing the value function V^π or Q^π using the Bellman equations provides the solution to this problem. Policy improvement, on the other hand, refers to the problem of deriving an improved policy π' given any base policy π, so that π' is at least as good as π and possibly better. The knowledge of V^π or Q^π allows for the derivation of an improved deterministic policy π' through a simple one-step look-ahead maximization procedure:

$$\pi'(s) = \arg\max_{a \in \mathcal{A}} \left\{ \mathcal{R}(s,a) + \gamma \sum_{s' \in \mathcal{S}} \mathcal{P}(s'|s,a) V^\pi(s') \right\}$$

$$\pi'(s) = \arg\max_{a \in \mathcal{A}} \left\{ Q^\pi(s,a) \right\}.$$

Note that this maximization does not need the MDP model when using the state-action value function. Once policy evaluation and policy improvement have been addressed, the derivation of an optimal policy for any MDP is straightforward. One can alternate between policy evaluation and policy improvement producing a sequence of improving policies until convergence to an optimal policy; this algorithm is known as policy iteration. Alternatively, one can iteratively compute an optimal value function V^* or Q^* and extract an optimal policy through a trivial step of policy improvement on top of V^* or Q^*; this algorithm is known as value iteration. In either case, value functions provide the means to the end.

The problem of deriving an optimal policy using the full MDP model is known as planning. Nevertheless, in many real-world sequential decision domains, the model is unknown. The problem of optimal decision making in an unknown stochastic environment is known as reinforcement learning, because the decision maker relies on the feedback received through interaction with the environment to reinforce or discourage past decisions. More specifically, the learner interacts with an unknown MDP and typically observes the state of the process and the immediate reward at every step; however, $\mathcal{P}$ and $\mathcal{R}$ are not accessible. At each step of interaction, the learner observes the current state s, chooses an action a, and observes the resulting next state s' and the reward received r, thus learning is based on (s,a,r,s') samples. The core problems in reinforcement learning are known as prediction and control. Prediction refers to the problem of learning the value function of a given policy π in an unknown MDP through interaction. Well-known algorithms for the prediction problem are Monte Carlo estimation and temporal difference (TD) learning. Control, on the other hand, refers to the problem of gradually learning a good or even optimal policy in an unknown MDP through interaction. Well-known algorithms for the control problem are SARSA and Q-learning. Again, value functions play a critical role in reinforcement learning; they are absolutely necessary for the prediction problem, and the majority of control approaches are value-function based.

Structure of Learning System

Value-Function Approximation

Most algorithms for planning or learning in MDPs rely on computing or learning a value function. However, if the state space of the process is fairly large, the exact (tabular) representation of a value function becomes problematic. Not only does memory space become insufficient very quickly, but also computing or learning accurately all the distinct entries of the function requires a tremendous amount of computation and data. This is known as the *curse of dimensionality*: the exponential growth of the state or action space as a function of the dimensionality of the state or action. The urgent need for solutions to large real-world sequential decision problems has drawn attention to approximate methods. These methods use function approximation techniques for approximating value functions; therefore, they sacrifice some representational accuracy in order to make the representation manageable in practice. Sacrificing accuracy in the representation of the value function is acceptable, since the ultimate goal is to find a good policy and not necessarily an accurate value function. As a result, value-function approximation methods cannot guarantee optimal solutions, but only good solutions. This is not to say that they are doomed to always finding suboptimal solutions; if an optimal solution lies within the space spanned by the value-function approximation scheme, it is possible that an optimal solution will be discovered.

Let $\hat{V}^{\pi}(s;w)$ be an approximation to the state value function $V^{\pi}(s)$ represented by a parametric approximation architecture with free parameters w. The key idea of value- function approximation is that the parameters w can be adjusted appropriately so that the approximate values are "close enough" to the original values,

$$\hat{V}^{\pi}(s;w) \approx V^{\pi}(s),$$

and, therefore, $\hat{V}^{\pi}$ can be used in place of the exact value function V^{π}. Similarly, let $\hat{Q}^{\pi}(s,a;w)$ be an approximation to the state-action value function $Q^{\pi}(s,a)$. Again, the goal is to adjust the parameters w so that

$$\hat{Q}^{\pi}(s,a;w) \approx Q^{\pi}(s,a),$$

and, therefore, $\hat{Q}^{\pi}$ can be used in place of the exact value function Q^{π}. Approximations $\hat{V}^{*}$ and $\hat{Q}^{*}$ of the optimal value functions V^{*} and Q^{*} are defined similarly. The characterization "close enough" ($\approx$) accepts a variety of interpretations in this context, and it does not necessarily refer to the minimization of some norm. Value-function approximation should be regarded as a *functional* approximation rather than as a pure *numerical* approximation, where "functional" refers to the ability of the approximation to play closely the functional role of the original value function within a decision making algorithm.

The benefits of value-function approximation are obvious. The storage requirements are much smaller compared to the tabular case, since only the parameters w need to be stored along with a compact description of the functional form of the architecture. In general, for most approximation architectures, the storage needs are independent of the size of the state space and/or the size of the action space. Furthermore, for most approximation architectures there is no restriction on the state space to be a finite set; it could be an infinite, or even a continuous, space. This flexibility nevertheless reveals the need for good generalization abilities on behalf of the architecture, since the approximate value function will have to provide good values over the entire state/state-action space, using data only from a limited subset of the space.

The main difficulty associated with value-function approximation, beyond the loss in accuracy, is the choice of the *projection method*, which is the method of finding appropriate parameters that maximize the accuracy of the approximation according to certain criteria and with respect to the target function. Typically, for ordinary function approximation, this is accomplished using a training set of examples of the form $\{s, V^{\pi}(s)\}$, $\{s, V^{*}(s)\}$, $\{(s,a), Q^{\pi}(s,a)\}$, or $\{(s,a), Q^{*}(s,a)\}$ that provide the true value of the target function at certain sample points s or (s,a) (supervised learning). Unfortunately, in the context of sequential decision making, the target value function is completely unknown. Had it been possible to compute it easily, value-function approximation would have been unnecessary. In fact, it is not possible to analytically compute the true value of the target value function even at certain isolated sample points due to interdependencies between the values at all points. The implication of this difficulty is that evaluation and projection to the approximation architecture must be blended together. This is usually achieved by trying to find values for the free parameters so that the approximate function retains some properties of the original exact value function. Another implication of using approximation for value functions is that all convergence properties of exact planning or learning algorithms are compromised. Therefore, significant attention must be paid to the choice of the approximation architecture and the evaluation and projection method to minimize the chances for divergence or oscillations.

Approximation Architectures

There are a variety of architectures available for value-function approximation: perceptrons, neural networks, splines, polynomials, radial basis functions, support vector machines, decision trees, CMACs, wavelets, etc. These architectures have diverse representational power and generalization abilities, and the most appropriate choice will heavily depend on the properties of the decision making problem at hand. The projection methods associated with these approximation architectures are typically designed for a supervised learning setting. For successful use in the context of decision making, combined evaluation and projection methods are necessary.

A broad categorization of approximation architectures distinguishes between nonlinear and linear architectures. The characterization "nonlinear" or "linear" refers to the way the free parameters enter into the architecture and not to the approximation ability of the architecture. Nonlinear architectures are usually more expressive than the linear ones, due to the complex interactions among their free parameters; however, tuning their parameters is a much more elaborate task compared to tuning the parameters of their linear counterparts. Linear architectures are perhaps the most popular choice for value-function approximation; interestingly, most theoretical results on convergence properties in the context of value-function approximation are restricted to linear architectures.

A *linear approximation architecture* approximates a function $V^{\pi}(s)$ or $Q^{\pi}(s,a)$ as a linear weighted combination of k *basis functions* (also called *features*):

$$\hat{V}^{\pi}(s;w) = \sum_{j=1}^{k} \phi_j(s) w_j = \phi(s)^{\top} w$$

$$\hat{Q}^{\pi}(s,a;w) = \sum_{j=1}^{k} \phi_j(s,a) w_j = \phi(s,a)^{\top} w.$$

The free *parameters* of the architecture are the coefficients w_j of the combination (also called *weights*). The basis functions ϕ_j are fixed, but arbitrary and, in general, nonlinear functions of s or (s,a). It is required that the basis functions ϕ_j are linearly independent to ensure that there are no redundant parameters and that the matrices involved in the computations are full rank. In general, $k \ll |\mathcal{S}|$ and $k \ll |\mathcal{S}||\mathcal{A}|$ and the basis functions ϕ_j have small compact descriptions. As a result, the storage requirements of a linear approximation architecture are much smaller than those of the tabular representation of a value function. There is a large variety of linear approximation architectures, and in fact, many common schemes for value-function approximation can be cast as linear architectures.

- *Lookup Table*. This is the exact tabular representation (There is no approximation under this scheme; it is included only to illustrate that exact representation belongs in the family of linear architectures.) suitable for problems with discrete state variables. Each basis function is an indicator function whose value is 1 only for a specific discrete input point (state or state-action) and 0 otherwise. Each parameter stores one value/entry of the table.
- *Discretization*. This is a common technique for turning a continuous space into discrete using a uniform- or variable-resolution grid. One indicator basis function is assigned to each cell of the discretization, and the corresponding parameter holds the value of that cell.

- *Tile Coding (CMAC)*. This scheme utilizes several overlapping discretizations (tilings) for better accuracy. It generates indicator basis functions for each cell of each tiling and concatenates the basis functions for all tilings. Each parameter corresponds to one cell in one tiling, but the value at each input point is computed additively from the values of all containing cells from all tilings.
- *State Aggregation*. This is a family of schemes where "similar" (by some metric) states are grouped together and are treated as one state. The similarity metric is usually formed through dimensionality reduction techniques for identifying the most significant dimensions in a high-dimensional input space, unlike conventional proximity measures in the same space. There is one indicator basis function for each group and a single value for all states in the group.
- *Polynomials*. This is a generic approximation scheme suitable for problems with several (continuous) state variables. Each basis function is a polynomial term composed of state variables up to a certain degree.
- *Radial Basis Functions (RBFs)*. This is another generic approximation scheme suitable for continuous state variables. Each basis function is a Gaussian with fixed mean and variance; the Gaussians are topologically arranged so that they cover the input space with some overlap.
- *Kernel Methods*. Kernels are symmetric functions between two points, and they are used to represent compactly dot products of feature vectors in high- or even infinite-dimensional spaces. The compactness of kernels allows for approximation schemes that essentially enjoy the flexibility provided by a huge or infinite number of basis functions. The basis functions, in this case, are implicitly defined through the choice of the kernel.
- *Partitioning*. This technique is used for constructing complex approximators by partitioning the state space in several subsets and using a different approximator in each one of them. If linear architectures are used in all partitions, then a set of basis functions for the global architecture can be constructed by concatenating the basis functions of the smaller linear architectures multiplying each subset with an indicator function for the corresponding partition.

Linear architectures offer several advantages: they are easy to implement and use, and their behavior is fairly transparent, both from an analysis standpoint and from a debugging and feature engineering standpoint. It is usually relatively easy to get some insight into the reasons for which a particular choice of features succeeds or fails. This is facilitated by the fact that the magnitude of each parameter is related to the importance of the corresponding feature in the approximation (assuming normalized features).

A *nonlinear approximation architecture* approximates a function $V^{\pi}(s)$ or $Q^{\pi}(s,a)$ using arbitrary parametric functions of s and (s,a), possibly in conjunction with some *features* ϕ computed over s and (s,a). The best-known representative of this category is the multilayer feed-forward neural networks, which use one or more layers of linear combinations followed by a nonlinear sigmoidal transformation (thresholding). In their simplest form (one layer), neural networks approximate value functions as

$$\begin{aligned}\hat{V}^{\pi}(s;w,\theta) &= \sum_{i=1}^{m}\theta_i\sigma\left(\sum_{j=1}^{k}\phi_j(s)w_{ji}\right)\\ &= \sum_{i=1}^{m}\theta_i\sigma\Big(\phi(s)^{\top}w_i\Big)\\ \hat{Q}^{\pi}(s,a;w,\theta) &= \sum_{i=1}^{m}\theta_i\sigma\left(\sum_{j=1}^{k}\phi_j(s,a)w_{ji}\right)\\ &= \sum_{i=1}^{m}\theta_i\sigma\Big(\phi(s,a)^{\top}w_i\Big).\end{aligned}$$

Common choices for the differentiable, bounded, and monotonically increasing function σ are the hyperbolic tangent function $\sigma(x) = \tanh(x) = (e^x - e^{-x})/(e^x + e^{-x})$ and the logistic function $\sigma(x) = 1/(1 + e^{-x})$. The free *parameters* of the architecture (also called *weights*) are the coefficients w_{ji} of the linear combinations of the inputs and the coefficients θ_i of the linear combination of the sigmoidal transformations for the output. Notice that the parameters w_{ji} enter nonlinearly into the approximation.

A key question in all approximation architectures is *how* features are generated and selected. The *feature generation and selection* problem is an open question that spans most of machine learning research and admits no easy and general answer. Prior domain-specific knowledge and experience can be very helpful in choosing appropriate features. Several recent studies also describe methods for automatically generating features targeted for value-function approximation (Menache et al. 2005; Mahadevan and Maggioni 2007; Parr et al. 2007).

Learning

Learning (or *training* or *parameter estimation*) in value-function approximation refers to parameter tuning methods that take as input a policy π, an approximation architecture for V^π/Q^π, and the full MDP model or samples of interaction with the process and output a set of parameters w^π such that $\hat{V}^\pi/\hat{Q}^\pi$ is a good approximation to V^π/Q^π. Learning also covers methods for the harder problem of taking an approximation architecture for V^*/Q^* and the model or samples and outputting a set of parameters w^* such that $\hat{V}^*/\hat{Q}^*$ is a good approximation to V^*/Q^*. The former problem is somewhat easier because the policy π, unlike an optimal policy π^*, is known, and therefore in the presence of a simulator of the process, the value function can be estimated at any isolated point using Monte Carlo estimation techniques based on repeated policy rollouts from that point. Each rollout is an execution of an episode starting from a state s (or state-action (s,a)) using policy π to obtain an unbiased estimate of the return of the policy from s (or (s,a)). In this case, value-function approximation can be cast as a classic supervised learning problem; the true value of V^π/Q^π is estimated at a subset of points to form a training set, which can be subsequently used to train the approximation architecture using supervised learning techniques. However, in the absence of a simulator or when seeking approximations to V^*/Q^*, evaluation and projection into the architecture have to be carried out simultaneously.

The true value function has two key properties: it satisfies the Bellman equations, and it is the fixed point of the Bellman operator. Learning in value-function approximation strives to find values for the free parameters so that the approximate function retains at least one of these properties to the extent this is possible. Learning methods that focus on satisfying the Bellman equations attempt to find an approximate function that minimizes the Bellman residual, the difference between the left- and the right-hand sides of the system of Bellman equations. On the other hand, learning methods that focus on the fixed point property attempt to find an approximate function that exhibits a fixed point behavior under the combined application of the Bellman operator and projection onto the space spanned by the basis functions. Experimental evidence suggests that it is really hard to satisfy both properties under approximation, and therefore these two approaches differ significantly in their solutions. The majority of existing learning methods focus on fixed point approximation, which experimentally has been shown to exhibit more stable behavior and delivers better policies. There are also proposals for combining the benefits of both approaches into a hybrid method (Johns et al. 2009).

The most widely used learning approach is based on gradient descent and is applicable to any approximation architecture that is differentiable with respect to its parameters. Any stochastic approximation learning method for tabular representations of value functions can be extended to approximate representations. For example, given any sample (s,a,r,s') of interaction with the process, the temporal difference (TD) learning update rule

$$V^\pi(s) \leftarrow V^\pi(s) + \alpha\Big(r + \gamma V^\pi(s') - V^\pi(s)\Big)$$

for tabular representations, where $\alpha \in (0,1]$ is the learning rate, becomes

$$w^{\pi} \leftarrow w^{\pi} + \alpha\Big(r + \gamma \hat{V}^{\pi}(s'; w^{\pi}) - \hat{V}^{\pi}(s; w^{\pi})\Big)\nabla_{w^{\pi}} \hat{V}^{\pi}(s; w^{\pi})$$

under an approximation scheme $\hat{V}^{\pi}$. Similarly, the SARSA update rule

$$Q^{\pi}(s,a) \leftarrow Q^{\pi}(s,a) + \alpha\Big(r + \gamma Q^{\pi}(s', \pi(s')) - Q^{\pi}(s,a)\Big)$$

for tabular representations becomes

$$w^{\pi} \leftarrow w^{\pi} + \alpha\Big(r + \gamma \hat{Q}^{\pi}(s', \pi(s'); w^{\pi}) - \hat{Q}^{\pi}(s,a; w^{\pi})\Big)\nabla_{w^{\pi}} \hat{Q}^{\pi}(s,a; w^{\pi})$$

under an approximation scheme $\hat{Q}^{\pi}$. Finally, the Q-learning update rule

$$Q^{*}(s,a) \leftarrow Q^{*}(s,a) + \alpha\Big(r + \gamma \max_{a' \in \mathcal{A}} \{Q^{*}(s', a')\} - Q^{*}(s,a)\Big)$$

for tabular representations under an approximation scheme $\hat{Q}^{*}$ becomes

$$w^{*} \leftarrow w^{*} + \alpha\Big(r + \gamma \max_{a' \in \mathcal{A}} \{\hat{Q}^{*}(s', a'; w^{*})\} - \hat{Q}^{*}(s,a; w^{*})\Big)\nabla_{w^{*}} \hat{Q}^{*}(s,a; w^{*}) \,.$$

These rules are applicable to any approximation architecture, linear or nonlinear. However, when using linear architectures they can be greatly simplified, because the gradient with respect to a parameter w_j is simply the corresponding basis function ϕ_j, for $j = 1, 2, \ldots, k$.

$$\text{TD: } w_j^{\pi} \leftarrow w_j^{\pi} + \alpha\Big(r + \gamma \phi(s')^{\top} w^{\pi} - \phi(s)^{\top} w^{\pi}\Big)\phi_j(s)$$

$$\text{SARSA: } w_j^{\pi} \leftarrow w_j^{\pi} + \alpha\Big(r + \gamma \phi(s', \pi(s'))^{\top} w^{\pi} - \phi(s,a)^{\top} w^{\pi}\Big)\phi_j(s,a)$$

$$Q\text{-learning: } w_j^{*} \leftarrow w_j^{*} + \alpha\Big(r + \gamma \max_{a' \in \mathcal{A}} \{\phi(s', a')^{\top} w^{*}\} - \phi(s,a)^{\top} w^{*}\Big)\phi_j(s,a)$$

More sophisticated learning approaches rely on retaining the desired value-function property in a batch manner by processing several samples collectively. A variety of least-squares techniques have been proposed for linear architectures giving rise to several least-squares reinforcement learning methods, such as least-squares temporal difference (LSTD) learning (Bradtke and Barto 1996), least-squares policy evaluation (LSPE) (Nedić and Bertsekas 2003), hybrid least-squares approximation (Johns et al. 2009), and least-squares policy iteration (LSPI) (Lagoudakis and Parr 2003). The parameters of a linear architecture can also be estimated using Linear Programming (de Farias and Van Roy 2003). Specialized learning algorithms have been proposed when using a kernel-based approximation architecture, based either on Gaussian process TD (GPTD) (Engel et al. 2003), Gaussian process SARSA (GPSARSA) (Engel et al. 2005), kernelized LSTD (KLSTD) and LSPI (KLSPI) (Xu et al. 2007), support vector regression (Bethke et al. 2008), or Gaussian process regression (Rasmussen and Kuss 2004; Bethke and How 2009). A unified view of kernelized value-function approximation is offered by Taylor and Parr (2009). On the other hand, boot-strapping – the updating of a value estimate based on other value estimates – is the main learning approach behind batch methods for nonlinear architectures, such as fitted Q-iteration (FQI) (Ernst et al. 2005).

Examples

Very close approximations of the state value function of optimal policies in two well-known problems are presented to illustrate the difficulty of value-function approximation. To obtain these close approximations, a fine discretization of the two-dimensional state space into a uniform grid of 250 × 250 was used for representation. The state-action value function Q was initially computed using approximate policy iteration (a sparse-matrix version of LSPI) with a set of indicator basis functions over the state grid and all actions and 500 (s, a, r, s') samples for each one of the 187,500 discrete cells (s, a), until convergence to a near-optimal policy; the state value function V was extracted from the Q values.

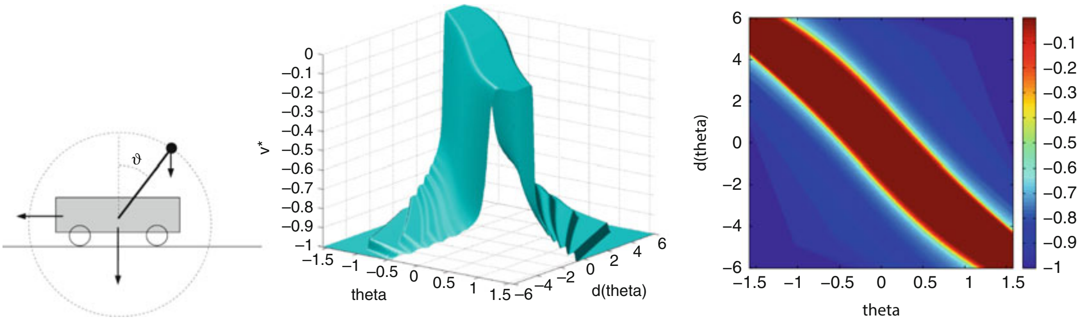
Inverted Pendulum

The *inverted pendulum* problem is to balance a pendulum of unknown length and mass at the upright position by applying forces to the cart it is attached to (Fig. 1, left). Three actions are allowed: left force LF (−50 Newtons), right force RF (+50 Newtons), or no force NF (0 Newtons). All three actions are noisy; Gaussian noise with $\mu = 0$ and $\sigma^2 = 10$ is added to the chosen action. The state space of the problem is continuous and consists of the vertical angle θ and the angular velocity $\dot{\theta}$ of the pendulum. The transitions are governed by the nonlinear dynamics of the system and depend on the current state and the current (noisy) control u:

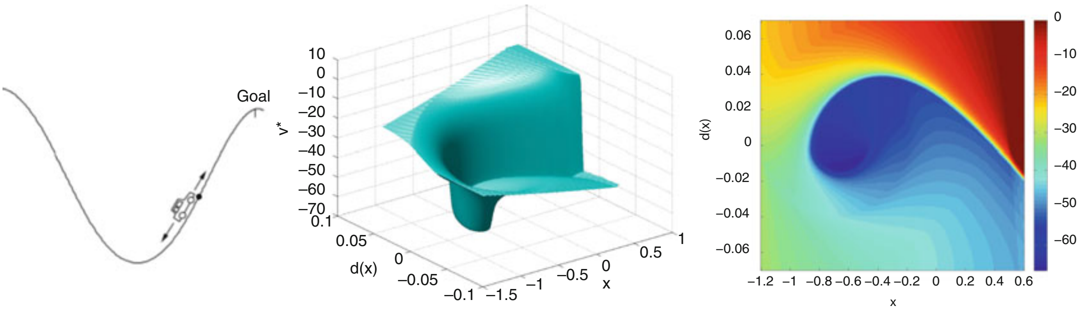
$$\ddot{\theta} = \frac{g\sin(\theta) - \alpha m l(\dot{\theta})^2\sin(2\theta)/2 - \alpha\cos(\theta)u}{4l/3 - \alpha m l\cos^2(\theta)},$$

where g is the gravity constant ($g = 9.8\,\mathrm{m/s^2}$), m is the mass of the pendulum (default: $m = 2.0\,\mathrm{kg}$), M is the mass of the cart (default: $M = 8.0\,\mathrm{kg}$), l is the length of the pendulum (default: $l = 0.5\,\mathrm{m}$), and $\alpha = 1/(m + M)$. The simulation step is $0.1\,\mathrm{s}$, thus the control input is given at a rate of $10\,\mathrm{Hz}$, at the beginning of each time step, and is kept constant during any time step. A reward of 0 is given as long as the angle of the pendulum does not exceed $\pi/2$ in absolute value (the pendulum is above the horizontal line). An angle greater than $\pi/2$ in absolute value signals the end of the episode and a reward (penalty) of -1. The discount factor of the process is 0.95.

Figure 1 shows a close approximation to the state value function V^* of an optimal policy for the inverted pendulum domain over the two-dimensional state space $(\theta, \dot{\theta})$. The value function indicates that states which potentially offer high return are clustered within a zone where θ and $\dot{\theta}$ have different signs and therefore the gravity force can be counteracted. Notice the nonlinearity of the function and the difficult approximation problem it presents.



Value Function Approximation, Fig. 1 Inverted pendulum: state value function of an optimal policy (3D and 2D) (Courtesy of Ioannis Rexakis)



Value Function Approximation, Fig. 2 Mountain car: state value function of an optimal policy (3D and 2D) (Courtesy of Ioannis Rexakis)

Mountain Car

The *mountain car* problem is to drive an underpowered car from the bottom of a valley between two mountains to the top of the mountain on the right (Fig. 2, left). The car is not powerful enough to climb any of the hills directly from the bottom of the valley even at full throttle; it must build some energy by climbing first to the left (moving away from the goal) and then to the right. Three actions are allowed: forward throttle FT (+1), reverse throttle RT (−1), or no throttle NT (0). All three actions are noisy; Gaussian noise with $\mu = 0$ and $\sigma^2 = 0.2$ is added to the chosen action. The state space of the problem is continuous and consists of the position x and the velocity $\dot{x}$ of the car along the horizontal axis. The transitions are governed by the nonlinear dynamics of the system and depend on the current state $(x(t), \dot{x}(t))$ and the current (noisy) control $u(t)$:

$$\begin{aligned} x(t+1) &= \text{B}{\small\text{OUND}}_x[x(t) + \dot{x}(t+1)] \\ \dot{x}(t+1) &= \text{B}{\small\text{OUND}}_{\dot{x}}[\dot{x}(t) \\ &\qquad + 0.001u(t) - 0.0025\cos(3x(t))] , \end{aligned}$$

where $\text{B}{\small\text{OUND}}_x$ is a function that keeps x within $[-1.2, 0.5]$, while $\text{B}{\small\text{OUND}}_{\dot{x}}$ keeps $\dot{x}$ within $[-0.07, 0.07]$. If the car hits the bounds of the position x, the velocity $\dot{x}$ is set to zero. A penalty of −1 is given at each step as long as the position of the car is below the right bound (0.5). As soon as the car position hits the right bound of the position, it has reached the goal; the episode ends successfully and a reward of 0 is given. The discount factor of the process is 0.99.

Figure 2 shows a close approximation to the state value function V^* of an optimal policy for the mountain car domain over the two-dimensional state space $(x, \dot{x})$. The value function indicates that in order to gain high return, the car has to follow a spiral in the state space that goes through states with progressively higher value. In practice, this means that the car has to move back and forth between the two mountains until sufficient energy is built to escape from the valley. Again, notice the high nonlinearity of the function and the hard approximation problem it presents.

Notation

The table summarizes the differences in names and symbols between the common notation (adopted here) and the alternative notation used in the literature.

Common notation		**Alternative notation**	
Name	**Symbol**	**Symbol**	**Name**
State space	$\mathcal{S}$	S	States
State	s, s'	i, j	State
Action space	$\mathcal{A}$	U	Controls
Action	a	u	Control
Transition model	$\mathcal{P}(s'\|s,a)$	$p_{ij}(u)$	Transition probabilities
Reward function	$\mathcal{R}$	g	Cost function
Discount factor	γ	α	Discount factor
Policy	π	μ	Policy
State value function	V	J	Cost-to-go function
State-action value function	Q	Q	Q-factors
Parameters/weights	w	r	Parameters
Learning rate	α	γ	Step size

▸ Inductive Bias

VC Dimension

Thomas Zeugmann
Hokkaido University, Sapporo, Japan

Motivation and Background

We define an important combinatorial parameter that measures the combinatorial complexity of a family of subsets taken from a given universe (learning domain) X. This parameter was originally defined by Vapnik and Chervonenkis (1971) and is thus commonly referred to as Vapnik-Chervonenkis dimension, commonly abbreviated as VC *dimension*. Subsequently, Dudley (1978, 1979) generalized Vapnik and Chervonenkis' (1971) results. The reader is also referred to Vapnik's (2000) book in which he greatly extends the original ideas. This results in a theory which is called structural risk minimization.

The importance of the VC dimension for ▸ PAC learning was discovered by Blumer et al. (1989) who introduced the notion to computational learning theory.

As Anthony and Biggs (1992, Page 71) have put it, "*The development of this notion is probably the most significant contribution that mathematics has made to Computational Learning Theory.*"

Recall that we use $|S|$ and $\wp(S)$ to denote the cardinality and the power set of any set S, respectively. We first define the VC dimension and provide a short explanation of its importance for ▸ PAC learning. Then we present some examples.

Definition

Let $X \neq \emptyset$ be any learning domain, let $\mathcal{C} \subseteq \wp(X)$ be any nonempty concept class, and let $S \subseteq X$ be any finite set. We set

$$\Pi_{\mathcal{C}}(S) = \{S \cap c \mid c \in \mathcal{C}\}\,.$$

1. S is said to be *shattered* by $\mathcal{C}$ iff $\Pi_{\mathcal{C}}(S) = \wp(S)$.
2. The VC *dimension* of $\mathcal{C}$ is the cardinality of the largest finite set $S \subseteq X$ that is shattered by $\mathcal{C}$.

   If arbitrary large finite sets S are shattered by $\mathcal{C}$, then the VC dimension of $\mathcal{C}$ is defined to be infinite.

Notation: By VC$(\mathcal{C})$ we denote the VC *dimension* of $\mathcal{C}$.

Remarks

As far as ▸ PAC learning is concerned, for a sample set S, the notion $\Pi_{\mathcal{C}}(S)$ has the following meaning. Essentially, $\Pi_{\mathcal{C}}(S)$ collects the set of *all subsets* of the sample set S which are made positive by some concept $c \in \mathcal{C}$. Consequently, $S \cap c$ represents the elements of S that are labeled as to be positive by the concept c. Hence, $\Pi_{\mathcal{C}}(S)$ is the collection of all such subsets taken over all $c \in \mathcal{C}$. If *every* subset of S can be labeled as to be positive by some concept $c \in \mathcal{C}$ and c does not make any other element of S positive, then S is shattered.

If VC$(\mathcal{C}) = d$ then there *exists* a finite set $S \subseteq X$ such that $|S| = d$, and S is shattered by $\mathcal{C}$. Moreover, *every* set $S \subseteq X$ with $|S| > d$ is *not* shattered by $\mathcal{C}$.

It is intuitively clear that an infinite VC dimension might enormously complicate learning. On the other hand, it is by no means obvious that a finite VC dimension may always guarantee the learnability of the corresponding concept class. However, this is a central theorem of the ▸ PAC learning theory. Moreover, the value of the VC dimension is a measure of the sample complexity. This holds for PAC learning and beyond. Further models where this is true comprise the ▸ online learning models (cf. Haussler et al. 1994; Maass and Turán 1990; Littlestone 1988), models of ▸ query-based learning (cf. Maass and Turán 1990), and others.

Examples

First, let $\mathcal{C}$ be any finite concept class. Then, since it requires 2^d distinct concepts to shatter a set of cardinality d, no set of cardinality larger than $\log|\mathcal{C}|$ can be shattered. Thus, $\log|\mathcal{C}|$ is always an upper bound for the VC dimension of finite concept classes. Here log denotes the logarithm to the base 2.

However, if the VC dimension can be determined, it usually gives a better bound than $\log|\mathcal{C}|$. To see this, let $\mathcal{L}_n = \{x_1, \bar{x}_1, x_2, \bar{x}_2, \ldots, x_n, \bar{x}_n\}$, $n \geq 1$ be a set of literals and let $X = \{0,1\}^n$ be the n-dimensional Boolean learning domain. Furthermore, let $\mathcal{C}_n \subseteq \wp(X)$ be the class of all concepts describable by a monomial including the empty monomial (representing $\{0,1\}^n$) and the conjunction of all literals (representing $\emptyset$). Then $|\mathcal{C}_n| = 3^n + 1$ and thus $\mathrm{VC}(\mathcal{C}) \leq n(\log 3) + 1$. But $\mathrm{VC}(\mathcal{C}_n) = n$ for all $n \geq 2$ and $\mathrm{VC}(\mathcal{C}_1) = 2$ as shown by Natschläger and Schmitt (1996). Note that the same is true for the class of all concepts describable by *monotone monomials*, i.e., monomials containing only non-negated literals.

Next, we consider the concept class $\mathcal{C}$ of all axis-parallel rectangles. So let $X = \mathbb{E}^2$ be the two-dimensional Euclidean space and $\mathcal{C} \subseteq \wp(\mathbb{E}^2)$ be the set of all axis-parallel rectangles, i.e., products of intervals on the x-axis with intervals on the y-axis. Then, it is not hard to see that $\mathrm{VC}(\mathcal{C}) = 4$.

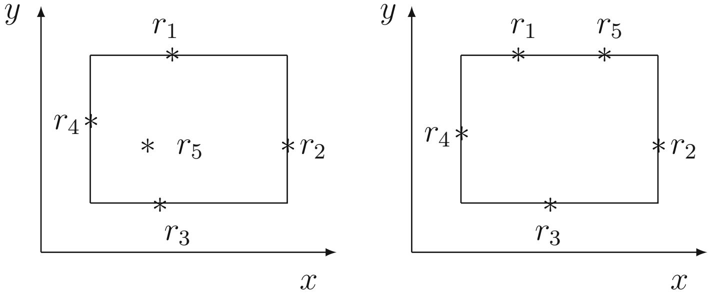
Clearly, we can shatter the empty set and sets of cardinality 1, 2, and 3. Now, let $S = \{r_1, r_2, r_3, r_4\}$ be such that r_1, r_2, r_3, r_4 are the middle points of the sides of some square. Then it is not hard to see that there are 16 concepts c_i, $1 \leq i \leq 16$, in $\mathcal{C}$ such that $\wp(S) = \{S \cap c_i \mid 1 \leq i \leq 16\}$. Hence, $\mathrm{VC}(\mathcal{C}) \geq 4$.

Next, let $S = \{r_1, r_2, r_3, r_4, r_5\}$ be any set of 5 pairwise different points. Let c be the smallest closed axis-parallel rectangle containing the points of S. Since c has only four sides, there must be some point $r \in S$, say r_5, such that r_5 lies either in the interior of c or r_5 lies on some side of c along with another point of S (cf. Fig. 1). Suppose S is shattered by $\mathcal{C}$. Then, there has to be a concept $c \in \mathcal{C}$ such that $\{r_1, r_2, r_3, r_4\} = S \cap c$. However, by construction we obtain that $\{r_1, r_2, r_3, r_4\} = S \cap c$ implies $r_5 \in S \cap c$, a contradiction. Thus, *no* set of cardinality 5 is shattered. Hence, $\mathrm{VC}(\mathcal{C}) = 4$.

The latter result can be easily generalized. Let $X = \mathbb{E}^n$, and let $\mathcal{C}$ be the set of all axis-parallel parallelepipeds in $\mathbb{E}^n$. Then $\mathrm{VC}(\mathcal{C}) = 2n$.

A further generalization is as follows. Let X be the real line (one-dimensional Euclidean

VC Dimension, Fig. 1 No set of cardinality 5 can be shattered by axis-parallel rectangles



space), i.e., $X = \mathbb{E}$, and let $\mathcal{C}$ be the set of all unions of at most s (closed or open) intervals for some fixed constant $s \geq 1$. Let $S = \{x_i \mid 1 \leq i \leq 2s,\ x_i < x_{i+1}$ for all $1 \leq i < 2s\}$. Then one easily verifies that S is shattered by $\mathcal{C}$. Hence, $\mathrm{VC}(\mathcal{C}) \geq 2s$. On the other hand, if S is any set of $2s + 1$ pairwise different points with $x_i < x_{i+1}$ for all $1 \leq i \leq 2s$, then no concept in $\mathcal{C}$ contains $x_1, x_3, \ldots, x_{2s+1}$ without also containing a point in $x_2, x_4, \ldots, x_{2s}$. Thus, no such S is shattered. Consequently, we have $\mathrm{VC}(\mathcal{C}) = 2s$.

Furthermore, we can generalize the observations made above by deriving some rules that turn out to be very useful to estimate the VC dimension of more complicated concept classes provided they can be constructed from simpler classes.

First, let $\mathcal{C}_1$ and $\mathcal{C}_2$ be concept classes such that $\mathcal{C}_1 \subseteq \mathcal{C}_2$. Then we clearly have

$$\mathrm{VC}(\mathcal{C}_1) \leq \mathrm{VC}(\mathcal{C}_2)\ .$$

Second, let X be any learning domain, let $\mathcal{C} \subseteq \wp(X)$ and define the complement of $\mathcal{C}$ to be $\overline{\mathcal{C}} = \{X \setminus c \mid c \in \mathcal{C}\}$. Then we have

$$\mathrm{VC}(\overline{\mathcal{C}}) = \mathrm{VC}(\mathcal{C})\ .$$

Third, consider two concept classes $\mathcal{C}_1$ and $\mathcal{C}_2$ defined over the same learning domain X. Let $\mathcal{C} = \mathcal{C}_1 \cup \mathcal{C}_2$ be the union of $\mathcal{C}_1$ and $\mathcal{C}_2$. Then,

$$\mathrm{VC}(\mathcal{C}) \leq \mathrm{VC}(\mathcal{C}_1) + \mathrm{VC}(\mathcal{C}_2) + 1\ .$$

Fourth, let $\mathcal{C}$ be any concept class such that $\mathrm{VC}(\mathcal{C}) = d$. Consider the $\mathcal{C}_s$ union (or intersection) of at most s concepts from $\mathcal{C}$, where $s \geq 1$ is any fixed constant, i.e., $\mathcal{C}_s = \{c \mid c = \bigcup_{1 \leq i \leq s} c_i\ ,\ c_i \in \mathcal{C}\}$ (or $\mathcal{C}_s = \{c \mid c = \bigcap_{1 \leq i \leq s} c_i\ ,\ c_i \in \mathcal{C}\}$). Then one can show that

$$\mathrm{VC}(\mathcal{C}_s) \leq 2ds \cdot \log(3s)\ .$$

Numerous further examples can be found in, e.g., Vapnik and Chervonenkis (1974), Haussler and Welz (1987), Anthony and Bartlett (1999), Wenocur and Dudley (1981), Karpinski and Werther (1994), Karpinski and Macintyre (1995), Sakurai (1995), and Mitchell et al. (1999).

Applications

Let us return to the notion $\Pi_{\mathcal{C}}(S)$ and let us generalize it a bit as follows. For any natural number $m \in \mathbb{N}$ and any nonempty concept class $\mathcal{C} \subseteq \wp(S)$, we set

$$\Pi_{\mathcal{C}}(m) = \max\{|\Pi_{\mathcal{C}}(S)| \mid S \subseteq X,\ |S| = m\}\ .$$

We can use the new notion to give an equivalent definition of the VC dimension of a concept class $\mathcal{C}$, i.e.,

$$\mathrm{VC}(\mathcal{C}) = \max\{d \mid d \in \mathbb{N},\ \Pi_{\mathcal{C}}(d) = 2^d\}\ .$$

Looking at $\Pi_{\mathcal{C}}(m)$ from the perspective of learning, we see the following. The argument m refers to the sample size. $\Pi_{\mathcal{C}}(m)$ is describing the maximum number of ways a sample of size m can be labeled by concepts taken from $\mathcal{C}$. Hence, the number $\Pi_{\mathcal{C}}(m)$ behaves as a measure of concept class complexity. What can be said about $\Pi_{\mathcal{C}}(m)$? Suppose $d = VC(\mathcal{C})$; then $m \leq d$ implies $\Pi_{\mathcal{C}}(m) = 2^m$. On the other hand, $m > d$ directly implies $\Pi_{\mathcal{C}}(m) < 2^m$. Therefore, we are interested in learning how fast $\Pi_{\mathcal{C}}(m)$ really grows provided $m > d$. The key ingredient to obtain the desired information is usually referred to as Sauer's Lemma (cf. Sauer 1972). Under the assumptions made above, it states that

$$\Pi_{\mathcal{C}}(m) \leq \sum_{i=0}^{d} \binom{m}{i},$$

$$\text{where} \quad \binom{m}{i} = 0 \quad \text{if } i > m\ .$$

Like many important results, Sauer's Lemma (cf. Sauer 1972) has several proofs and generalizations have been studied, too. We refer the reader to Anthony and Biggs (1992), Kearns and Vazirani (1994), and Gurvits (1997) for a more detailed exposition.

Let us first look at the case $m \le d$ already considered. For this case Sauer's Lemma is telling us that

$$\Pi_{\mathcal{C}}(m) \le \sum_{i=0}^{d} \binom{m}{i} = 2^m,$$

and thus, we get an exponential bound. The interesting aspect is that in the remaining cases, the bound is *polynomial*. For simplifying notation, we set

$$\Phi(d,m) = \sum_{i=0}^{d} \binom{m}{i}.$$

Using combinatorial arguments and Stirling approximation, one can show that

1. $\Phi(0,m) = \binom{m}{0} = 1$ for all $m \in \mathbb{N}$.
2. $\Phi(d,1) = \binom{1}{0} + \binom{1}{1} = 2$ for all $d \in \mathbb{N}, d \ge 1$.
3. $\Phi(d,m) = \Phi(d,m-1) + \Phi(d-1,m-1)$ for all $d,m \in \mathbb{N}, d \ge 1,\ m \ge 2$.
4. $\Phi(d,m) \le m^d + 1$ for all $d \ge 0, m \ge 0$.
5. $\Phi(d,m) \le m^d$ for all $d \ge 2, m \ge 2$.
6. $\Phi(d,m) \le (\frac{em}{d})^d$ for all $m \ge d \ge 1$.

That is, (4) through (6) provide a bound polynomial in m for $\Pi_{\mathcal{C}}(m)$ whenever VC($\mathcal{C}$) is finite. This insight is fundamental for ▶ PAC learning and other learning models.

Linial et al. (1991) initiated the study of the complexity problem of computing the VC dimension of a finite family of concepts defined over a finite learning domain. Given any finite learning domain X of cardinality n and any concept class $\mathcal{C} \subseteq \wp(X)$ of cardinality r, one can represent the concept class $\mathcal{C}$ by an $r \times n$ matrix M such that $M_{ij} = 1$ iff $x_j \in c_i$. Then each row of M represents a concept $c \in \mathcal{C}$ and each column represents a point in X. The *discrete VC dimension decision problem* is then, given a $\{0,1\}$-valued matrix M and an integer $d \ge 1$ as input, to decide whether or not $VC(\mathcal{C}) \le d$, and the *discrete VC dimension problem* is, given a $\{0,1\}$-valued matrix M as input, to determine $VC(\mathcal{C})$.

Linial et al. (1991) showed that the discrete VC dimension decision problem to be solvable in time $O(rn^d)$ and that the discrete VC dimension problem can be solved in time $O(rn^{\log r})$. Further progress was made by Shinohara (1995) who showed that the discrete VC dimension decision problem is in the complexity class $\mathrm{SAT}_{\log^2 n}$ and hard for the complexity class $\mathrm{SAT}^{\mathrm{CNF}}_{\log^2 n}$, where $\mathcal{P} \subseteq \mathrm{SAT}^{\mathrm{CNF}}_{\log^2 n} \subseteq \mathrm{SAT}_{\log^2 n} \subseteq \mathcal{NP}$ (see Shinohara (1995) for details). Moreover, Papadimitriou and Yannakakis (1996) defined a new complexity class $\mathcal{LOGNP}$ and showed the VC dimension decision problem to be complete for this class.

However, the matrix representation of a concept class may be exponentially larger than a parameterized representation of it, e.g., the concept class may be generated by a circuit. Representing concept classes by circuits, Schaefer (1999) showed the discrete VC dimension problem (modified in the canonical way) to be Σ_3^p complete. For a definition of the complexity class Σ_3^p, we refer to Arora and Barak (2009).

Furthermore, we refer the reader to Goldberg and Jerrum (1995) who succeeded in bounding the VC dimension of concept classes parameterized by real numbers.

Finally, the notion of the VC dimension can be generalized to sets of indicator functions and to sets of real functions (cf. Vapnik 2000, Section 3.6). These generalizations play an important role in statistical learning theory.

Version Space

Claude Sammut
The University of New South Wales, Sydney, NSW, Australia

Definition

Mitchell (1977, 1982) defines the *version space* for a learning algorithm as the subset of hypotheses consistent with the training examples. That is, the ▶ hypothesis language is capable of describing a large, possibly infinite, number of concepts. When searching for the target concept, we are only interested in the subset of sentences in the hypothesis language that are consistent with the training examples, where consistent means that the examples are correctly classified (assuming deterministic concepts and no ▶ noise in the data). While the version space may be infinite, it can often be represented in a compact manner by maintaining only its *bounds*, the most specific (▶ Most Specific Hypothesis) and ▶ most general hypotheses. Any hypothesis that is more general than a hypothesis in the most specific bound and more specific than a hypothesis in the most general bound is in the version space.

Weight

Risto Miikkulainen
Department of Computer Science, The
University of Texas at Austin, Austin, TX, USA

Synonyms

Connection strength; Synaptic efficacy

Definition

In a ▶ neural networks, connections between neurons typically have weights that indicate how strong the connection is. The neuron computes by forming a weighted sum of its input, i.e., the activation of each input neuron is multiplied by the corresponding connection weight. Adapting such weights is the most important way of learning in neural networks. Connection weights are loosely modeled after the synaptic efficacies in biological neurons, where they determine how large a positive or negative change in the membrane potential each input spike generates (see ▶ Biological Learning: Synaptic Plasticity, Hebb Rule and Spike Timing Dependent Plasticity). In most models, all connection parameters are abstracted into a weight: attenuation or interaction of the potentials and connection delays are usually not taken into account. The weights are usually real-valued numbers ($-\infty \ldots \infty$), although in some algorithms, intended for VLSI implementation, the range and precision of these values can be restricted (or weights eliminated altogether). Weights in some methods can be restricted to positive values if the inputs are known to be positive and the method is based on comparing the similarity to the weights (as in e.g., ▶ Self-Organizing Maps, ▶ Adaptive Resonance Theory, and ▶ Radial Basis Function Networks). Most learning methods are based on adjusting the weight values. The weights are often initialized to small random values, although if enough is known about the input space and the task, more systematic initialization can improve performance significantly. The weights are then adjusted based on local information that is available on either side of the connection. Usually, only small modifications are made in each learning step to avoid disrupting what the network already knows, and learning converges over time to a setting of values that solves the task.

Word Sense Disambiguation

Rada Mihalcea
University of North Texas, Denton, TX, USA

Synonyms

Learning word senses; Solving semantic ambiguity

Definition

Ambiguity is inherent to human language. In particular, word sense ambiguity is prevalent in all natural languages, with a large number of the words in any given language carrying more than one meaning. For instance, the English noun *plant* can mean *green plant* or *factory*; similarly the French word *feuille* can mean *leaf* or *paper*. The correct sense of an ambiguous word can be selected based on the context where it occurs, and correspondingly the problem of word sense disambiguation is defined as the task of automatically assigning the most appropriate meaning to a polysemous word within a given context.

Motivation and Background

Word sense disambiguation is considered one of the most difficult problems in natural language processing, due to the high semantic ambiguity that is typically associated with language. It was first noted as a problem in the context of machine translation, when Warren Weaver, in his famous 1949 memorandum, pointed out word ambiguity as one of the problems that needed to be solved in order to enable automatic translations between the languages of the world (Weaver 1995). More than 50 years later, word sense ambiguity is still regarded as an important and difficult research problem, and it has been demonstrated to have a potentially significant impact on several natural language processing applications.

Applications

In addition to machine translation, the role of word sense disambiguation has also been explored in connection to other applications, such as monolingual information retrieval, cross-language information retrieval, question answering, knowledge acquisition, information extraction, text classification, and others. In particular, a significant amount of work has been carried out in areas related to information retrieval, where the resolution of word ambiguity has been shown to have an impact on both the precision of the system (by allowing for matches only between identical word meanings in the query and in the documents), as well as the recall of the system (by performing query expansion using synonyms of selected word meanings).

Brief History

Over the years, the field of word sense disambiguation has undergone steady improvements in both quality and scope, moving from the rule-based systems using hand crafted knowledge that were popular in the 1970s and 1980s, to the more advanced corpus-based methods used in the 1990s, and to the current hybrid systems that rely on a mix of knowledge-based and corpus-based resources, minimizing the need of sense annotated data and taking advantage of the Web. The shift from small-scale rule-based systems to large-scale data-driven methods has also implied an increase in coverage, with early systems typically addressing a handful of ambiguous words for which hand-coded rules were available, while many of the current systems have the ability to address all or almost all content words in unrestricted text.

Methods

Current word sense disambiguation systems are divided into three main categories:

Knowledge-based: These systems rely mainly on information drawn from lexical resources, such as dictionaries or thesauruses. The Lesk algorithm (Lesk 1986) is one of the most well-known knowledge-based word sense disambiguation methods. It decides the meaning of a word based on a measure of similarity among the definitions provided by a dictionary. For instance, for the phrase *pine cone*, the algorithm will select the meaning of *kind of evergreen tree* for *pine*, and *fruit of evergreen tree* for *cone*, as these are the definitions with the highest lexical overlap among all the possible definitions provided by a dictionary.

Unsupervised corpus-based: These approaches typically consist of algorithms for clustering word sense occurrences in a corpus, without making explicit reference to a sense inventory. The clustering can be performed in a monolingual environment, in which case different word occurrences are represented by features derived from their immediate context (Schutze 1998). Alternatively, a clustering of word senses can also be performed using cross-lingual evidence drawn from the translations observed in a parallel corpus (Ng et al. 2003). This line of work is often referred to as word sense discrimination, as the word meanings are not disambiguated against a sense inventory, but are discriminated against each other.

Supervised corpus-based: These methods are the focus of the current chapter, and they consist primarily of machine learning algorithms applied on large sense-annotated corpora. Supervised algorithms have been typically applied to one word at a time, although experiments have also been carried out for their application to all words in unrestricted text. While sense-annotated corpora have usually been constructed by hand, recent work has also explored various approaches for the automatic generation of such data, which has been used successfully in conjunction with machine learning algorithms.

Structure of the Learning System

Among the various knowledge-based and data-driven word sense disambiguation methods that have been proposed to date, supervised systems have been constantly observed as leading to the highest performance. In these systems, the sense disambiguation problem is formulated as a supervised learning task, where each sense-tagged occurrence of a particular word is transformed into a feature vector, which is then used in an automatic learning process.

Given a target word and a set of examples where this word occurs, each occurrence being annotated with the correct sense, a supervised system will attempt to learn how to automatically annotate occurrences of the given word in new, previously unseen, contexts. This process is accomplished in two steps. First, representative features are extracted from the context of the ambiguous word; this step is applied to the annotated examples (training) as well as the unlabeled examples (test). Second, a machine learning algorithm is applied on the feature vectors, and consequently the most likely sense is assigned to the test occurrences of the target word.

Features

Research in supervised word sense disambiguation has considered two main types of features to model occurrences of ambiguous words:

$W-1$	$W+1$	$P-1$	$P+1$	Growth	Flowering	Industrial	Staff	Sense
Flowering	Helps	Adj	Verb	Y	Y	N	N	Green plant
Industrial	Is	Adj	Verb	N	N	Y	Y	Factory

Contextual features, which are extracted from the immediate vicinity of the ambiguous word. These features usually consist of the words before and after the target word (a window size of 3–10 words is typical), their parts of speech, words in a syntactic dependency with the target word (e.g., the subject of the verb, the noun modified by an adjective), position in the sentence, and the like. For instance, the adjective *green* could be one of the contextual features extracted from the context *the green plant* for the ambiguous word *plant*.

Topical features, which are represented by the words most frequently co-occurring with a given meaning of the target word. These words are usually determined by counting the number of times each word occurs in the context of a word meaning, divided by the total number of occurrences in the context of the word regardless of its meaning. For instance, the *factory* meaning of *plant* could have topical features such as *industrial* and *work*, whereas the *green plant* meaning of *plant* might have features such as *animal* and *water*.

As an example of feature vector construction, consider the following two contexts provided for the ambiguous word *plant*:

The/det growth/noun of/prep a/det seedling/noun into/prep a/det flowering/adj **plant**/noun helps/verb children/noun investigate/verb the/det conditions/noun that/prep plants/noun need/verb for/prep growth/ noun.

The/det operations/noun staff/noun in/prep an/det industrial/adj **plant**/noun is/verb typically/adv measured/verb in/prep asset/noun utilization/noun.

The following two feature vectors are constructed:

Machine Learning

Provided a set of feature vectors representing different occurrences of an ambiguous target word, the goal of the machine learning system is to learn how to predict the most likely sense for a new occurrence. The word sense disambiguation literature describes experiments with a large number of machine learning algorithms, including decision lists (Yarowsky 2000), instance-based learning (Ng and Lee 1996), Naïve Bayes and decision trees (Pedersen 1998), support vector machines (Lee and Ng 2002), and others. A comparison of several machine learning algorithms for word sense disambiguation is provided in Lesk (1986) and Mooney (1996).

Generation of Sense-Tagged Corpora

One of the main drawbacks associated with the supervised methods for word sense disambiguation is the cost incurred in the process of building sense-tagged corpora. Despite their high performance, the applicability of these supervised systems is limited to those few words for which sense-tagged data is available, and their accuracy is strongly connected to the amount of labeled data available at hand.

Sense annotations have been typically carried out by humans, which resulted in several publicly available data sets, such as those made available during the Senseval evaluations (http://www.senseval.org). However, despite the effort that went into the construction of these data sets, their applicability is limited to a handful of approximately 100 ambiguous words.

To address the sense-tagged data bottleneck problem, different methods for automatic sense-tagged data annotation have been proposed in the past, with various degrees of success. One such method relies on monosemous relatives extracted from dictionaries, which can be used to identify ambiguity-free occurrences in large corpora (Leacock et al. 1998; Mihalcea 1999). Another method relies on automatically bootstrapped disambiguation patterns, which can be used to generate a large number of sense-tagged examples (Mihalcea 2002; Yarowsky 1995). The use of volunteer contributors to create sense-annotated corpora has also been explored in the Open Mind Word Expert system (Chklovski and Mihalcea 2002). Finally, in recent work, Wikipedia was identified as a rich source of word sense annotations, which can be used to build supervised word sense disambiguation systems (Mihalcea 2007).

Word Sense Discrimination

Word sense discrimination is sometimes used as a synonym for ▸ word sense disambiguation. Note, however, that these two terms refer to somewhat different problems, as word sense discrimination implies a distinction between different word meanings in a corpus (without reference to a sense inventory), whereas word sense disambiguation refers to a sense assignment using a given sense inventory.

Z

Zero-One Loss

Zero-one loss is a common ► loss function used with ► classification learning. It assigns 0 to loss for a correct classification and 1 for an incorrect classification.
